PREFACE

This volume contains the full-length papers presented at the **VII European Congress on Computational Methods in Applied Sciences and Engineering** (ECCOMAS Congress 2016) that was held on June 5-10, 2016 on the Crete Island, Greece.

The main objective of the quadrennial ECCOMAS Congresses is to provide a forum for presentation and discussion of state-of-the-art advances in computational methods in applied sciences and engineering, including basic methodologies, scientific developments and industrial applications and to serve as a platform for establishing links between research groups of academia and industry with common as well as complementary activities. About 2,200 papers were presented at the ECCOMAS Congress by authors from 53 countries around the world. This volume, consists of 667 full length accepted papers which will be indexed by SCOPUS database with access to the pdf file of the paper.

The ECCOMAS Congress 2016 is organized by the Institute of Structural Analysis and Antiseismic Research of the National Technical University of Athens under the support of the Greek Association for Computational Mechanics (GRACM), the Institute of Research and Development for Computational Methods in Engineering Sciences (ICMES) and the Computer Applications and Education in Engineering Sciences (CAEES).

The editor of this volume would like to thank all authors for their contributions. Special thanks go to the colleagues who contributed to the organization of the Minisymposia and to the reviewers who, with their work, contributed to the scientific quality of this e-book.

M. Papadrakakis
National Technical University of Athens, Greece

V. Papadopoulos
National Technical University of Athens, Greece

G. Stefanou
Aristotle University of Thessaloniki, Greece

V. Plevris
Oslo and Akershus University College of Applied Sciences, Oslo, Norway

ACKNOWLEDGEMENTS

The conference organizers acknowledge the support towards the organization of the 7th European Congress on Computational Methods in Applied Sciences and Engineering, to the following organizations:

- Greek Association for Computational Mechanics (GRACM)
- Institute of Structural Analysis and Antiseismic Research, National Technical University of Athens
- John Argyris Foundation
- Institute of Research and Development for Computational Methods in Engineering Sciences (ICMES)
- Computer Applications and Education in Engineering Sciences (CAEES)
- Region of Crete
- Municipality of Hersonissos

Plenary Speakers

We would also like to thank the Plenary and Semi-Plenary Speakers for their help in the setting up of a high standard Scientific Programme.

Plenary Speakers: Alexandre Ern, Charbel Farhat, Gerhard A. Holzapfel, Antonio Huerta, Thomas J.R. Hughes, Alfio Quarteroni, Ole Sigmund, Theodosios P. Tasios

Semi-Plenary Speakers: Assyr Abdulle, Olivier Allix, Lourenco Beirao da Veiga, Andreas G. Boudouvis, Annalisa Buffa, Ramon Codina, Laura De Lorenzis, Bernard Geurts, Kyriakos Giannakoglou, Antonio J. Gil, Dan Givoli, Anthony Gravouil, George Karniadakis, Mats G. Larson, Kim Meow Liew, Wing Kam Liu, Federico Negri, Shinji Nishiwaki, Ursula Rasthofer, Ernst Rank, Cord-Christian Rossow, Giancarlo Sangalli, Jörg Schröder, Bert Sluys, Christian Soize, Roberto Verzicco, Barbara Wohlmuth

SUMMARY

Preface..... iii

Acknowledgements..... iv

Contents..... xvii

VOLUME I

SEMI-PLENARY LECTURES 1

MINISYMPOSIA

MS 102 - COMPUTATIONAL MODELS IN BIOMECHANICS AND MECHANOBIOLOGY 27
Organized by Estefania Peña, Renato Natal Jorge, Miguel A. Martínez, Pedro S. Martins

MS 103 - MECHANICS OF BIOLOGICAL TISSUES 55
Organized by Markus Böl, Gerhard A. Holzapfel

MS 105 - SIMULATION OF CARDIOVASCULAR PROCEDURES AND DEVICES 81
Organized by Ferdinando Auricchio, Michele Conti, Simone Morganti, Alessandro Reali, Alessandro Veneziani

MS 106 - DIRECT AND INVERSE METHODS FOR CARDIOVASCULAR AND PULMONARY BIOMECHANICS 98
Organized by Wolfgang A. Wall, C. Alberto Figueroa, Marek Behr

MS 108 - NUMERICAL METHODS FOR COUPLED PROBLEMS IN BIOMEDICAL APPLICATIONS 105
Organized by Martina Bukac, Annalisa Quaini

MS 111 - POPULATION BALANCE MODELING: CURRENT STATUS, FUTURE PROSPECTS AND NOVEL APPLICATIONS FROM NANOPARTICLES' SYNTHESIS TO (LUNG) CANCER 120
Organized by Georgios Lolas, Georgios Bourantas, Panagiotis Gavriliadis, Konstantinos Syrigos

MS 112 - ANEURYSMS: SOLID MECHANICS, FLUID MECHANICS, AND MECHANOBIOLOGY 137
Organized by Christian J. Cyron, Sven Hirsch, Philippe Bijlenga, Roland C. Aydin, Anne M. Robertson, Gerhard A. Holzapfel

MS 113 - MATHEMATICAL AND NUMERICAL MODELING OF THE HEART 155
Organized by Luca Dede', Luca Pavarino, Alfio Quarteroni

MS 115 - TUMOR GROWTH MODELING AND THE MECHANICAL ASPECTS OF CANCER 178
Organized by Hector Gomez, Assad Oberai, Krishna Garikipati, Kristen Mills, Thomas J.R. Hughes

MS 201 - MICROSTRUCTURE-DRIVEN DEFORMATION AND FAILURE IN CRYSTALLINE MATERIALS 188
Organized by Pilar Ariza, Lucia Nicola, Angelo Simone

MS 202 - CIVIL ENGINEERING MATERIALS AND STRUCTURES UNDER EXTREME LOADINGS 216
Organized by Fabrice Gatuingt, Frédéric Dufour, Panagiotis Kotronis

MS 203 - COMPUTATIONAL METHODS FOR MODELLING INSTABILITIES IN SOLIDS & STRUCTURES 254
Organized by Spyros A. Karamanos

MS 204 - IMPACT AND CRASH MECHANICS 273
Organized by Manfred Bischoff, Fabian Duddeck

MS 205 - PROBABILISTIC APPROACH TO NUMERICAL SIMULATION OF FRACTURE 323
Organized by Alexander V. Gerasimov

MS 301 - METHODS FOR CUT AND COMPOSITE MESHES: THEORY, ALGORITHMS AND APPLICATIONS 373
Organized by Mats G. Larson, André Massing

MS 302 - MESH GENERATION AND ADAPTION 384
Organized by Josep Sarrate, Xevi Roca, Rafael Montenegro, Eloi Ruiz

MS 303 - CURVED MESH GENERATION FOR HIGH-ORDER METHODS 417
Organized by Xevi Roca, Josep Sarrate

MS 304 - COMPUTATIONAL MODELLING OF ADDITIVE PRODUCTION PROCESSES 469
Organized by Dirk Hartmann, Stefan Kollmannsberger, Ernst Rank, Utz Wever

MS 305 - ADVANCED MESHING METHODS FOR INDUSTRIAL APPLICATIONS 480
Organized by Frederic Alauzet, Thierry Coupez, Alain Dervieux, Adrien Loseille

MS 306 - LATTICE SPRING METHODS FOR LINEAR AND NONLINEAR CONTINUA 511
Organized by Ioannis Doltsinis

MS 403 - PARTICLE-BASED METHODS IN FLUID MECHANICS 539
Organized by Sergio Idelsohn, Eugenio Oñate

MS 404 - SIMULATION OF ENVIRONMENTAL FLOWS 650
Organized by Pablo Ortiz, Piotr K. Smolarkiewicz, Joanna Szmelter

MS 405 - COMPUTATIONAL MODELING OF MULTIPHASE FLOWS: ADVANCED METHODS, INTERFACE PHENOMENA AND ENVIRONMENTAL APPLICATIONS 750
Organized by Adeline Montlaur, Santiago Arias Calderón, Martin Kronbichler

MS 406 - ADVANCES IN COMPUTATIONAL METHODS FOR GAS-LIQUID TWO-PHASE FLOW 788
Organized by Byeong Rog Shin, Takeo Kajishima

MS 408 - MANIPULATION AND CONTROL OF TURBULENT FLOW 831
Organized by Markus Rütten, Christina Voß

MS 409 - CURRENT TRENDS IN MODELLING AND SIMULATION OF TURBULENT FLOWS 865
Organized by Suad Jakirlić

MS 410 - COMPLEX FLUID FLOWS IN ENGINEERING: MODELLING, SIMULATION AND OPTIMIZATION 949
Organized by Stefanie Elgeti, Philipp Knechtges

MS 411 - NON-NEWTONIAN HEAT AND FLUID FLOW SUBJECTED TO MAGNETIC FORCES 1061
Organized by Laszlo Konozsy, Dimitris Drikakis

MS 412 - NUMERICAL METHODS FOR WAVES AND FLOWS IN COASTAL AND DEEP WATER HYDRODYNAMICS 1093
Organized by Nina Shokina, Yuri Shokin, Leonid Chubarov, Gayaz Khakimzyanov, Vadym Aizinger, Denys Dutykh

MS 414 - NEW TRENDS IN NUMERICAL METHODS FOR MULTI-MATERIAL COMPRESSIBLE FLUID FLOWS 1139
Organized by Andy Barlow, Michael Dumbser, Raphaël Loubère, Pierre-Henri Maire, Rob Rieben, Mikhail Shashkov, François Vilar

MS 415 - COMPUTATIONAL NON-NEWTONIAN FLUID MECHANICS 1205
Organized by Georgios Georgiou, John Tsamopoulos

MS 501 - ALGORITHMIC ASPECTS OF HIGH-PERFORMANCE COMPUTING FOR MECHANICS AND PHYSICS 1237
Organized by Santiago Badia, Victor Calo, Javier Principe

MS 503 - HPC-BASED SIMULATIONS FOR THE ENGINEERING REALM AND INDUSTRIAL APPLICATIONS 1277
Organized by Makoto Tsubokura, Mariano Vázquez, Takayuki Aoki

MS 504 - NUMERICAL METHODS AND TOOLS FOR KEY EXASCALE COMPUTING CHALLENGES IN ENGINEERING AND APPLIED SCIENCES 1352
Organized by Eugenio Oñate, Manolis Papadrakakis, Peter Wriggers

MS 505 - INTERACTIVE SIMULATIONS IN COMPUTATIONAL ENGINEERING 1392
Organized by Adrian Harwood, Petra Wenisch

MS 506 - ACCURACY AND EFFICIENCY OF APPROXIMATE COMPUTATIONS IN SCIENCE AND ENGINEERING 1409
Organized by Aram Soroushian

MS 601 - SHOCK WAVE-BOUNDARY LAYER INTERACTION AND ITS CONTROL 1455
Organized by Piotr Doerffer, George Barakos

MS 602 - INNOVATIVE METHODS FOR FLUID-STRUCTURE-INTERACTION 1498
Organized by E. Harald van Brummelen, Roger Ohayon, Trond Kvamsdal

MS 603 - COMPUTATIONAL METHODS IN FLUID-STRUCTURE INTERACTION WITH IMPACT ON INDUSTRIAL APPLICATIONS 1582
Organized by Elisabeth Longatte, Yannick Hoarau, Marianna Braza

MS 605 - FRICTIONAL CONTACTS WITH LUBRICATION – BASICS AND APPLICATIONS 1623
Organized by Michael Müller, Thomas Hagemann

MS 606 - COMPUTATIONAL MODELING OF HYDRAULIC FRACTURING 1637
Organized by Gianluca Cusatis, Gilles Pijaudier-Cabot, Günther Meschke

MS 607 - ADVANCES IN COMPUTATIONAL METHODS FOR LIQUID-VAPOR FLOWS WITH PHASE TRANSFER PROCESSES 1672
Organized by Rémi Abgrall, Pietro M. Congedo, Tore Flåtten, Bernhard Müller, Marica Pelanti, Maria Giovanna Rodio

MS 608 - ADVANCES IN TIME INTEGRATION FOR SOLID, FLUID AND COUPLED SYSTEMS 1709
Organized by Ilinca Stanciulescu, Peter Betsch

MS 609 - ADVANCED COMPUTATIONAL MODELING OF BATTERIES AND FUEL CELLS 1838
Organized by Edwin Knobbe, Wolfgang A. Wall

MS 610 - NUMERICAL METHODS TO STUDY THE CONTACT MECHANICS OF DRY, ADHESIVE AND LUBRICATED ROUGH SURFACES 1850
Organized by Carmine Putignano, Daniele Dini

MS 612 - NUMERICAL SIMULATIONS FOR SMART-CITY APPLICATIONS 1876
Organized by Julien Waeytens, Rachida Chakir

MS 615 - COMPUTATIONAL MODELS IN MAGNETOHYDRODYNAMICS 1886
Organized by Oleg Zikanov

MS 701 - ADVANCED MATERIALS: COMPUTATIONAL ANALYSIS OF PROPERTIES AND PERFORMANCE 1893
Organized by Vadim V. Silberschmidt, Valery P. Matveenko

MS 702 - MODELING OF NANOFILLED COMPOSITES 1971
Organized by Konstantinos I. Tserpes

MS 705 - IDENTIFICATION OF MATERIAL MODELS 2003
Organized by Danuta Szeliga, Wacław Kuś, Tadeusz Burczyński, Jan Kusiak

MS 706 - MODELING OF FIBER-BASED STRUCTURES - TEXTILES AND TEXTILE REINFORCED COMPOSITES 2010
Organized by Yordan Kyosev, Philippe Boisse, Nahiene Hamila, Damien Durville

MS 707 - MICROMECHANICAL MODELLING: COMPETITION BETWEEN ANALYTICAL AND NUMERICAL METHODS 2039
Organized by Siegfried Schmauder, Vera Petrova

MS 711 - FOURIER-BASED METHODS FOR COMPUTING THE BEHAVIOR OF HETEROGENEOUS MATERIALS DEVELOPMENTS, EXTENSIONS AND APPLICATIONS 2099
Organized by Lionel Gélébart, Hervé Moulinec, Franz Roters, François Willot

MS 712 - SMART MATERIAL SYSTEMS AND STRUCTURES 2110
Organized by Mieczysław Kuczma, Pavel Krejči, Jörg Schröder, Georgios E. Stavroulakis, Gwidon Szefer

MS 713 - MICROSTRUCTURE-BASED MODELLING OF HETEROGENEOUS MATERIALS 2134
Organized by Jan Zeman, Jan Novak, Guillermo Díaz

MS 714 - STRENGTH, FATIGUE AND STABILITY OF COMPOSITE STRUCTURES 2182
Organized by Raimund Rolfes, Martin Ruess, Kai-Uwe Schröder

VOLUME II

MINISYMPOSIA

MS 715 - COMPUTATIONAL ANALYSIS OF COMPOSITE STRUCTURES 2210
Organized by Efstathios E. Theotokoglou

MS 801 - MULTISCALE COMPUTATIONAL HOMOGENIZATION FOR BRIDGING SCALES IN THE MECHANICS AND PHYSICS OF COMPLEX MATERIALS 2266
Organized by Julien Yvonnet, Kenjiro Terada, Peter Wriggers, Marc Geers

MS 802 - ADVANCES IN THE MODELLING OF MULTI-SCALE, MULTI-PHYSICS AND MULTI-UNCERTAINTY PROBLEMS 2323
Organized by Francisco M. Andrade Pires, Chengfeng Li

MS 805 - ADVANCED MULTI-PHYSICS AND MULTI-SCALE TECHNIQUES FOR MODELING INELASTIC PROCESSES IN SOLIDS: DAMAGE, FRACTURE AND CONTACT MECHANICS 2353
Organized by Mauro Corrado, Marco Paggi, José Reinoso

MS 806 - MULTISCALE MODELLING OF MATERIALS AND STRUCTURES 2363
Organized by Tadeusz Burczyński, Xavier Oliver, Maciej Pietrzyk, Alfredo Huespe

MS 807 - ADVANCED COMPUTATIONAL STRATEGIES FOR MODELLING, SIMULATION AND CHARACTERISATION OF MULTI-SCALE HETEROGENEOUS MATERIALS 2449
Organized by Stéphane Bordas, Daniel Dias-da-Costa, Fabrice Pierron, Timon Rabczuk, Pierre Kerfriden, Pascal Lava

MS 808 - MULTISCALE AND MULTIPHYSICS MODELING OF CEMENTITIOUS MATERIALS 2460
Organized by Jörg F. Unger, Thomas Titscher

MS 809 - MULTISCALE STOCHASTIC FINITE ELEMENT METHODS 2471
Organized by George Stefanou, Xi Frank Xu, Yu Ching Wu

MS 811 - MULTISCALE MODELING OF CONCRETE AND CONCRETE STRUCTURES 2501
Organized by Herbert Mang, Yong Yuan

MS 901 - ISOGEOMETRIC METHODS 2514
Organized by Yuri Bazilevs, David J. Benson, Rene De Borst, Thomas J.R. Hughes, Trond Kvamsdal, Alessandro Reali, Giancarlo Sangalli, Clemens V. Verhoosel

MS 902 - INNOVATIVE NUMERICAL APPROACHES FOR MULTI-PHYSICS PROBLEMS 2558
Organized by Anna Pandolfi, Laurent Stainier, Kerstin Weinberg

MS 903 - ADVANCES IN FICTITIOUS DOMAIN METHODS FOR SOLID MECHANICS 2566
Organized by Alexander Düster, Ernst Rank, Stefan Kollmannsberger, Andreas Schröder

MS 905 - DISCONTINUOUS GALERKIN METHODS: NEW TRENDS AND APPLICATIONS 2614
Organized by Sonia Fernández-Méndez, Nicoletta Franchina

MS 906 - MATHEMATICAL ADVANCES IN ISOGEOMETRIC ANALYSIS 2715
Organized by Annalisa Buffa, John A. Evans, Thomas J.R. Hughes, Giancarlo Sangalli

MS 907 - REGULARIZED ENRICHED APPROXIMATIONS AND QUADRATURE FOR DISCONTINUITIES, SINGULARITIES AND CONTINUOUS-DISCONTINUOUS TRANSITION 2726
Organized by Elena Benvenuti, Giulio Ventura, José M.A. César de Sá

MS 908 - VERIFICATION AND VALIDATION OF STRUCTURAL MECHANICS SIMULATION MODELS 2734
Organized by George Lampeas

MS 910 - HIGH ORDER CFD METHODS: CONCLUSIONS AND OUTLOOK 2843
Organized by Koen Hillewaert, John Ekaterinaris, Peter Vincent, Norbert Kroll, Norbert Huynh, Z.J. Wang

MS 911 - NUMERICAL METHODS IN THE MECHANICS OF GENERALIZED CONTINUA 2869
Organized by Elena Atroshchenko, Jack S. Hale, George Bourantas, Stéphane P.A Bordas

MS 912 - HIGH-ORDER METHODS, SENSITIVITY ANALYSIS AND ADAPTATION FOR THE NAVIER STOKES EQUATIONS 2883
Organized by Vincent Couaillier, Rémi Abgrall, Eusebio Valero

MS 913 - HIGH-ORDER METHODS FOR POLYGONAL AND POLYHEDRAL MESHES 2930
Organized by Lourenço Beirao da Veiga, Franco Brezzi, Donatella Marini, Alessandro Russo

MS 916 - DIRECT METHODS FOR LIMIT STATES OF MATERIALS AND STRUCTURES 2971
Organized by Konstantinos V. Spiliopoulos, Dieter Weichert

MS 917 - MESOSCOPIC METHODS FOR COMPLEX FLUIDS AND SOFT MATTER 3026
Organized by Zhen Li, Wenxiao Pan, Igor V. Pivkin

MS 918 - COMPUTER ALGEBRA SYSTEMS IN MODELLING STATIC AND DYNAMIC PROBLEMS IN MECHANICS OF SOLIDS 3045
Organized by Alexander V. Matrosov, Dmitriy P. Goloskokov

MS 919 - RECENT ADVANCES IN NUMERICAL SIMULATION AND ANALYSIS OF KINETIC MODELS 3113
Organized by E. Harald van Brummelen, Manuel Torrilhon

MS 921 - RECENT ADVANCES IN BOUNDARY ELEMENT METHODS 3139
Organized by Gernot Beer, Luiz Wrobel, Martin Schan

MS 922 - HIGH-ORDER METHODS FOR ELASTIC WAVES AND THEIR APPLICATION 3211
Organized by Thomas Hagstrom, Daniel Appelo

MS 923 - NOVEL DISCRETIZATION METHODS – MATHEMATICAL AND MECHANICAL ASPECTS 3224
Organized by Jörg Schröder, Peter Wriggers, Ferdinando Auricchio, Carsten Carstensen

MS 1001 - STRUCTURAL AND MULTIDISCIPLINARY OPTIMIZATION 3239
Organized by J.F. Aguilar Madeira, Helder C. Rodrigues

MS 1002 - EVOLUTIONARY ALGORITHMS AND METAHEURISTICS IN CIVIL ENGINEERING AND CONSTRUCTION MANAGEMENT 3473
Organized by Jorge Magalhaes-Mendes, David Greiner

MS 1003 - ADVANCES IN DESIGN OPTIMIZATION OF STRUCTURES AND MATERIALS 3534
Organized by Zhen Luo, Zhan Kang

MS 1004 - AERODYNAMIC STRATEGIES FOR THE GLOBAL OPTIMIZATION OF FLYING CONFIGURATIONS IN SUPERSONIC FLOW 3596
Organized by Adriana Nastase, Catalin Nae

MS 1005 - MONITORING AND CONTROL OF STRUCTURES 3630
Organized by Resat Oyguc

MS 1006 - PARAMETER IDENTIFICATION IN SOLID MECHANICS 3652
Organized by A. Gil Andrade-Campos, Marco Rossi, Sandrine Thuillier, Franck Toussaint, Marta C. Oliveira

MS 1007 - ADDITIVE MANUFACTURING AND OPTIMIZATION 3689
Organized by Ekkehard Ramm, Ole Sigmund, Pierre Duysinx, Wing Kam Liu

MS 1008 - ULTRASONIC GUIDED WAVES TESTING AND MONITORING 3753
Organized by Yaacoubi Slah, Nico Declercq

MS 1009 - ADJOINT METHODS FOR STEADY & UNSTEADY OPTIMIZATION 3770
Organized by Kyriakos C. Giannakoglou, Jens Dominik Mueller

MS 1010 - INVERSE PROBLEMS, DESIGN AND OPTIMIZATION 4061
Organized by Marcelo J. Colaço, Helcio R. B. Orlande, George S. Dulikravich

MS 1011 - SURROGATE-ASSISTED EVOLUTIONARY ALGORITHMS IN AERODYNAMIC DESIGN/OPTIMIZATION 4082
Organized by Varvara Asouti, Esther Andrés, Emiliano Iuliano

MS 1013 - SOLUTION OF LARGE-SCALE INVERSE PROBLEMS 4164
Organized by Clint Dawson, Steve Mattis, Troy Butler, Lindley Graham

MS 1014 - DESIGN OPTIMIZATION AND INVERSE PROBLEMS FOR WAVE PROPAGATION PROBLEMS 4178
Organized by Martin Berggren

MS 1101 - REDUCED BASIS, POD AND PGD MODEL ORDER REDUCTION TECHNIQUES 4187

THERMODYNAMICS OF IRREVERSIBLE AGGREGATION 120
Themis Matsoukas

MS 112: ANEURYSMS: SOLID MECHANICS, FLUID MECHANICS, AND MECHANOBIOLOGY
RELATIVE ROLES OF MECHANICS AND BIOCHEMISTRY IN THE INITIATION AND PROGRESSION OF CEREBRAL ANEURYSM THROMBOSIS 137
Malebogo Ngoepe, Yiannis Ventikos

TECHNIQUES TO INTEGRATE PATIENT-SPECIFIC SIMULATION OF ANEURYSMAL BLOOD FLOW INTO THE CLINICAL WORKFLOW 147
Gábor Závodszky, Roland Joó-Kovács, György Paál, István Szikora

MS 113: MATHEMATICAL AND NUMERICAL MODELING OF THE HEART
PROXIMAL ISOVELOCITY SURFACE FOR DIFFERENT MITRAL VALVE HOLE GEOMETRIES 155
Alexandre This, Hernán G. Morales, Odile Bonnefous

COMPARISON OF TETRAHEDRAL AND HEXAHEDRAL MESHES FOR FINITE ELEMENT SIMULATION OF CARDIAC ELECTRO-MECHANICS 164
Bernardo Lino De Oliveira, Joakim Sundnes

MS 115: TUMOR GROWTH MODELING AND THE MECHANICAL ASPECTS OF CANCER
A PARAMETRIC STUDY OF A MULTIPHASE POROUS MEDIA MODEL FOR TUMOR SPHEROIDS AND ENVIRONMENT INTERACTIONS 178
P. Mascheroni, D.P. Boso, C. Stigliano, M. Carfagna, L. Preziosi, P. Decuzzi, B.A. Schrefler

200 DAMAGE, FRACTURE AND FAILURE

MS 201: MICROSTRUCTURE-DRIVEN DEFORMATION AND FAILURE IN CRYSTALLINE MATERIALS
STABILITY OF ASYMMETRIC GRAIN BOUNDARIES IN GRAPHENE 188
J.P. Mendez, F. Arca, M.P. Ariza

DEFORMATION-DIFFUSION COUPLED ANALYSIS OF LONG-TERM HYDROGEN DIFFUSION IN NANOFILMS 197
Xingsheng Sun, Pilar Ariza, Kevin Wang

MESH OBJECTIVE DAMAGE MODELING OF DUCTILE FRACTURE AT VISCO-PLASTIC CONTINUUM RESPONSE ... 209
Senad Razanica, Ragnar Larsson, B. Lennart Josefson

MS 202: CIVIL ENGINEERING MATERIALS AND STRUCTURES UNDER EXTREME LOADINGS

EQUIVALENT SDOF MODEL FOR ESTIMATING BLAST-INDUCED DYNAMIC REACTIONS OF EQUILATERAL TRIANGULAR HARDENED WALL ELEMENTS 216
Sebastian Mendes, Liling Cao, Douglas Heinze, Elisabeth Malsch

MODELLING STRATEGIES OF PRESTRESSING TENDONS AND REINFORCEMENT BARS IN CONCRETE STRUCTURES 234
Antoine Llau, Ludovic Jason, Frédéric Dufour, Julien Baroth

MODELING AND SIMULATION FOR AN OPTIMIZED DESIGN OF A DYNAMIC BEND TEST. 242
Rana Akiki, Fabrice Gatuingt, Cédric Giry, Nicolas Schmitt, Lavinia Stéfan

MS 203: COMPUTATIONAL METHODS FOR MODELLING INSTABILITIES IN SOLIDS & STRUCTURES

ON STABILITY LOSS OF A THIN-WALLED SPHERICAL SHELL SUBJECTED TO EXTERNAL PRESSURE AND INTERNAL HOMOGENEOUS CORROSION 254
Emmanuel Gutman, Rudolf Bergman, Semyon Levitski

EFFICIENCY OF DAMAGE-PLASTICITY MODELS IN CAPTURING COMPACTION-EXPANSION TRANSITION OF CONCRETE UNDER DIFFERENT COMPRESSION LOADING CONDITIONS 261
Reza Mousavi, Masoud D. Champiri, Kaspar J. Willam

MS 204: IMPACT AND CRASH MECHANICS

A SIMPLIFIED MODEL OF A STEEL COLUMN SUBJECTED TO IMPACT 273
Piseth Heng, Mohammed Hjiaj, Jean-Marc Battini

MATERIAL MODELLING OF CAST ALUMINIUM BY APPLICATION OF THE WILKINS DAMAGE MODEL 287
Christian Mühlstätter, Matthias Hartmann

FINITE ELEMENT SIMULATION OF CRACK PROPAGATION AND DELAMINATION IN LAYERED SHELLS DUE TO BLADE CUTTING 295
Federica Confalonieri, Aldo Ghisi, Umberto Perego

EVOLUTIONARY LEVEL SET METHOD FOR CRASHWORTHINESS TOPOLOGY OPTIMIZATION 309
Mariusz Bujny, Nikola Aulig, Markus Olhofer, Fabian Duddeck

MS 205: PROBABILISTIC APPROACH TO NUMERICAL SIMULATION OF FRACTURE

NUMERICAL SIMULATION OF HIGH-VELOCITY INTERACTION ELEMENTS WITH THIN-WALLED STRUCTURES ... 323
Alexander V. Gerasimov, Sergey V. Pashkov

NUMERICAL SIMULATION OF MULTILAYER COMPOSITES FAILURE UNDER DYNAMIC LOADING 334
Sergey A. Zelepugin, Aleksey S. Zelepugin, Vladimir F. Tolkachev

SIMULATION OF MECHANICAL PROPERTIES OF CERAMIC PARTS PRODUCED BY ADDITIVE TECHNOLOGIES IN WIDE RANGE OF LOADING RATES 341
Vladimir A. Skripnyak, Evgeniya Skripnyak, Vladimir V. Skripnyak, Irina K. Vaganova

FRACTURE OF THIN METAL SHEETS WITH DISTRIBUTION OF GRAIN SIZES IN THE LAYERS 355
Natalia V. Skripnyak, Vladimir V. Skripnyak, Vladimir A. Skripnyak

BRITTLE OR QUASI-BRITTLE FRACTURE OF CERAMIC NANOCOMPOSITES UNDER DYNAMIC LOADING 366
Evgeniya G. Skripnyak, Vladimir A. Skripnyak, Vladimir V. Skripnyak, Natalia V. Skripnyak, Irina K. Vaganova

300 DISCRETIZATION METHODS, GRID, MESH AND SOLID GENERATION

MS 301: METHODS FOR CUT AND COMPOSITE MESHES: THEORY, ALGORITHMS AND APPLICATIONS
REMOVING THE STABILIZATION PARAMETER IN FITTED AND UNFITTED SYMMETRIC NITSCHE FORMULATIONS 373
Christoph Lehrenfeld

MS 302: MESH GENERATION AND ADAPTION
A SEMI-UNSTRUCTURED TURBOMACHINERY MESHING LIBRARY WITH FOCUS ON MODELING OF SPECIFIC GEOMETRICAL FEATURES 384
Marco Stelldinger, Thomas Giersch, Felix Figaschewsky, Arnold Kühhorn

CARTESIAN MESHES WITH DYNAMIC LOCAL WAVELET-BASED REFINEMENT FOR FLOW AROUND BODY PROBLEMS. 402
Kirill Merkulov, Igor Menshov, Andrew Plenkin

A MESH GENERATION METHOD FOR HISTORICAL MONUMENTAL BUILDINGS: AN INNOVATIVE APPROACH ... 409
Giovanni Castellazzi, Antonio Maria D'Altri, Stefano De Miranda, Francesco Ubertini, Gabriele Bitelli, Alessandro Lambertini, Ilenia Selvaggi, Antonio Tralli

MS 303: CURVED MESH GENERATION FOR HIGH-ORDER METHODS
HIGH-ORDER CURVED MESH GENERATION BY USING A FINE LINEAR TARGET MESH 417
Verena Schmid, Hadrien Beriot, Onur Atak, Gwenael Gabard

AUTOMATIC GENERATION OF 3D UNSTRUCTURED HIGH-ORDER CURVILINEAR MESHE 428
Michael Turner, David Moxey, Spencerj.Sherwin, Joaquim Peiro

MESH GENERATION FOR THE 2D NURBS-ENHANCED FINITE ELEMENT METHOD 444
Ruben Sevilla, Luke Rees, Oubay Hassan

IMAGE SEGMENTATION TECHNIQUES FOR BIOMEDICAL MODELING: ELECTROPHYSIOLOGY AND HEMODYNAMICS 454
Alexander Danilov, Roman Pryamonosov, Alexandra Yurova

A CONSISTENTLY LINEARISED SOLID MECHANICS BASED MESH DEFORMATION TECHNIQUE FOR HIGH ORDER CURVED ELEMENTS 462
Roman Poya, Ruben Sevilla, Antonio Gil

MS 304: COMPUTATIONAL MODELLING OF ADDITIVE PRODUCTION PROCESSES
VALIDATION OF MODELLING ASSUMPTIONS FOR THE BUILDUP SIMULATION OF LASER BEAM MELTING ON THE BASIS OF THE RESIDUAL STRESS DISTRIBUTION 469
Fabian Bayerlein, Christian Zeller, Martin Wunderer, Johannes Weirather, Michael F. Zäh, Markus Schmid, Georg Schlick, Roland Hessert, Michael Hofmann, Thomas Uihlein

MS 305: ADVANCED MESHING METHODS FOR INDUSTRIAL APPLICATIONS
MESHING OCEAN DOMAINS FOR COASTAL ENGINEERING APPLICATIONS 480
Alexandros Avdis, Christian Jacobs, Simon Mouradian, Jon Hill, Matthew Piggott

HIGH-ORDER TRACKING METHOD FOR THE SIMULATION OF BURNING FRONTS IN 3D 493
Denis Gueyffier, Bastien Andrieu

SINGULAR MESH GENERATION FROM MULTIPLE OVERSET MESHES: A TOOL FOR INDUSTRIAL APPLICATIONS...501
Gennaro Abbruzzese, Marta Cordero Gracia, Mariola Gómez López, Nuno Vinha

MS 306: LATTICE SPRING METHODS FOR LINEAR AND NONLINEAR CONTINUA
GENERATING TRIANGULAR LATTICES FOR SURFACES WITH IRREGULAR BOUNDARY 511
Tatiana Sá Marques, Vitor Dias Da Silva

WAVE TRANSMISSION THROUGH NONLINEAR IMPACTING METAMATERIAL UNIT 526
Arnab Banerjee, Raj Das, Emilio Calius

400 FLOW PROBLEMS

MS 403: PARTICLE-BASED METHODS IN FLUID MECHANICS
A PARTICLE FINITE ELEMENT METHOD FOR MACHINING SIMULATIONS 539
Juan Manuel Rodríguez Prieto, Pär Jonsén, Ales Svoboda

DYNAMICS OF DUST PARTICLES NEAR THE ROUND BELL SUCTION INLET 554
Olga Averkova, Konstantin Logachev, Artur Logachev, Elena Tolmacheva

RECOVERY OF DIFFERENTIATION/INTEGRATION COMPATIBILITY OF MESHLESS OPERATORS VIA LOCAL ADAPTATION OF THE POINT CLOUD IN THE CONTEXT OF NODAL INTEGRATION 568
Gabriel Fougeron, Guillaume Pierrot, Denis Aubry

MODELING OF NON-SPHERICAL, ELONGATED PARTICLES FOR INDUSTRIAL SUSPENSION FLOW SIMULATION ... 586
Jakob Dominik Redlinger-Pohn, Lisa Maria König, Christoph Kloss, Christoph Goniva, Stefan Radl

A LAGRANGIAN FINITE ELEMENT METHOD FOR THE SIMULATION OF 3D COMPRESSIBLE FLOWS 600
Massimiliano Cremonesi, Attilio Frangi

A LAGRANGIAN PFEM APPROACH TO THE NUMERICAL SIMULATION OF 3D LARGE SCALE LANDSLIDES IMPINGING IN WATER RESERVOIRS 608
Massimiliano Cremonesi, Francesco Ferri, Umberto Perego

A NUMERICAL INVESTIGATION OF FLOW DYNAMICS OVER A TRAPEZOIDAL SMOOTH OPEN CHANNEL ……..... 619
Giacomo Viccione

A NUMERICAL INVESTIGATION OF LIQUID IMPACT ON PLANAR SURFACES. …….. 627
Giacomo Viccione, Vittorio Bovolin, Eugenio Pugliese Carratelli

AERODYNAMICS OF AN UNSTEADY PARTICLE FLOW IN THE CHUTE …….. 638
Olga Averkova, Ivan Logachev, Konstantin Logachev

MS 404: SIMULATION OF ENVIRONMENTAL FLOWS
PROJECTION-BASED MODEL REDUCTION FOR FINITE ELEMENT APPROXIMATION OF SHALLOW WATER FLOWS …….. 650
Matthew Farthing, Alexander Lozovskiy, Christopher Kees

EFFICIENT TWO-DIMENSIONAL SIMULATION MODELS FOR HYDRAULIC AND MORPHODYNAMIC TRANSIENTS..670
Pilar Garcia-Navarro, Javier Murillo, Mario Morales-Hernandez, Carmelo Juez, Asier Lacasta

ADDRESSING THE CHALLENGES OF IMPLEMENTATION OF HIGH-ORDER FINITE-VOLUME SCHEMES FOR ATMOSPHERIC DYNAMICS ON UNSTRUCTURED MESHES …….. 684
Panagiotis Tsoutsanis, Dimitris Drikakis

MODELLING OF LONG WAVES (SEICHES) IN CASCAIS BAY …….. 709
Vera Bras, Antonio Trigo-Teixeira

A MESHLESS METHOD FOR SIMULATION OF PARTICLE-DRIVEN GRAVITY CURRENTS WITH OBSTACLES ……. 720
Karel Kovářík, Jozef Mužík, Dana Sitányiová

APPLICATION OF THE SHALLOW WATER EQUATIONS TO REAL FLOODING CASE …….. 735
Hani Ali, Pierre-Yves Lagrée, Jose-Maria Fullana

MS 405: COMPUTATIONAL MODELING OF MULTIPHASE FLOWS: ADVANCED METHODS, INTERFACE PHENOMENA AND ENVIRONMENTAL APPLICATIONS
A MULTIPHASE MODEL FOR THE NUMERICAL SIMULATION OF ICE-FORMATION IN SEA-WATER …….. 750
Vanessa Covello, Antonella Abbà, Luca Bonaventura, Alessandro Della Rocca, Lorenzo Valdettaro

A 3D CFD NUMERICAL STUDY OF THE BUBBLE GENERATION PROCESS INTO A BUBBLE T-JUNCTION GENERATOR AND ITS COMPARISON WITH EXPERIMENTAL DATA: PART I …….. 772
Santiago Arias, Adeline Montlaur

MS 406: ADVANCES IN COMPUTATIONAL METHODS FOR GAS-LIQUID TWO-PHASE FLOW
COUPLING OF FLUID STUCTURE INTRACTION SOLVER WITH A VOF METHOD FOR MULTIPHASE STRUCTURE INTERACTION …….. 788
Daniele Cerroni, Roberto Da Via', Sandro Manservisi, Filippo Menghini

A METHOD OF CHAINED ANALYTICAL WAVE STRUCTURES FOR LARGE SCALE STRATIFIED TWO-PHASE PIPE FLOWS …….. 806
Andreas Holm Akselsen

MS 408: MANIPULATION AND CONTROL OF TURBULENT FLOW
MODELING OF EXCITATION OF CONTROLLING DISTURBANCES IN SWEPT WING BOUNDARY LAYER BY MEANS OF PLASMA ACTUATORS 831
Sergey Chernyshev, Andrey Kiselev, Aleksandr Kuryachii

NUMERICAL SIMULATION OF INTERACTION PROCESS BETWEEN DIELECTRIC BARRIER DISCHARGE AND DUCT FLOW 844
Pavel Semenev, Dmitriy Pudovikov, Pavel Toktaliev

IMPLEMENTATION OF POD AND DMD METHODS IN APACHE SPARK FRAMEWORK FOR SIMULATION OF UNSTEADY TURBULENT FLOW IN THE MODEL COMBUSTOR 857
Mikhail Kalugin, Sergei Strijhak

MS 409: CURRENT TRENDS IN MODELLING AND SIMULATION OF TURBULENT FLOWS
NUMERICAL VALIDATION OF A FOUR PARAMETER LOGARITHMIC TURBULENCE MODEL 865
Daniele Cerroni, Roberto Da Vià, Sandro Manservisi, Filippo Menghini

LARGE-EDDY SIMULATION AND FAR FIELD ACOUSTICS OF A SUBSONIC HOT JET 878
O. Labbé

ON THE APPLICATION OF MODERN TURBULENCE MODELS IN THE FLOW LAMINARIZATION PROBLEMS 893
Sergey Chernyshev, Aleksander Ivanov, Andrey Kiselev, Dmitriy Sboev, Leonid Teperin, Petr Vorotnikov, Valeriy Vozhdaev

ASSESSMENT OF RANS AND DES METHODS FOR THE AHMED BODY 912
Emmanuel Guilmineau, Gan Bo Deng, Alban Leroyer, Patrick Queutey, Michel Visonneau, Jeroen Wackers

A WAY TO IMPROVE JET MODELING WITHIN RANS EQUATION SYSTEM 922
Alexey Troshin

A MODIFIED SSG/LLR-ω REYNOLDS STRESS MODEL FOR PREDICTING BLUFF BODY AERODYNAMICS 936
Csaba Klajbár, László Könözsy, Karl W. Jenkins

MS 410: COMPLEX FLUID FLOWS IN ENGINEERING: MODELLING, SIMULATION AND OPTIMIZATION
NUMERICAL ANALYSIS OF RAREFIED GAS FLOWS USING THE ACADEMIC CFD CODE GALATEA 949
Angelos Klothakis, Georgios Lygidakis, Ioannis Nikolos

TOPOLOGY OPTIMIZATION FOR FLUID FLOW EMPLOYING LOCAL OPTIMALITY CRITERIA 967
Philip Sarstedt, Gerhard Kachel, Jörg Ettrich, Karl Bühler

NUMERICAL SIMULATION OF THE CONJUGATE HEAT TRANSFER IN THE COOLING SYSTEM OF THE COMBUSTION CHAMBERS OF THE AVIATION RAMJET ON THE ENDOTHERMIC FUELS 979
Vadim Volokhov, Pavel Toktaliev, Sergei Martynenko

SENSITIVITY STUDY OF THE NUMERICAL SETUP FOR AN AUTOMATIC OPTIMIZATION PROCEDURE FOR A HYDRAULIC MACHINE 992
Alexander Tismer, Markus Schlipf, Stefan Riedelbauch

ADVANCES IN GEOMETRICAL PARAMETRIZATION AND REDUCED ORDER MODELS AND METHODS FOR COMPUTATIONAL FLUID DYNAMICS PROBLEMS IN APPLIED SCIENCES AND ENGINEERING: OVERVIEW AND PERSPECTIVES 1013
F. Salmoiraghi, F. Ballarin, G. Corsi, A. Mola, M. Tezzele, G. Rozza

NEAR WALL BEHAVIOR OF IMPLICIT LARGE EDDY SIMULATIONS 1032
Ioannis Kokkinakis, Dimitris Drikakis

VALIDATION AND VERIFICATION OF A 2D LATTICE BOLTZMANN SOLVER FOR INCOMPRESSIBLE FLUID FLOW 1046
Tamás István Józsa, Máté Szőke, Tom-Robin Teschner, László Könözsy, Irene Moulitsas

MS 411: NON-NEWTONIAN HEAT AND FLUID FLOW SUBJECTED TO MAGNETIC FORCES
VALIDATION OF A MAGNETO- AND FERRO-HYDRODYNAMIC MODEL FOR NON-ISOTHERMAL FLOWS IN CONJUNCTION WITH NEWTONIAN AND NON-NEWTONIAN FLUIDS 1061
László Könözsy, Pietro Scienza, Dimitris Drikakis

NUMERICAL STUDY OF MAGNETIC PARTICLES CONCENTRATION IN BIOFLUID (BLOOD) UNDER THE INFLUENCE OF HIGH GRADIENT MAGNETIC FIELD IN MICROCHANNEL 1084
Vassilios Loukopoulos, George Bourantas, Dimitrios Labropoulos, Vassilios-Martin Nikiforidis, Stéphane Bordas, George Nikiforidis

MS 412: NUMERICAL METHODS FOR WAVES AND FLOWS IN COASTAL AND DEEP WATER HYDRODYNAMICS
NEW ALGORITHM FOR NUMERICAL SIMULATION OF SURFACE WAVES WITHIN THE FRAMEWORK OF THE FULL NONLINEAR DISPERSIVE MODEL 1093
Zinaida Fedotova, Oleg Gusev, Gayaz Khakimzyanov

NUMERICAL MODELLING OF SURFACE WAVES IN THE FRAMEWORK OF THE SHALLOW WATER MODEL 1104
Nina Shokina, Gayaz Khakimzyanov

ON NUMERICAL METHODS FOR SOLVING RUN-UP PROBLEMS. COMPARATIVE ANALYSIS OF NUMERICAL ALGORITHMS AND NUMERICAL RESULTS. 1127
Leonid Chubarov, Alexandr Rychkov, Gayaz Khakimzyanov, Yurii Shokin

MS 414: NEW TRENDS IN NUMERICAL METHODS FOR MULTI-MATERIAL COMPRESSIBLE FLUID FLOWS
EULERIAN CALCULATIONS OF MULTIMATERIAL FLOWS WITH SUB-CELL RECONSTRUCTION OF INTERFACES ... 1139
Igor Menshov, Pavel Zakharov

SOME ACOUSTIC-TRANSPORT SPLITTING SCHEMES FOR TWO-PHASE COMPRESSIBLE FLOWS 1151
Simon Peluchon, Gérard Gallice, Pierre-Henri Maire

LAGRANGE-FLUX EULERIAN SCHEMES FOR COMPRESSIBLE MULTIMATERIAL FLOWS 1165
Florian De Vuyst, Thibault Gasc, Renaud Motte, Mathieu Peybernes, Raphael Poncet

ISOTROPY–PRESERVING SLOPE LIMITERS FOR FINITE VOLUME METHODS ON SQUARE MESHES 1179
Jan Velechovsky, Marianne Francois

BUILDING A MORE EFFICIENT LAGRANGE-REMAP SCHEME THANKS TO PERFORMANCE MODELING 1191
Thibault Gasc, Florian De Vuyst, Mathieu Peybernes, Raphaël Poncet, Renaud Motte

MS 415: COMPUTATIONAL NON-NEWTONIAN FLUID MECHANICS
DEVELOPMENT OF CONFINED VISCOPLASTIC FLOWS WITH HETEROGENEOUS WALL SLIP 1205
Pandelitsa Panaseti, Maria Philippou, Zacharias Kountouriotis, Georgios Georgiou

SQUEEZE FLOW OF VISCOPLASTIC BINGHAM MATERIAL 1215
Larisa Muravleva

500 HIGH PERFORMANCE COMPUTING

MS 501: ALGORITHMIC ASPECTS OF HIGH-PERFORMANCE COMPUTING FOR MECHANICS AND PHYSICS
PSEUDOMULTIGRID GAUSS–SEIDEL METHOD FOR LARGE SCALE AND HIGH PERFORMANCE COMPUTING 1237
Sergey Martynenko, Vadim Volokhov, Pavel Toktaliev

ALGORITHM FOR FAST SIMULATIONS OF SPACE-TIME FINITE ELEMENT METHOD 1260
Marcin Skotniczny, Anna Paszynska, Maciej Paszynski

HYBRID PARALLELISATION OF AN ALGORITHMICALLY DIFFERENTIATED ADJOINT SOLVER 1268
Pavanakumar Mohanamuraly, Jan Christian Huckelheim, Jens-Dominik Mueller

MS 503: HPC-BASED SIMULATIONS FOR THE ENGINEERING REALM AND INDUSTRIAL APPLICATIONS
EFFICIENT PARALLEL GEOMETRY DISTRIBUTION FOR THE SIMULATION OF COMPLEX FLOWS 1277
Andreas Lintermann

LARGE-SCALE FREE-SURFACE FLOW SIMULATION USING LATTICE BOLTZMANN METHOD ON MULTI-GPU CLUSTERS 1294
Naoyuki Onodera, Kunihide Ohashi,

LARGE-SCALE LES ANALYSIS OF AUTOMOTIVE ENGINE COOLING FAN 1305
Yuji Kobayashi, Kenji Yoshida, Itsuhei Kohri, Masaharu Sakai, Hideo Asano

DIRECT AEROACOUSTIC SIMULATION RELATED WITH MODE CHANGE IN A RECORDER 1315
Hiroshi Yokoyama, Ryoma Hamasuna, Akira Miki, Hirofumi Onitsuka, Akiyoshi Iida

NUMERICAL ANALYSIS OF RADIO FREQUENCY BLACKOUT FOR ATMOSPHERIC REENTRY VEHICLE USING CFD-CEM COMBINED METHOD 1325
Yusuke Takahashi, Reo Nakasato, Nobuyuki Oshima

DIRECT FEM LARGE SCALE COMPUTATION OF TURBULENT MULTIPHASE FLOW IN URBAN WATER SYSTEMS AND MARINE ENERGY 1339
Ezhilmathi Krishnasamy, Johan Hoffman, Johan Jansson

MS 504: NUMERICAL METHODS AND TOOLS FOR KEY EXASCALE COMPUTING CHALLENGES IN ENGINEERING AND APPLIED SCIENCES
KINETIC MODELS AND ALGORITHMS FOR SOLUTION OF THE MAGNETOGASDYNAMIC PROBLEMS ON THE MODERN SUPERCOMPUTING SYSTEMS 1352
Boris Chetverushkin, Nicola D'Ascenzo, A. Saveliev, Valeri Saveliev

ERROR ANALYSIS AND QUANTIFICATION IN NEURON SIMULATIONS 1366
Francesco Casalegno, Francesco Cremonesi, Stuart Yates, Michael L. Hines, Felix Schürmann, Fabien Delalondre

EVALUATION OF SPARSE LINEAR ALGEBRA OPERATIONS IN TRILINOS 1381
Mohammad Siahatgar, Gabriele Von Voigt

MS 505: INTERACTIVE SIMULATIONS IN COMPUTATIONAL ENGINEERING
AUTOMATIC VISUALIZATION AND CONTROL OF ARBITRARY NUMERICAL SIMULATIONS 1392
Jan P. Springer, Helen Wright

MS 506: ACCURACY AND EFFICIENCY OF APPROXIMATE COMPUTATIONS IN SCIENCE AND ENGINEERING
DIRECT TIME-DOMAIN INTEGRATION APPROACH FOR VISCOELASTIC SYSTEMS INVOLVING VARIOUS DAMPING MODELS 1409
Zhe Ding, Li Li, Yujin Hu

ON THE PERFORMANCE OF A COMPUTATIONAL COST REDUCTION TECHNIQUE APPLIED TO COOLING TOWERS TRANSIENT ANALYSIS 1421
Aram Soroushian, Amin Jahani Mehrnoosh, Yalda Zarabimanesh, Mohammad Hadi Ghondaghsaz, Ali Baiani, Ali Zakizade

A DIFFERENT LOOK AT THE RICHARDSON EXTRAPOLATION LEADING TO A NEW PROPOSITION 1432
Aram Soroushian

ON THE FREQUENCY CONTENT OF ERRORS ORIGINATED IN A TIME INTEGRATION COMPUTATIONAL COST REDUCTION TECHNIQUE 1443
Aram Soroushian, Mahmood Hosseini, Seyed Mohammad Khalkhali

600 INTERDISCIPLINARY COUPLED AND CONTACT PROBLEMS

MS 601: SHOCK WAVE-BOUNDARY LAYER INTERACTION AND ITS CONTROL
NUMERICAL SIMULATION OF TRANSONIC BUFFET AND ITS CONTROL USING TANGENTIAL JET BLOWING 1455
Ksenia Abramova, Kamil Khairullin, Alexander Ryzhov, Vitaly Soudakov

SHOCK WAVE BOUNDARY LAYER INTERACTION IN PROFILE CASCADES REPRESENTING ROTOR BLADINGS OF THE LAST STAGE OF LARGE OUTPUT STEAM TURBINES 1464
Martin Luxa, David Simurda, Jaromir Prihoda, Jana Vachova

SHOCK WAVE BOUNDARY LAYER INTERACTION INVESTIGATION: CONTROL BY ROD VORTEX GENERATORS AND THEIR APPLICATION ON HELICOPTER ROTOR BLADES 1474
Fernando Tejero Embuena, Piotr Doerffer, Pawel Flaszynski

ANALYSIS OF EFFECTS OF SHAPE AND LOCATION OF MICRO - TURBULATORS ON UNSTEADY SHOCKWAVE - BOUNDARY LAYER INTERACTION IN TRANSONIC FLOW 1484
Janusz Sznajder, Tomasz Kwiatkowski

MS 602: INNOVATIVE METHODS FOR FLUID-STRUCTURE-INTERACTION
ASSESSMENT OF THE FLUID-STRUCTURE INTERACTION CAPABILITIES FOR AERONAUTICAL APPLICATIONS OF THE OPEN-SOURCE SOLVER SU2. 1498
Ruben Sanchez, Heather L. Kline, David Thomas, Anil Variyar, Marcello Righi, Thomas D. Economon, Juan J. Alonso, Rafael Palacios, Grigorios Dimitriadis, Vincent Terrapon

CONVERGENCE ANALYSIS OF COUPLING ITERATIONS FOR THE UNSTEADY TRANSMISSION PROBLEM WITH MIXED DISCRETIZATIONS 1530
Azahar Monge, Philipp Birken

USING IMPROVED RADIAL BASIS FUNCTIONS METHODS FOR FLUID-STRUCTURE COUPLING AND MESH DEFORMATION 1545
Giorgos Strofylas, Georgios Mazanakis, Sotirios Sarakinos, Georgios Lygidakis, Ioannis Nikolos

A MONOLITHIC FLUID-STRUCTURE INTERACTION METHOD, APPLICATION TO A PISTON PROBLEM 1564
Felix Ischinger, Martijn Anthonissen, Barry Koren

MS 603: COMPUTATIONAL METHODS IN FLUID-STRUCTURE INTERACTION WITH IMPACT ON INDUSTRIAL APPLICATIONS
SLAMMING IMPACT SIMULATION OF 2D WATER ENTRY FOR RIGID STRUCTURES 1582
Omar Hashim Hassoon, Mostapha Tarfaoui, A. El Malki

A MESH MORPHING BASED FSI METHOD USED IN AERONAUTICAL OPTIMIZATION APPLICATIONS 1594
Matej Andrejašič, David Eržen, Emiliano Costa, Stefano Porziani, Marco Evangelos Biancolini, Corrado Groth

A PATH-CONSERVATIVE OSHER-TYPE SCHEME FOR AXIALLY SYMMETRIC COMPRESSIBLE FLOWS IN FLEXIBLE TUBES 1613
Julia Leibinger, Michael Dumbser, Uwe Iben

MS 605: FRICTIONAL CONTACTS WITH LUBRICATION – BASICS AND APPLICATIONS
LIMITING SHEAR STRESS FORMULATION FOR TEHL SIMULATION 1623
Thomas Lohner, Klaus Michaelis, Karsten Stahl

MS 606: COMPUTATIONAL MODELING OF HYDRAULIC FRACTURING
THE XFEM FOR A SIMPLIFIED MODEL IN HYDRAULIC FRACTURING 1637
Markus Schätzer, Thomas-Peter Fries

SENSITIVITY ANALYSIS OF HYDRAULIC FRACTURING USING AN EXTENDED FINITE ELEMENT METHOD FOR THE PKN MODEL 1647
Hasini Garikapati, Clemens V. Verhoosel, Harald Van Brummelen, Pedro Diez

NUMERICAL MODELLING OF COUPLED HYDRO-THERMAL PROCESSES OF THE SOULTZ HETEROGENEOUS GEOTHERMAL SYSTEM 1659
Musa Dahiru Aliyu, Hua-Peng Chen

MS 607: ADVANCES IN COMPUTATIONAL METHODS FOR LIQUID-VAPOR FLOWS WITH PHASE TRANSFER PROCESSES
A LOW DIFFUSIVE APPROACH FOR TWO PHASE FLOWS 1672
Alberto Beccantini

A LARGE TIME STEP ROE SCHEME APPLIED TO TWO-PHASE FLOW 1693
Sofia Lindqvist, Halvor Lund

MS 608:ADVANCES IN TIME INTEGRATION FOR SOLID, FLUID AND COUPLED SYSTEMS
ENERGY CONSERVING TIME INTEGRATION BASED ON GALERKIN-VARIATIONAL INTEGRATORS WITH CONSTRAINTS 1709
Matthias Bartelt, Michael Groß

MIXED INTEGRATORS FOR STRUCTURE-PRESERVING SIMULATIONS IN NONLINEAR STRUCTURAL DYNAMICS 1736
Alexander Janz, Peter Betsch, Christian Hesch

ENERGY AND MOMENTUM CONSERVING VARIATIONAL BASED TIME INTEGRATION OF ANISOTROPIC HYPERELASTIC CONTINUA 1765
Michael Groß, Rajesh Ramesh, Julian Dietzsch

STRUCTURE-PRESERVING OPTIMAL CONTROL OF DISCRETE MECHANICAL SYSTEMS 1789
Peter Betsch, Christian Becker

VARIATIONAL INTEGRATORS OF MIXED ORDER FOR DYNAMICAL SYSTEMS WITH MULTIPLE TIME SCALES AND SPLIT POTENTIALS 1818
Theresa Wenger, Sina Ober-Blöbaum, Sigrid Leyendecker

CO-SIMULATION OF LARGE MBD, FEA AND DEM SYSTEMS 1832
Jose Ortiz, Neil Macdonald

MS 609: ADVANCED COMPUTATIONAL MODELING OF BATTERIES AND FUEL CELLS
STOCHASTIC 3D MODELING OF AMORPHOUS MICROSTRUCTURES - A POWERFUL TOOL FOR VIRTUAL MATERIALS TESTING 1838
Matthias Neumann, Volker Schmidt

MS 610: NUMERICAL METHODS TO STUDY THE CONTACT MECHANICS OF DRY, ADHESIVE AND LUBRICATED ROUGH SURFACES
PERCOLATION PROPERTIES OF THE FREE VOLUME GENERATED BY TWO ROUGH SURFACES IN CONTACT 1850
Paolo Cinat, Marco Paggi, Claudia Borri

A PARAMETRICALLY TIME-DEPENDENT METHODOLOGY FOR RECIPROCATING CONTACT MECHANICS BETWEEN VISCOELASTIC SOLIDS 1856
Carmine Putignano, Giuseppe Carbone, Daniele Dini

STATISTICAL AND GEOMETRICAL CHARACTERISTICS OF RANDOMLY ROUGH SURFACES USED FOR CONTACT SIMULATIONS. 1864
Rafael Schouwenaars, Carlos G. Figueroa, Víctor Hugo Jacobo, Armando Ortiz

MS 612: NUMERICAL SIMULATIONS FOR SMART-CITY APPLICATIONS
NUMERICAL OPTIMIZATION OF NEAR-ROAD VEGETATION BARRIERS 1876
Ludek Benes, Viktor Sip

MS 615: COMPUTATIONAL MODELS IN MAGNETOHYDRODYNAMICS
LARGE EDDY SIMULATIONS OF MAGNETIC FIELD EFFECT ON TURBULENT FLOW IN A SQUARE DUCT 1886
Jie Mao, Kunlei Zhang, Zhongquan Tan, Ke Liu

700 MATERIALS

MS 701: ADVANCED MATERIALS: COMPUTATIONAL ANALYSIS OF PROPERTIES AND PERFORMANCE
OPTIMAL DESIGN AND ADDITIVE MANUFACTURING OF NOVEL REINFORCING ELEMENTS FOR COMPOSITE MATERIALS 1893
Francesco Fabbrocino, Ilenia Farina, Ada Amendola, Luciano Feo, Fernando Fraternali

A TEMPERATURE SENSITIVE CRYSTAL PLASTICITY MODEL FOR THE PREDICTION OF HIGH TEMPERATURE MECHANICAL BEHAVIOUR OF MULTI-PHASE TIAL ALLOY 1909
M. Umer Ilyas, M. Rizviul Kabir

LAYOUT OPTIMIZATION OF PIEZOELECTRIC ELEMENTS WITH EXTERNAL ELECTRIC CIRCUITS IN SMART CONSTRUCTIONS BASED ON SOLUTION OF THE NATURAL VIBRATIONS PROBLEM 1920
Nataliia Iurlova, Valerii P. Matveenko, Dmitriy A. Oshmarin, Nataliya V. Sevodina, Maksim A. Yurlov

DETERMINATION OF OPTIMAL PARAMETERS FOR A PASSIVE RL-CIRCUIT BY SOLVING THE PROBLEM ON NATURAL VIBRATIONS OF ELECTROELASTIC BODIES 1930
Maksim Yurlov, Valerii P. Matveenko, Dmitriy A. Oshmarin, Nataliya V. Sevodina, Nataliya A. Iurlova

COMPUTATIONAL MODELLING OF MECHANICAL BEHAVIOR OF BIOLOGICAL TISSUES FOR BIOMEDICAL APPLICATIONS 1940
Simin Li, Yang Liu, Juan Du, Begum Zeybek, Lorenzo Zani, Mark P. Lewis, Vadim V. Silberschmidt

ANALYSIS OF FIBRE BRAGG GRATINGS SENSORS OPTIMAL PLACEMENT FOR MONITORING OF DAMAGE PROPAGATION IN LAMINATE COMPOSITES 1950
Mikhail Tashkinov

SEVEN DIFFERENT WAYS TO MODEL VISCOELASTICITY IN A GEOMETRICALLY EXACT SETTING 1959
Alexey Shutov

MS 702: MODELING OF NANOFILLED COMPOSITES
SIMULATING ATOMIC FORCE MICROSCOPY FOR THE DETERMINATION OF THE ELASTIC PROPERTIES OF NANOPARTICLE REINFORCED EPOXY RESIN 1971
Johannes Fankhänel, Andreas Kempe, Raimund Rolfes

MULTI-SCALE FINITE ELEMENT ANALYSIS OF GRAPHENE/POLYMER NANOCOMPOSITES ELECTRICAL PERFORMANCE 1984
Asimina Manta, Matthieu Gresil, Constantinos Soutis

MS 705: IDENTIFICATION OF MATERIAL MODELS
THE BOOTSTRAP APPROACH TO THE STATISTICAL SIGNIFICANCE OF PARAMETERS IN RSM MODEL 2003
Jacek Pietraszek, Leszek Wojnar

MS 706: MODELING OF FIBER-BASED STRUCTURES - TEXTILES AND TEXTILE REINFORCED COMPOSITES
INVERSE IDENTIFICATION OF THE BENDING STIFFNESS OF A BRAIDED POLYETHYLENE TWINE SUBJECT TO LARGE DEFORMATION: APPLICATION TO THE IDENTIFICATION OF THE MESH OPENING RIGIDITY OF FISHING NETS 2010
Barthélémy Morvan, Guilhem Bles, Nicolas Dumergue, Daniel Priour

MULTI-SCALE FRAMEWORK FOR MODELLING CARBON FIBRE WEAVES BASED ON STOCHASTIC REINFORCEMENT GEOMETRY 2029
Andy Vanaerschot, Karen Soete, Stepan Lomov, Dirk Vandepitte

MS 707: MICROMECHANICAL MODELLING: COMPETITION BETWEEN ANALYTICAL AND NUMERICAL METHODS
MULTISCALE MODELING OF THERMO-ELASTIC PROPERTIES OF MICROCRACKED MATERIAL 2039
Antonino Favata, Patrizia Trovalusci, Renato Masiani

EFFECTIVE ELASTICITY COEFFICIENTS IN DRY POROUS MATERIALS. NUMERICAL AND SEMI-ANALYTICAL APPROACHES 2050
Vladimir Sladek, Bruno Musil, Jan Sladek

INFLUENCE OF MICRO CRACKS ON EFFECTIVE MATERIAL PROPERTIES IN FIBER REINFORCED SMART COMPOSITE MATERIALS 2073
Michael Wünsche, Jan Sladek, Vladimir Sladek

DEFECT ACCUMULATION IN NANOPOROUS WEAR-RESISTANT COATINGS UNDER COLLECTIVE RECRYSTALLIZATION. SIMULATION BY HYBRID CELLULAR AUTOMATON METHOD 2080
Dmitry Moiseenko, Pavel Maksimov, Sergey Panin, Viktor Panin

MS 711: FOURIER-BASED METHODS FOR COMPUTING THE BEHAVIOR OF HETEROGENEOUS MATERIALS DEVELOPMENTS, EXTENSIONS AND APPLICATIONS
NONLINEAR COMPOSITE VOXELS AND FFT-BASED HOMOGENIZATION 2099
Matthias Kabel, Andreas Fink, Felix Ospald, Matti Schneider

MS 712: SMART MATERIAL SYSTEMS AND STRUCTURES
A THERMODYNAMICALLY CONSISTENT FINITE STRAIN MICRO-SPHERE FRAMEWORK FOR PHASE-TRANSFORMATION 2110
Richard Ostwald, Thorsten Bartel, Andreas Menzel

OPTIMAL CONTROL TUNNING IN SMART STRUCTURES WITH DELAMINATIONS 2123
Panos Koutsianitis, Amalia Moutsopoulou, Georgios Drosopoulos, Georgios Tairidis, Georgia Foutsitzi, Georgios Stavroulakis

MS 713: MICROSTRUCTURE-BASED MODELLING OF HETEROGENEOUS MATERIALS
DEPENDENCE OF THE MECHANICAL PROPERTIES OF PENTAMODE MATERIALS ON THE LATTICE MICROSTRUCTURE 2134
Ada Amendola, Francesco Fabbrocino, Luciano Feo, Ferdinando Auricchio, Fernando Fraternali

HOMOGENIZATION TECHNIQUES FOR ACCURATE AND APPROXIMATE ESTIMATES FOR OVERALL PROPERTIES OF MICROCRACKED VISCOELASTIC MASONRIES 2151
Amna Rekik, Alain Gasser

APPLICATION OF POLAR ELASTICITY TO THE PROBLEM OF PURE BENDING OF A THICK PLATE 2162
Svitlana Fedorova, Jiří Burša

ARTIFICIAL MICROSTRUCTURE GENERATOR FOR DUAL-PHASE STEELS 2172
Yuliang Hou, Alexandre Dumon, Pièrre Culière, Mohamed Rachik

MS 714: STRENGTH, FATIGUE AND STABILITY OF COMPOSITE STRUCTURES
ON THE STRUCTURAL DESIGN OF IMPERFECTION SENSITIVE LAMINATED COMPOSITE SHELL STRUCTURES SUBJECTED TO AXIAL COMPRESSION 2182
Linus Friedrich, Pawel Lyssakow, Garth Pearce, Martin Ruess, Chiara Bisagni, Kai-Uwe Schröder

STRENGTH AND WEIGHT EQUIVALENT SUBSTITUTION OF LARGE SANDWICH PANELS BY MONOLITHIC CFRP STRUCTURES 2190
Martin Meindlhumer, Martin Schagerl

ROBUST INTEGRAL COMPOSITE AIRCRAFT STRUCTURES 2202
Tamas Havar

MS 715: COMPUTATIONAL ANALYSIS OF COMPOSITE STRUCTURES
MINIMAL MASS DESIGN OF STRENGTHENING TECHNIQUES FOR PLANAR AND CURVED MASONRY STRUCTURES 2210
Gerardo Carpentieri, Francesco Fabbrocino, Mariella De Piano, Valentino Paolo Berardi, Luciano Feo, Fernando Fraternali

MODELING OF FIBER-REINFORCED PLASTICS TAKING INTO ACCOUNT THE MANUFACTURING PROCESS …….. 2220
Cherry Ann Reclusado, Sumito Nagasawa

CONVERGENCE ANALYSIS OF STRESS FIELDS TO HOMOGENIZATION PREDICTIONS IN OPTIMAL PERIODIC COMPOSITE DESIGN …….. 2236
Pedro Coelho, Rui Reis, José Guedes

A NUMERICAL STUDY FOR THE BUCKLING CAPACITY OF WIND TURBINE BLADES: GEOMETRY, LOADING AND MATERIAL INFLUENCE …….. 2247
Efstathios E. Theotokoglou, George A. Balokas, Evgenia K. Savvaki

800 MULTISCALE PROBLEMS

MS 801: MULTISCALE COMPUTATIONAL HOMOGENIZATION FOR BRIDGING SCALES IN THE MECHANICS AND PHYSICS OF COMPLEX MATERIALS

A SEMI-IMPLICIT MICROPLAR DISCRETE-TO-CONTINUUM METHOD FOR GRANULAR MATERIALS …….. 2266
Kun Wang, Waiching Sun

MODELING OF LOW-ALLOYED TRIP-STEELS BASED ON DIRECT MICRO-MACRO SIMULATIONS …….. 2280
Stefan Prüger, Ashutosh Gandhi, Daniel Balzani

HOMOGENIZATION METHOD FOR DESIGNING NOVEL ARCHITECTURED CELLULAR MATERIALS …….. 2292
Zheng-Dong Ma

A HOMOGENIZATION TECHNIQUE FOR ELASTO-PLASTIC COMPOSITES …….. 2316
Federica Covezzi, Stefano De Miranda, Sonia Marfia, Elio Sacco

MS 802: ADVANCES IN THE MODELLING OF MULTI-SCALE, MULTI-PHYSICS AND MULTI-UNCERTAINTY PROBLEMS

THEORETICAL PREDICTION OF PLASTIC INSTABILITY FOR ASYMMETRICAL MATERIALS …….. 2323
Shenghua Wu, Nannan Song, F. M. Andrade Pires

MULTISCALE SIMULATION OF THREE-DIMENSIONAL UNSTEADY GAS FLOWS IN MICROCHANNELS OF TECHNICAL SYSTEMS …….. 2331
Viktoriia Podryga, Yury Karamzin, Tatiana Kudryashova, Sergey Polyakov

HIGHER-ORDER ASYMPTOTIC HOMOGENIZATION OF PERIODIC MATERIALS WITH LOW SCALE SEPARATION …….. 2346
M. Mohammed Ameen, R.H.J. Peerlings, M.G.D. Geers

MS 805: ADVANCED MULTI-PHYSICS AND MULTI-SCALE TECHNIQUES FOR MODELING INELASTIC PROCESSES IN SOLIDS: DAMAGE, FRACTURE AND CONTACT MECHANICS

MESO-SCALE MODELING OF HYBRID INDUSTRIAL/RECYCLED STEEL FIBER-REINFORCED CONCRETE …….. 2353
Antonio Caggiano, Diego Said Schicchi, Guillermo Etse, Enzo Martinelli

MS 806: MULTISCALE MODELLING OF MATERIALS AND STRUCTURES
THE KIRKENDALL SHIFT AND FRENKEL EFFECT DURING MULTI-COMPONENT DIFFUSION PROCESS 2363
Bartek Wierzba

CRACK PATH FIELD AND STRAIN INJECTION TECHNIQUES IN DYNAMIC FRACTURE SIMULATIONS 2372
Oriol Lloberas-Valls, Alfredo E. Huespe, Javier Oliver, Ivo F. Dias

HYBRID FE/XFE FINITE ELEMENT MODEL FOR SIMULATION OF BRITTLE-DUCTILE FRACTURES IN DUAL-PHASE STEEL GRADES. 2390
Konrad Perzynski, Lukasz Madej

EFFECTIVE MESO AND MACRO PROPERTIES FOR FIBRE-REINFORCED-POLYMER CURING COUPLED TO VISCO-ELASTICITY 2398
Rolf Mahnken, Christian Dammann

ON APPLICATION OF THE MESHLESS FINITE DIFFERENCE METHOD TO NUMERICAL HOMOGENIZATION 2417
Irena Jaworska

A MESOSCALE STUDY OF DEFORMATION AND FAILURE OF ANGLE-PLY LAMINATES UNDER TENSILE LOADING BY MEANS OF NUMERICAL HOMOGENIZATION 2426
Marek Romanowicz

MODELING OF PHASE CHANGES IN MICRO-DOMAIN INDUCED BY AN ULTRASHORT LASER PULSE 2437
Ewa Majchrzak, Lukasz Turchan, Jolanta Dziatkiewicz

MS 807: ADVANCED COMPUTATIONAL STRATEGIES FOR MODELLING, SIMULATION AND CHARACTERISATION OF MULTI-SCALE HETEROGENEOUS MATERIALS
VALIDATION OF A DISCRETE CRACK MODEL FOR LIGHTWEIGHT AGGREGATE CONCRETE BEAMS 2449
D. Dias-Da-Costa, R. Graça-E-Costa, R.N.F. Carmo

MS 808: MULTISCALE AND MULTIPHYSICS MODELING OF CEMENTITIOUS MATERIALS
REINFORCEMENT CORROSION IN CONCRETE DUE TO CARBONATION AND CHLORIDE INGRESS UP AND BEYOND INDUCTION PERIOD 2460
Karolina Hájková, Libor Jendele, Vit Šmilauer, T. Sajdlová, Jan Červenka

MS 809: MULTISCALE STOCHASTIC FINITE ELEMENT METHODS
THE STOCHASTIC FINITE ELEMENT METHOD FOR NUCLEAR APPLICATIONS 2471
José David Arregui Mena, Lee Margetts, Llion Evans, D. V. Griffiths, Anton Shterenlikht, Luis Cebamanos, Paul M Mummery

DETERMINATION OF MESOSCALE RANDOM FIELDS FOR THE APPARENT PROPERTIES OF SPATIALLY RANDOM COMPOSITES 2484
Dimitrios Savvas, George Stefanou

MS 811: MULTISCALE MODELING OF CONCRETE AND CONCRETE STRUCTURES
NUMERICAL SIMULATION OF THE AUTOGENOUS SHRINKAGE OF HARDENING PORTLAND CEMENT PASTE ... 2501
Peng Gao, Guang Ye, Jiangxiong Wei, Qijun Yu

900 NUMERICAL SIMULATION METHODS

MS 901: ISOGEOMETRIC METHODS
ANALYSIS OF LAMINATED COMPOSITE PLATES USING ISOGEOMETRIC COLLOCATION METHOD 2514
G. S. Pavan, K. S. Nanjunda Rao

MODELLING STIFFENED LIGHTWEIGHT STRUCTURES WITH ISOGEOMETRIC ANALYSIS VIA MORTAR METHODS 2531
Malte Woidt, Kay Sommerwerk, Matthias C. Haupt, Peter Horst

DOMAIN DECOMPOSITION SOLUTION SCHEMES FOR LARGE-SCALE IGA PROBLEMS 2541
George Stavroulakis, Dimitris Tsapetis, Manolis Papadrakakis

MS 902: INNOVATIVE NUMERICAL APPROACHES FOR MULTI-PHYSICS PROBLEMS
NUMERICAL PROPERTIES OF A DISCONTINUOUS GALERKIN FOMULATION FOR ELECTRO-THERMAL COUPLED PROBLEMS 2558
Lina Homsi, Christophe Geuzaine, Ludovic Noels

MS 903: ADVANCES IN FICTITIOUS DOMAIN METHODS FOR SOLID MECHANICS
TOWARDS LATTICE-BOLTZMANN ON DYNAMICALLY ADAPTIVE GRIDS — MINIMALLY-INVASIVE GRID EXCHANGE IN ESPRESSO 2566
Michael Lahnert, Carsten Burstedde, Christian Holm, Miriam Mehl, Georg Rempfer, Florian Weik

AUTOMATIC CONFORMAL DECOMPOSITION OF ELEMENTS CUT BY NURBS 2591
Jakob W. Steidl, Thomas-Peter Fries

A DESIGN-THROUGH-ANALYSIS APPROACH USING THE FINITE CELL METHOD 2601
Benjamin Wassermann, Tino Bog, Stefan Kollmannsberger, Ernst Rank

MS 905: DISCONTINUOUS GALERKIN METHODS: NEW TRENDS AND APPLICATIONS
DISCONTINUOUS GALERKIN COMPUTATION OF GASEOUS MIXTURE COAXIAL JETS 2614
Nicoletta Franchina, Marco Savini, Francesco Bassi

DISCONTINUOUS GALERKIN SOLUTION OF THE REYNOLDS-AVERAGED NAVIER–STOKES AND KL-KT-LOG(W) TRANSITION MODEL EQUATIONS 2632
A. Bassi, Alessandro Colombo, Antonio Ghidoni, Marco Lorini, Gianmaria Noventa

A STUDY OF MULTIGRID SMOOTHERS USED IN COMPRESSIBLE CFD BASED ON THE CONVECTION DIFFUSION EQUATION 2648
Philipp Birken, Jonathan Bull, Antony Jameson

HIGH-ORDER LINEARLY IMPLICIT TWO-STEP PEER METHODS FOR THE DISCONTINUOUS GALERKIN SOLUTION OF THE INCOMPRESSIBLE RANS EQUATIONS 2664
Francesco Carlo Massa, Gianmaria Noventa, Francesco Bassi, Alessandro Colombo, Antonio Ghidoni, Marco Lorini
OUTPUT-BASED SPACE-TIME ADAPTATION WITH NON-VARIATIONAL TIME INTEGRATION 2684
Krzysztof Fidkowski

MATRIX-FREE MODIFIED EXTENDED BACKWARD DIFFERENTIATION FORMULAE APPLIED TO THE DISCONTINUOUS GALERKIN SOLUTION OF COMPRESSIBLE UNSTEADY VISCOUS FLOWS 2697
Alessandra Nigro, Carmine De Bartolo, Andrea Crivellini, Francesco Bassi

MS 906: MATHEMATICAL ADVANCES IN ISOGEOMETRIC ANALYSIS
PRECONDITIONERS FOR ISOGEOMETRIC ANALYSIS BASED ON SOLVERS FOR SYLVESTER EQUATION 2715
Giancarlo Sangalli, Mattia Tani

MS 907: REGULARIZED ENRICHED APPROXIMATIONS AND QUADRATURE FOR DISCONTINUITIES, SINGULARITIES AND CONTINUOUS-DISCONTINUOUS TRANSITION
EFFECTIVE 3D REGULARIZED XFEM FOR PULL-OUT OF STEEL BARS IN CONCRETE, BENDING AND SHEAR TESTS ON FRP-REINFORCED CONCRETE BEAMS 2726
Elena Benvenuti, Nicola Orlando

MS 908: VERIFICATION AND VALIDATION OF STRUCTURAL MECHANICS SIMULATION MODELS
EXPERIMENTAL VALIDATION OF COMPOSITE STRUCTURES IN EXPLICIT IMPACT ANALYSIS 2734
Konstantinos Fotopoulos, George Lampeas

CODE VERIFICATION IN SHELL ANALYSIS BY THE METHOD OF MANUFACTURED SOLUTIONS 2745
Michael Gfrerer, Martin Schanz

EXPERIMENTAL VALIDATION OF A MODEL UPDATE PROCEDURE FOCUSING ON SMALL GEOMETRIC DEVIATIONS 2757
Thomas Maywald, Arnold Kühhorn, Sven Schrape

OPTIMUM DESIGN, FINITE ELEMENT MODEL UPDATING AND DYNAMIC ANALYSIS OF A FULL LAMINATED GLASS PANORAMIC CAR ELEVATOR 2774
Dimitrios Giagopoulos, Iraklis Chatziparasidis

INVESTIGATION IN THE MECHANICAL BEHAVIOUR OF LOW-VELOCITY IMPACTED CFRP PLATES UNDER DIFFERENT BOUNDARY CONDITIONS 2786
Süleyman Arslan, Zamaan Sadeghi, Athanasios Dafnis, Kai-Uwe Schröder

A NEW SHELL FINITE ELEMENT WITH DRILLING DEGREES OF FREEDOM AND ITS RELATION TO EXISTING FORMULATIONS 2803
Robert Winkler, Dimitrios Plakomytis

MS 910: HIGH ORDER CFD METHODS: CONCLUSIONS AND OUTLOOK
CURVED GRID GENERATION AND DG COMPUTATION FOR THE DLR-F11 HIGH LIFT CONFIGURATION 2843
Ralf Hartmann, Harlan Mcmorris, Tobias Leicht

BS1 - DNS OF THE TAYLOR-GREEN VORTEX AT RE = 1600 2859
Andrea Mastellone, Luigi Cutrone, Francesco Capuano

MS 911: NUMERICAL METHODS IN THE MECHANICS OF GENERALIZED CONTINUA
THE STRUCTURAL SYMMETRY WITHIN THE CONTEXT OF NONLOCAL ELASTICITY 2869
Aurora Angela Pisano, Paolo Fuschi

ISOGEOMETRIC GALERKIN METHODS FOR GRADIENT-ELASTIC BARS, BEAMS, MEMBRANES AND PLATES 2876
Jarkko Niiranen, Sergei Khakalo, Viacheslav Balobanov, Josef Kiendl, Antti H. Niemi, Bahram Hosseini, Alessandro Reali

MS 912: HIGH-ORDER METHODS, SENSITIVITY ANALYSIS AND ADAPTATION FOR THE NAVIER STOKES EQUATIONS
ADAPTIVE MESH REFINEMENT TECHNIQUES FOR HIGH-ORDER FINITE-VOLUME WENO SCHEME 2883
Harshavardhana Srinivasan, Panagiotis Tsoutsanis

IMPLEMENTATION OF A LOW-MACH NUMBER MODIFICATION FOR HIGH-ORDER FINITE-VOLUME SCHEMES FOR ARBITRARY HYBRID UNSTRUCTURED MESHES 2900
Nicholas Simmonds, Panagiotis Tsoutsanis, Adrian Gaylard

APPROPRIATE COMBINATIONS OF CONTROLLER PARAMETERS FOR UNSTEADY FLOW SIMULATIONS WITH ADAPTIVE TIME STEP CONTROL 2916
Kathrin Kozulovic, Graham Ashcroft

MS 913: HIGH-ORDER METHODS FOR POLYGONAL AND POLYHEDRAL MESHES
ADAPTIVE BEM-BASED FEM ON POLYGONAL MESHES FROM VIRTUAL ELEMENT METHODS 2930
Steffen Weißer

VEM AND TOPOLOGY OPTIMIZATION ON POLYGONAL MESHES 2941
Paola F. Antonietti, Matteo Bruggi, Simone Scacchi, Marco Verani

THE VIRTUAL ELEMENT METHOD FOR DISCRETE FRACTURE NETWORK FLOW AND TRANSPORT SIMULATIONS 2953
Matias Fernando Benedetto, Stefano Berrone, Andrea Borio, Sandra Pieraccini, Stefano Scialo

MS 916: DIRECT METHODS FOR LIMIT STATES OF MATERIALS AND STRUCTURES
COMPOSITE FEM MODELS FOR LIMIT AND SHAKEDOWN ANALYSIS 2971
Leonardo Leonetti, Giovanni Garcea, Hung Nguyen-Xuan

ON SHAKEDOWN OF ELASTIC-PLASTIC BODIES WITH TEMPERATURE DEPENDENT PROPERTIES 2983
Michael Peigney

A NUMERICAL STUDY ON THE ENDURANCE LIMIT OF PARTICULATE REINFORCED METAL MATRIX COMPOSITES (PRMMCS) USING THE DIRECT METHOD AND THE STATISTICAL LEARNING 2994
Geng Chen, Bezold Alexander, Christoph Broeckmann, Dieter Weichert

SHAKEDOWN ANALYSIS OF PLATE BENDING UNDER STOCHASTIC UNCERTAINTY BY CHANCE CONSTRAINED PROGRAMMING 3007
Ngoc Trinh Tran, Thanh Ngoc Tran, H.G. Matthies, G.E. Stavroulakis, M. Staat

LIMIT ANALYSIS LOCUS OF HIGH STRENGTH STEEL PLATES UNDER NON-QUADRATIC YIELD CRITERIA 3020
Konstantinos Nikolaou, Christos Bisbos

MS 917: MESOSCOPIC METHODS FOR COMPLEX FLUIDS AND SOFT MATTER
PARTICLE BASED SIMULATION OF FLUID FLOW IN PERIODICALLY GROOVED CHANNELS 3026
Dorothea Kasiteropoulou, Theodoros Karakasidis, Antonios Liakopoulos

MS 918: COMPUTER ALGEBRA SYSTEMS IN MODELLING STATIC AND DYNAMIC PROBLEMS IN MECHANICS OF SOLIDS
HIGH COMPUTATIONAL EFFICIENCY THROUGH GENERIC ANALYTICAL FORMULATION FOR LINEAR SOIL PRESSURE DISTRIBUTION OF RIGID SPREAD RECTANGULAR FOOTINGS 3045
John Bellos, Nikolaos P. Bakas

A REAL-SPACE MODAL ANALYSIS METHOD FOR NON-PROPORTIONAL DAMPED STRUCTURES 3065
Evgueni Stanoev

A FORCE-BASED FORMULATION FOR THE ANALYSIS OF 3-DIMENSIONAL INELASTIC STRUCTURAL FRAMES ... 3091
Theodoros Patsios, Konstantinos Spiliopoulos

THE FEATURES OF ANALYTICAL SOLUTIONS OF BOUNDARY VALUE PROBLEMS OF THE ELASTICITY THEORY FOR FINITE DOMAINS WITH ANGULAR POINTS OF A BOUNDARY 3107
Alexander Kerzhaev, Mikhail Kovalenko, Irina Menshova

MS 919: RECENT ADVANCES IN NUMERICAL SIMULATION AND ANALYSIS OF KINETIC MODELS
DISCRETE VELOCITY MODELS: A STUDY OF THE HYDRODYNAMIC LIMIT 3113
Hans Babovsky

MESO - MACRO MODELS FOR A HARD SPHERE GAS 3121
Sergey Bogomolov, Natalya Esikova, Artem Kuvshinnikov

MS 921: RECENT ADVANCES IN BOUNDARY ELEMENT METHODS
ADVANCES IN THE BOUNDARY ELEMENT METHOD IN GEOMECHANICS 3139
Gernot Beer

ENERGETIC BEM FOR THE NUMERICAL SOLUTION OF DAMPED WAVE PROPAGATION EXTERIOR PROBLEMS 3159
Alessandra Aimi, Mauro Diligenti, Chiara Guardasoni

MODELLING THE PROCESS OF SEQUENTIAL EXCAVATION WITH THE BOUNDARY ELEMENT METHOD 3168
Christian Duenser, Gernot Beer

GREEN'S FUNCTION FOR THE EVALUATION OF ANCHOR LOSSES IN MEMS 3181
Attilio Frangi, Massimiliano Cremonesi

EFFICIENT BOUNDARY ELEMENT FORMULATION OF THERMOELASTICITY 3190
Relindis Rott, Martin Schanz

A CHEBYSHEV INTERPOALTION-BASED FAST MULTIPOLE METHOD FOR POROELASTICITY 3201
Barbara Knöbl, Thomas Traub, Martin Schanz

MS 922: HIGH-ORDER METHODS FOR ELASTIC WAVES AND THEIR APPLICATION
ENERGY STABLE HIGH ORDER FINITE DIFFERENCE METHODS ON STAGGERED GRIDS: AN INITIAL INVESTIGATION 3211
Ossian O'Reilly, Tomas Lundquist, Jan Nordström

MS 923: NOVEL DISCRETIZATION METHODS – MATHEMATICAL AND MECHANICAL ASPECTS
ALTERNATIVE TO RETURN -MAPPING ALGORITH FOR COMPUTING PLASTIC STRAIN. APPLICATION TO DILATANT MATERIALS 3224
Siegfried Maiolino

DISCONTINUOUS GALERKIN METHOD WITH REDUCED INTEGRATION SCHEME FOR THE BOUNDARY TERMS IN ALMOST INCOMPRESSIBLE LINEAR ELASTICITY 3231
Hamid Reza Bayat, Stephan Wulfinghoff, Stefanie Reese

1000 OPTIMIZATION, INVERSE PROBLEMS AND CONTROL

MS 1001: STRUCTURAL AND MULTIDISCIPLINARY OPTIMIZATION
A METHOD FOR BI-DIRECTIONAL COUPLING OF STRUCTURE AND SYSTEM IN THE OPTIMISATION OF MULTI-FUNCTIONAL COMPONENTS 3239
Ajit Panesar, Ian Ashcroft, Ricky Wildman, Richard Hague

SHAPE-TOPOLOGY OPTIMIZATION FOR DESIGNING SHELL STRUCTURES 3249
Hirotaka Nakayama, Masatoshi Shimoda

ON A NASH GAME FOR TOPOLOGY OPTIMIZATION UNDER LOAD-UNCERTAINTY – FINDING THE WORST LOAD 3259
Carl-Johan Thore

ANALYSIS AND DESIGN OF REINFORCED CONCRETE STRUCTURES AS A TOPOLOGY OPTIMIZATION PROBLEM 3271
Matteo Bruggi

ADJOINT OPTIMAL CONTROL PROBLEMS FOR FLUID-STRUCTURE INTERACTION SYSTEMS 3280
Daniele Cerroni, Roberto Da Vià, Sandro Manservisi, Filippo Menghini, Luca Zaniboni

APPLICATION OF WHIRL FLUTTER OPTIMIZATION-BASED SOLUTION TO FULL-SPAN MODEL OF TWIN TURBOPROP AIRCRAFT 3293
Jiri Cecrdle

ON THE CONSIDERATION OF UNCERTAINTY IN DESIGN: OPTIMIZATION – RELIABILITY – ROBUSTNESS 3310
Nicolas Lelièvre, Pierre Beaurepaire, Cécile Mattrand, Nicolas Gayton, Abdelkader Ostmane

A NEW OPTIMIZED ANISOTROPIC MOVING LEAST SQUARES SURROGATE MODEL WITH MAXIMIZED PROGNOSIS 3321
Kevin Cremanns, Dirk Roos

LATIN HYPERCUBE SAMPLING BASED ON ADAPTIVE ORTHOGONAL DECOMPOSITION 3333
Dirk Roos

A BENCHMARK OF CONTEMPORARY METAMODELING ALGORITHMS 3344
Can Bogoclu, Dirk Roos

TOPOLOGY OPTIMIZATION USING A KRIGING-ASSISTED GENETIC ALGORITHM WITH A NOVEL LEVEL SET REPRESENTATION APPROACH 3361
Mitsuo Yoshimura, Koji Shimoyama, Takashi Misaka, Shigeru Obayashi

TOPOLOGY OPTIMIZATION OF CONTACT PROBLEMS BASED ON ALLEN CAHN APPROACH 3377
Andrzej Myslinski

ON THE OPTIMAL DESIGN OF CABLE-STAYED BRIDGES 3386
Gerardo Carpentieri, Mariano Modano, Francesco Fabbrocino, Luciano Feo, Fernando Fraternali

A MIXED-INTEGER LINEAR PROGRAMMING APPROACH FOR GLOBAL DISCRETE SIZE OPTIMIZATION OF FRAME STRUCTURES 3395
Roxane Van Mellaert, Kristo Mela, Teemu Tiainen, Markku Heinisuo, Geert Lombaert, Mattias Schevenels

A SUPER-STRUCTURE BASED OPTIMISATION APPROACH FOR BUILDING SPATIAL DESIGNS 3409
Koen Van Der Blom, Sjonnie Boonstra, Hèrm Hofmeyer, Michael Emmerich

BENDING STIFFNESS OF A MULTILAYERED PLATE 3423
Petr Tovstik, Tatiana M. Tovstik

EFFICIENT SIZING OF STRUCTURES UNDER STRESS CONSTRAINTS 3436
Zhi Hong, Mostafa Abdalla

TOPOLOGY OPTIMIZATION OF WAVE BARRIERS FOR RAILWAY INDUCED VIBRATIONS IN BUILDINGS 3461
Cédric Van Hoorickx, Mattias Schevenels, Geert Lombaert

MS 1002: EVOLUTIONARY ALGORITHMS AND METAHEURISTICS IN CIVIL ENGINEERING AND CONSTRUCTION MANAGEMENT

MULTIOBJECTIVE OPTIMIZATION USING GENETIC ALGORITHMS IN TIME-COST CONSTRUCTION PROJECT SCHEDULING PROBLEM 3473
Jorge Magalhães-Mendes

APPLICATION OF GENETIC ALGORITHMS TO STRUTTED SHEET PILE WALL DESIGN OPTIMIZATION 3485
Mohamed Eid, Remon Isaac

NASH EVOLUTIONARY ALGORITHMS: TESTING PROBLEM SIZE IN RECONSTRUCTION PROBLEMS IN FRAME STRUCTURES 3493
David Greiner, Jacques Periaux, Jose M. Emperador, Blas Galván, Gabriel Winter

OPTIMUM DESIGN OF REINFORCED CONCRETE FRAMES ACCORDING TO EC8 AND MC2010 WITH GENETIC ALGORITHMS 3505
Panagiotis Mergos

CALIBRATION OF THE NUMERICAL MODEL OF A STAND IN DRAGÃO STADIUM BASED ON GENETIC ALGORITHMS 3519
Jorge Leite, Diogo Ribeiro, Hugo Marques, Rui Calçada

MS 1003: ADVANCES IN DESIGN OPTIMIZATION OF STRUCTURES AND MATERIALS
DESIGN OF ISOTROPIC MICROSTRUCTURES VIA A TWO-SCALE APPROACH 3534
Alexis Faure, Georgios Michailidis, Rafael Estevez, Guillaume Parry, Grégoire Allaire

SHAPE OPTIMIZATION OF GRAPHENE SHEETS FOR MAXIMUM FUNDAMENTAL FREQUENCY 3546
Jin-Xing Shi, Masatoshi Shimoda

TOPOLOGY OPTIMIZATION WITH AN IMPLICIT FUNCTION AND PARAMETERIZED CUTTING SURFACE 3553
Peter Dunning

TOPOLOGY OPTIMIZATION OF PERIODIC STRUCTURES FOR COUPLED ACOUSTIC-STRUCTURE SYSTEMS 3565
William Martins Vicente, Renato Picelli, Renato Pavanello, Yi Min Xie

BESO APPROACH TO TOPOLOGY OPTIMIZATION OF GAN PHONONIC CRYSTALS 3583
Luca D'Alessandro, Bichoy Bahr, Luca Daniel, Dana Weinstein, Raffaele Ardito

MS 1004: AERODYNAMIC STRATEGIES FOR THE GLOBAL OPTIMIZATION OF FLYING CONFIGURATIONS IN SUPERSONIC FLOW
LOW BOOM / LOW DRAG SMALL SIZE SUPERSONIC AIRCRAFT DESIGN 3596
Atsushi Ueno, Yasushi Watanabe, Itham Salah El Din, Richard Grenon, Gerald Carrier

DEVELOPMENT OF PHYSICAL METHODS OF THE SUPERSONIC AIRPLANE NEAR-FIELD INVESTIGATION AIMED AT THE SONIC BOOM MINIMIZATION 3612
Sergey Chernyshev, Alexander Ivanov, Andrey Kiselev, Vladimir Mosharov, Leonid Teperin

GLOBAL OPTIMIZATION OF THE SHAPE OF AN AEROSPACE VEHICLE, VIA ITERATIVE OPTIMUM-OPTIMORUM STRATEGY 3621
A. Nastase

MS 1005: MONITORING AND CONTROL OF STRUCTURES
SHAPE IDENTIFICATION ANALYSIS OF CAVITY IN RESIN STRUCTURE BASED ON THERMAL NONDESTRUCTIVE TESTING METHOD 3630
Kotaro Maruoka, Takahiko Kurahashi, Tetsuro Iyama

DESIGN AND INSTALLATION OF A PERMANENT MONITORING SYSTEM FOR PALAZZO LOMBARDIA IN MILANO, ITALY 3640
Marta Berardengo, Alfredo Cigada, Stefano Manzoni, Marcello Vanali

MS 1006: PARAMETER IDENTIFICATION IN SOLID MECHANICS
AN INVERSE PROBLEM STRATEGY BASED ON FORWARD MODEL EVALUATIONS: GRADIENT-BASED OPTIMIZATION WITHOUT ADJOINT SOLVES 3652
Miguel Aguilo

COHESIVE ZONE MODEL IDENTIFICATION WITH DCB TEST PARAMETER ESTIMATION SENSITIVITY 3676
Racine Ly, Julien Jumel, Martin Shanahan, Florian Lavelle

MS 1007: ADDITIVE MANUFACTURING AND OPTIMIZATION
TOPOLOGY OPTIMIZATION FOR ADDITIVE MANUFACTURING WITH CONTROLLABLE SUPPORT STRUCTURE COSTS 3689
Matthijs Langelaar

STUDY OF TOPOLOGY OPTIMIZATION PARAMETERS AND SCAFFOLD STRUCTURES IN ADDITIVE MANUFACTURING 3700
Alain Garaigordobil, Ruben Ansola, Estrella Veguería

FINITE ELEMENT APPROXIMATION OF A TIME-DEPENDENT TOPOLOGY OPTIMIZATION PROBLEM 3711
Matteo Bruggi, Nicola Parolini, Francesco Regazzoni, Marco Verani

DESIGNING MANUFACTURABLE VISCOELASTIC DEVICES USING A TOPOLOGY OPTIMIZATION APPROACH WITHIN A TRULY-MIXED FEM FRAMEWORK 3724
Paolo Venini, Marco Pingaro, Carlo Cinquini

ISO-XFEM FOR TOPOLOGY OPTIMIZATION OF STRUCTURES UNDER MULTIPLE LOAD CASES AND ACCELERATION LOADING 3739
Meisam Abdi, Ian Ashcroft, Ricky Wildman

MS 1008: ULTRASONIC GUIDED WAVES TESTING AND MONITORING
LAMINATE ELEMENT METHOD AND ITS APPLICATION TO THE STUDY OF GUIDED WAVE RESONANCE PHENOMENA IN LAYERED ELASTIC STRUCTURES WITH DEFECTS 3753
Evgeny Glushkov, Natalia Glushkova, Artem Eremin, Rolf Lammering

INVESTIGATIONS OF MECHANICAL GUIDED WAVES PROPAGATION IN PIPES REPAIRED LOCALLY BY COMPOSITE PATCHES 3761
Slah Yaacoubi, Weina Ke, F. Dahmene, M. El Mountassir

MS 1009: ADJOINT METHODS FOR STEADY & UNSTEADY OPTIMIZATION

TWO-STEPS SHAPE OPTIMIZATION ALGORITHM IMPROVING HYDRODYNAMICS STABILITY 3770
Takashi Nakazawa

ON THE CORRECT APPLICATION OF AD CHECKPOINTING TO ADJOINT MPI-PARALLEL PROGRAMS 3778
Ala Taftaf, Laurent Hascoët

SPHERICITY: MESH OPTIMIZATION FOR ARBITRARY ELEMENT TOPOLOGY 3797
Pavlos Alexias, Eugene De Villiers

LINKING PARAMETRIC CAD WITH ADJOINT SURFACE SENSITIVITIES 3812
Ilias Vasilopoulos, Dheeraj Agarwal, Marcus Meyer, Trevor T. Robinson, Cecil G. Armstrong

A CODE-COUPLING APPROACH TO THE IMPLEMENTATION OF DISCRETE ADJOINT SOLVERS BASED ON AUTOMATIC DIFFERENTIATION 3828
Jan Backhaus, Anna Engels-Putzka, Christian Frey

CAD KERNEL AND GRID GENERATION ALGORITHMIC DIFFERENTIATION FOR TURBOMACHINERY ADJOINT OPTIMIZATION 3843
Ismael Sanchez Torreguitart, Tom Verstraete, Lasse Mueller

ALTERNATIVE SOLUTION ALGORITHMS FOR PRIMAL AND ADJOINT INCOMPRESSIBLE NAVIER-STOKES 3858
Mattia Oriani, Guillaume Pierrot

DEFROSTER NOZZLE SHAPE OPTIMIZATION USING THE CONTINUOUS ADJOINT METHOD 3883
Lefki Germanou, Evangelos Papoutsis-Kiachagias, Antoine Delacroix, Kyriakos Giannakoglou

SENSITIVITY ANALYSIS FOR FORCED RESPONSE IN TURBOMACHINERY USING AN ADJOINT HARMONIC BALANCE METHOD 3893
Anna Engels-Putzka, Christian Frey

A TWO-LEVEL HYBRID APPROACH FOR OPTIMAL ACTIVE FLOW CONTROL ON A THREE-ELEMENT AIRFOIL 3912
Anil Nemili, Emre Özkaya, Nicolas R. Gauger, Felix Kramer, Frank Thiele

TRANSITION FROM 2D CONTINUOUS ADJOINT LEVEL SET TOPOLOGY TO SHAPE OPTIMIZATION 3928
J.R.L. Koch, E.M. Papoutsis-Kiachagias, K.C. Giannakoglou

AERODYNAMIC SHAPE OPTIMIZATION USING THE TRUNCATED NEWTON METHOD AND CONTINUOUS ADJOINT 3942
Mehdi Ghavami Nejad, Evangelos M. Papoutsis-Kiachagias, Kyriakos C. Giannakoglou

UNSTEADY ADJOINT TO THE CUT-CELL METHOD USING MESH ADAPTATION ON GPU'S 3957
Konstantinos Samouchos, Stergios Katsanoulis, Kyriakos Giannakoglou

SHAPE OPTIMIZATION OF TURBOMACHINERY ROWS USING A PARAMETRIC BLADE MODELLER AND THE CONTINUOUS ADJOINT METHOD RUNNING ON GPUS 3972
K.T. Tsiakas, F. Gagliardi, X.S. Trompoukis, K.C. Giannakoglou

GEOMETRIC CONTINUITY CONSTRAINTS FOR ADJACENT NURBS PATCHES IN SHAPE OPTIMISATION 3985
Xingchen Zhang, Yang Wang, Mateusz Gugala, Jens-Dominik Mueller

TOWARDS MULTIDISCIPLINARY ADJOINT OPTIMIZATION OF TURBOMACHINERY COMPONENTS 3999
Marc Schwalbach, Tom Verstraete

TOWARDS AN OUTPUT-BASED RE-MESHING FOR TURBOMACHINERY APPLICATIONS 4011
Mateusz Gugala, Marcus Meyer, Jens-Dominik Mueller

OPTIMISATION OF A U-BEND USING A CAD-BASED ADJOINT METHOD WITH DIFFERENTIATED CAD KERNEL 4023
Salvatore Auriemma, Mladen Banovic, Orest Mykhaskiv, Herve Legrand, Jens-Dominik Mueller, Tom Verstraete, Andrea Walther

A CONTINUOUS ADJOINT APPROACH FOR VEHICLE INTERIOR NOISE REDUCTION 4035
Christos Kapellos, Michael Hartmann

A MIXED OPERATOR OVERLOADING AND SOURCE TRANSFORMATION APPROACH FOR ADJOINT CFD COMPUTATION 4047
Zahrasadat Dastouri, Sinan Gezgin, Uwe Naumann

MS 1010: INVERSE PROBLEMS, DESIGN AND OPTIMIZATION

EFFICIENT CALIBRATION OF DISCRETE ELEMENT MATERIAL MODEL PARAMETERS USING LATIN HYPERCUBE SAMPLING AND KRIGING 4061
Michael Rackl, Carolin D. Görnig, Kevin J. Hanley, Willibald A. Günthner

UPDATING PRIOR PARAMETERS BASED ON LIKELIHOOD FUNCTION-BAYESIAN METHOD FOR PARAMETER ESTIMATION AT HIGH MEASUREMENT UNCERTAINTY 4073
Sankaran Somasundharam, K Srinivas Reddy

MS 1011: SURROGATE-ASSISTED EVOLUTIONARY ALGORITHMS IN AERODYNAMIC DESIGN/OPTIMIZATION

CONSTRAINED MULTI-POINT AERODYNAMIC SHAPE OPTIMIZATION OF THE VISCOUS DPW WING THROUGH EVOLUTIONARY PROGRAMMING AND SUPPORT VECTOR MACHINES 4082
Daniel González Juárez, Esther Andrés Pérez, Mario Jaime Martin Burgos

SURROGATE-BASED GLOBAL OPTIMIZATION OF A CYLINDER BY THE USE OF EVOLUTIONARY ALGORITHMS, SUPPORT VECTOR MACHINES AND NON UNIFORM B-SPLINES 4092
Eesther Andrés-Pérez, Daniel González-Juárez, Mario J. Martin-Burgos, Leopoldo Carro-Calvo, Sancho Salcedo-Sanz

PERFORMANCE COMPARISON OF KRIGING AND SVR SURROGATE MODELS APPLIED TO THE OBJECTIVE FUNCTION PREDICTION WITHIN AERODYNAMIC SHAPE OPTIMIZATION 4104
Daniel Viúdez-Moreiras, Esther Andrés-Pérez, Daniel González-Juárez, Mario J. Martin Burgos

HEAT TRANSFER OPTIMIZATION OF A RIBBED SURFACE USING SURROGATE-ASSISTED GENETIC ALGORITHMS 4117
Panagiotis Tsirikoglou, Ghader Ghorbaniasl, Simon Abraham, Chris Lacor

MULTI-FIDELITY EXTENSION TO NON-INTRUSIVE PROPER ORTHOGONAL DECOMPOSITION BASED SURROGATES 4129
Tariq Benamara, Piotr Breitkopf, I. Lepot, Caroline Sainvitu

EVOLUTIONARY AERODYNAMIC SHAPE OPTIMIZATION THROUGH THE RBF4AERO PLATFORM 4146
Dimitrios Kapsoulis, Varvara Asouti, Kyriakos Giannakoglou, Stefano Porziani, Emiliano Costa, Corrado Groth, Ubaldo Cella, Marco Evangelos Biancolini

THE RBF4AERO BENCHMARK TECHNOLOGY PLATFORM 4156
Massimo Bernaschi, Alessandro Sabellico, Giorgio Urso, Emiliano Costa, Stefano Porziani, Fabrizio Lagasco, Corrado Groth, Ubaldo Cella, Marco Evangelos Biancolini, Dimitrios H.Kapsoulis, Varvara G. Asouti, Kyriakos C. Giannakoglou

MS 1013: SOLUTION OF LARGE-SCALE INVERSE PROBLEMS
DATA ASSIMILATION USING MRI DATA 4164
Geir Nævdal, Ove Sævareid, Rolf J. Lorentzen

MS 1014: DESIGN OPTIMIZATION AND INVERSE PROBLEMS FOR WAVE PROPAGATION PROBLEMS
FULL-WAVEFORM INVERSION FOR THE RECONSTRUCTION OF ELECTROMAGNETIC PROPERTY PROFILES USING PLANE MICROWAVES 4178
Namho Joh, Jun Won Kang

1100 REDUCTION METHODS

MS 1101: REDUCED BASIS, POD AND PGD MODEL ORDER REDUCTION TECHNIQUES
REDUCED BASIS METHOD FOR POISSON-BOLTZMANN EQUATION 4187
Cleophas Kweyu, Martin Hess, Lihong Feng, Matthias Stein, Peter Benner

AN ITERATIVE MODEL ORDER REDUCTION SCHEME FOR A SPECIAL CLASS OF BILINEAR DESCRIPTOR SYSTEMS APPEARING IN CONSTRAINT CIRCUIT SIMULATION 4196
Pawan Goyal, Peter Benner

ELECTRICAL FIELDS SIMULATION IN HETEROGENOUS DOMAINS USING THE PROPER GENERALIZED DECOMPOSITION 4213
Chady Ghnatios, Francisco Chinesta, Anais Barasinski

MODEL ORDER REDUCTION IN STRUCTURAL DYNAMICS 4221
Raul Rodriguez Sanchez, Martin Buchschmid, Gerhard Müller

TOWARDS A NON-INTRUSIVE PROPER GENERALIZED DECOMPOSITION SCHEME FOR MODEL ORDER REDUCTION 4248
Xi Zou, Pedro Díez, Michele Conti, Ferdinando Auricchio

A PGD-BASED TIME SPACE DECOMPOSITION FOR THE UNSTEADY NAVIER-STOKES EQUATIONS APPLIED TO INCOMPRESSIBLE FLOWS 4263
Michel Visonneau

MS 1103: MATHEMATICAL SURROGATE MODELLING IN ELECTROMAGNETICS

RATIONAL MODELING OF MULTIVARIATE MULTI-FIDELITY DATA 4284
Elizabeth Rita Samuel, Dirk Deschrijver, Luc Knockaert, Tom Dhaene, Annie Cuyt

ON THE USE OF S-PARAMETER TRANSFORMATIONS TO IMPROVE SURROGATE MODEL BEHAVIOUR OF MULTIPORT NETWORKS 4295
Petrie Meyer

RECENT ADVANCES IN SURROGATE MODELLING OF REFLECTOR ANTENNA SYSTEMS 4302
Dirk De Villiers

A SHORT-TIME PRONY METHOD FOR THE DETECTION OF TRANSIENTS 4313
Annie Cuyt, Wen-Shin Lee, Min-Nan Tsai

SURROGATE MODELING OF ANTENNA RADIATION CHARACTERISTICS BY GAUSSIAN PROCESSES 4322
Jan Pieter Jacobs, Dirk De Villiers

ACCELERATION OF MESH-BASED PHYSICAL OPTICS FOR ELECTROMAGNETIC SCATTERING ANALYSIS 4330
Dao P. Xiang, Matthys M. Botha

DESIGN OF AXIALLY SYMMETRIC POWER COMBINERS USING SURROGATE BASED OPTIMIZATION 4339
Ryno Beyers, Dirk De Villiers

1200 STRUCTURAL STABILITY AND DYNAMICS

MS 1201: COMPUTATIONAL STRUCTURAL DYNAMICS

FLEXURAL VIBRATION ANALYSIS OF GRAPHENE NANOPLATELETS REINFORCED NANOCOMPOSITE BEAMS 4351
Jie Yang, Chuang Feng

DYNAMIC RESPONSE OF REAL OFFSHORE WIND TURBINES ON MONOPILES IN STRATIFIED SEABED 4361
Guillermo M. Álamo, Juan J. Aznárez, Luis A. Padrón, Alejandro E. Martínez-Castro, Rafael Gallego, Orlando Maeso

DYNAMIC ANALYSIS OF SPECIAL CARS ON UNEVEN ROADS 4377
Szymon Tengler

STRUCTURED SPATIAL DISCRETIZATION OF DYNAMICAL SYSTEMS 4398

WAVE PROPAGATION IN THIN PRETWISTED ANISOTROPIC STRIPS 4406
Maloth Thirupathi, Mira Mitra, P J Guruprasad

NUMERICAL ROUTINE FOR DYNAMIC ANALYSIS OF TRANSMISSION LINES GUYED TOWERS SUBMITTED TO BROKEN CABLE 4416
Thiago Brazeiro Carlos, João Kaminski Jr.

INVARIANCE OF EIGENFREQUENCIES AND EIGENMODES UNDER GEOMETRIC TRANSFORMATION IN ELONGATED ELASTIC STRUCTURES 4436
Maryam Morvaridi, Michele Brun

MS 1202: ADVANCED BEAM MODELS

A COMPUTATIONALLY EFFECTIVE FORMULATION TO FINITE ROTATIONS - SMALL STRAINS DESCRIPTION OF BEAM ELEMENTS 4445
Salvatore Lopez

A COROTATIONAL FINITE ELEMENT TO MODEL BENDING VIBRATIONS OF METALLIC STRANDS 4455
Francesco Foti

3D BEAM-COLUMN FINITE ELEMENT UNDER NON-UNIFORM SHEAR STRESS DISTRIBUTION DUE TO SHEAR AND TORSION 4467
Paolo Di Re, Daniela Addessi, Filip C. Filippou

SINGULARLY PERTURBED PROBLEMS IN MECHANICS (SOME FUNDAMENTAL ASPECTS OF DESIGNING AND COMPUTING) 4481
Lyudmila K. Kuzmina

A DEGENERATE-CONTINUUM BASED TIMOSHENKO BEAM APPROACH FOR THE AEROELASTIC ANALYSIS OF THE WIND TURBINE BLADES 4488
Anthoula Panteli, Dimitris Manolas, Konstantinos Spiliopoulos

DYNAMICS OF WIND TURBINE BLADES USING A GEOMETRICALLY-EXACT BEAM FORMULATION 4503
Celso Faccio Junior, Alfredo Gay Neto

EXTENDED FORMULA FOR THE CRITICAL VELOCITY OF A LOAD MOVING ON A BEAM SUPPORTED BY A FINITE DEPTH FOUNDATION 4520
Zuzana Dimitrovová

FIRST-ORDER DISPLACEMENT-BASED ZIGZAG THEORIES FOR COMPOSITE LAMINATES AND SANDWICH STRUCTURES: A REVIEW 4528
Marco Di Sciuva

MS 1203: THE MODELS AND INVESTIGATIONS METHODS OF DYNAMICS OF THE SOLIDS SYSTEMS WITH DRY FRICTION

VIRTUAL TESTBENCH FOR THE OMNI WHEEL DYNAMICS SIMULATION: NEW CONTACT TRACKING ALGORITHM 4553
Ivan Kosenko, Sergey Stepanov, Kirill Gerasimov, Mikhail Stavrovskiy

MODEL AND INVESTIGATION OF DYNAMICS OF SOLID SYSTEM WITH TWO MASSIVE ECCENTRICS ON A ROUGH PLANE 4572
Sergey Semendyaev, Alexey Tsyganov

NON-REGULAR VEHICLE DYNAMICS. APPLICATION TO COLLISION 4584
Ahmed Bouzar Essaidi, Bachir Menkouz, Moussa Haddad, Taha Chettibi

TESTING, SIMULATING AND UNDERSTANDING UNDER-PLATFORM DAMPER DYNAMICS 4599
Chiara Gastaldi, Muzio M. Gola

MS 1204: NONLINEAR DYNAMICS OF ROTATING STRUCTURES
A NEW DYNAMIC SUBSTRUCTURING METHOD FOR NONLINEAR AND DISSIPATIVE SYSTEMS 4611
Colas Joannin, Benjamin Chouvion, Fabrice Thouverez

SOME REMARKS ON TIME INTEGRATION OF 3D ROTOR-STATOR ASSEMBLY 4624
Benoit Prabel

DELAYED FEEDBACK CONTROL METHOD FOR CALCULATING SPACE-TIME PERIODIC SOLUTIONS OF VISCOELASTIC PROBLEMS 4638
Ustim Khristenko, Patrick Le Tallec

COMBINING FINITE ELEMENT ANALYSIS AND ANALYTICAL MODELLING FOR EFFICIENT SIMULATIONS OF NON-LINEAR GEAR DYNAMICS 4655
Shadi Sweiki, Jakub Korta, Antonio Palermo, Rocco Adduci, Domenico Mundo

DAMPING INDUCED BY DRY FRICTION: ANALYSES AND EXPERIMENTS FOR MODELING IMPROVEMENT 4664
Marc-André Douville, Béatrice Faverjon, Eric Chatelet, Georges Jacquet-Richardet

MS 1206: ADVANCES IN NUMERICAL METHODS FOR LINEAR AND NON-LINEAR DYNAMICS AND WAVE PROPAGATION
RAYLEIGH METHOD APPLIED TO A 46-M-HIGH CONCRETE MAST 4674
Alexandre De M. Wahrhaftig, Reyolando M. L. R. F. Brasil

A DISPERSION MINIMIZED MIMETIC METHOD FOR A COLD PLASMA MODEL 4682
Vrushali A. Bokil, Vitaliy Gyrya, Duncan A. Mcgregor

A VOLUME-AGGLOMERATION MULTIRATE TIME ADVANCING APPROACH 4703
Emmanuelle Itam, Stephen Wornom, Bruno Koobus, Alain Dervieux

THERMOMECHANICAL NUMERICAL SIMULATION OF IMPACTS ON ELASTIC-PLASTIC SOLIDS WITH THE FINITE VOLUME METHOD 4717
Thomas Heuzé

MS 1207: COMPUTATIONAL SIMULATION OF SMART STRUCTURES AND MATERIALS
TRANSVERSE WAVE PROPAGATION IN A ONE-DIMENSIONAL STRUCTURE COUPLED TO ITS ELECTRICAL ANALOGUE: COMPARISON OF TRANSFER MATRIX MODELS 4728
Boris Lossouarn, Mathieu Aucejo, Jean-François Deü

MS 1208: BIFURCATIONS AND STABILITY
BUCKLING OF ANNULAR PLATE JOINT WITH CIRCULAR BEAM 4741
Sergei Filippov, Maria Boyarskaya

THE CURL AND FLUTING OF PAPER: THE EFFECT OF ELASTO-PLASTICITY 4752
Anna-Leena Erkkilä, Teemu Leppänen, Tero Tuovinen

STABILITY OF STEEL STRUCTURES WITH CLEARANCES AND IMPERFECTION 4770
Katarzyna Rzeszut, Andrzej Garstecki

MS 1209: DYNAMIC ANALYSIS OF BEAMS UNDER MOVING VEHICLES: APPLICATION TO RAILWAY TRACK MODELLING, DESIGN AND REHABILITATION
NUMERICAL ANALYSIS FOR THE DYNAMIC RESPONSE CHARACTERISTICS OF THE PRESTRESSED CONCRETE SLEEPER 4780
Tsutomu Watanabe, Kodai Matsuoka, Shintaro Minoura

NUMERICAL DYNAMIC ANALYSIS OF BEAMS ON NONLINEAR ELASTIC FOUNDATIONS UNDER HARMONIC MOVING LOAD 4794
Diego Froio, Roberto Moioli, Egidio Rizzi

MS 1210: ADVANCES IN MODELING AND ANALYSIS OF FGM STRUCTURES
ELASTOSTATIC AND MODAL AND BUCKLING ANALYSIS OF SPATIAL FGM BEAM STRUCTURES 4810
Justin Murin, Mehdi Aminbaghai, Juraj Hrabovsky, Vladimir Kutis, Juraj Paulech, Stephan Kugler

THERMO-ELASTICITY IN SHELL STRUCTURES MADE OF FUNCTIONALLY GRADED MATERIALS 4838
Stephan Kugler, Peter Fotiu, Justin Murin

FINITE BEAM ELEMENT WITH PIEZOELECTRIC LAYERS AND FUNCTIONALLY GRADED MATERIAL OF CORE 4863
Vladimír Kutiš, Justín Murín, Juraj Paulech, Juraj Hrabovský, Roman Gogola, Jakub Jakubec

NUMERICAL SOLUTION OF DIFFERENTIAL EQUATIONS WITH NON-CONSTANT COEFFICIENTS 4878
Juraj Hrabovský, Justín Murín, Mehdi Aminbaghai, Vladimír Kutiš, Juraj Paulech

TWO-WAY COUPLED ELECTRO-THERMAL ANALYSIS OF FGM SYSTEM CALCULATED BY THE NEW LINK FINITE ELEMENT 4888
Juraj Paulech, Vladimír Kutiš, Juraj Hrabovský, Justín Murín, Roman Gogola, Tibor Sedlár, Gabriel Gálik

MS 1211: COMPUTATIONAL STRATEGIES FOR STRUCTURAL ROBUSTNESS ASSESSMENT
PROGRESSIVE COLLAPSE FRAGILITY MODELS OF RC FRAMED BUILDINGS BASED ON PUSHDOWN ANALYSIS 4900
Emanuele Brunesi, Roberto Nascimbene, Fulvio Parisi

MECHANICAL PROPERTIES OF S355 UNDER EXTREME COUPLED EFFECT OF HIGH TEMPERATURES AND HIGH STRAIN RATES 4920
Daniele Forni, Bernardino Chiaia, Ezio Cadoni

IMPLEMENTATION OF PROGRESSIVE DAMAGE IN FINITE ELEMENT CODES FOR THE ASSESSMENT OF ROBUSNTESS 4928
Domenico Asprone, Bernardino Chiaia, Valerio De Biagi, Gaetano Manfredi, Fulvio Parisi

SEISMIC RESIDUAL CAPACITY ASSESSMENT OF FRAMED STRUCTURES DAMAGED BY EXCEPTIONAL ACTIONS 4942
Antonio Formisano, Giuseppe Iazzetta, Giuseppe Marino, Francesco Fabbrocino, Raffaele Landolfo

MS 1212: DYNAMICS AND SEISMIC RESPONSE OF ROCKING AND SELF-CENTERING STRUCTURES
ROCKING RESPONSE OF MASONRY BLOCK STRUCTURES USING MATHEMATICAL PROGRAMMING 4959
Francesco Portioli, Lucrezia Cascini, Raffaele Landolfo

CONTROLLED ROCKING, DISSIPATIVE CONTROLLED ROCKING AND MULTI-HIERARCHICAL ACTIVATION: NUMERICAL ANALYSIS AND EXPERIMENTAL TESTING 4969
Royce Liu, Alessandro Palermo

THE ROLE OF THE PRESTRESSED TENDONS ON THE SEISMIC PERFORMANCE OF HYBRID ROCKING BRIDGE BENTS 4983
Anastasios I. Giouvanidis, Elias G. Dimitrakopoulos

MODELLING CONTACT IN ROCKING STRUCTURES WITH A NONSMOOTH DYNAMICS APPROACH 4997
Anastasios I. Giouvanidis, Elias G. Dimitrakopoulos

A SIMPLE ANALYTICAL MODEL FOR THE ROCKING PREWEC SYSTEM 5010
Dimitrios Kalliontzis, Sri Sritharan

AN ANALYTICAL MODEL FOR DYNAMIC RESPONSE OF AN ELASTIC SDOF SYSTEM FIXED ON TOP OF A ROCKING SINGLE-STORY FRAME STRUCTURE: EXPERIMENTAL VALIDATION 5023
Jonas A. Bachmann, Christoph Jost, Quentin Studemann, Michalis F. Vassiliou, Bozidar Stojadinovic

SMOOTH-ROCKING OSCILLATOR UNDER NATURAL ACCELEROGRAMS 5063
Blerta Lipo, Gianmarco De Felice

EXPERIMENTAL INVESTIGATION OF THE SEISMIC RESPONSE OF A COLUMN ROCKING AND ROLLING ON A CONCAVE BASE 5074
Jonas A. Bachmann, Patrick Blöchlinger, Matthias Wellauer, Michalis F. Vassiliou, Bozidar Stojadinovic

SEISMIC ASSESSMENT OF MASONRY ROCKING COLUMNS AND FRAMES UNDER GROUND MOTION EXCITATIONS 5098
Ioannis Kavvadias, Lazaros Vasiliadis

PARAMETRIC INVESTIGATION OF THE DYNAMIC RESPONSE OF RIGID BLOCKS SUBJECTED TO SYNTHETIC NEAR-SOURCE GROUND MOTION RECORDS 5113
Michalis Fragiadakis, Ioannis Psycharis, Yenan Cao, George P. Mavroeidis

A MACRO-ELEMENT FORMULATION FOR ROCKING FLEXIBLE BODIES WITH A DEFORMABLE BASE 5129
Evangelos Avgenakis, Ioannis N. Psycharis

MS 1213: INNOVATIVE STRUCTURAL SYSTEMS FOR SEISMIC RESISTANT BUILDINGS

NONLINEAR ANALYSIS AND EXPERIMENTAL BEHAVIOUR OF AN INNOVATIVE STEEL FRAME WITH REINFORCED CONCRETE INFILL WALLS 5142
Andrea Dall'Asta, Graziano Leoni, Francesco Morelli, Walter Salvatore, Alessandro Zona

MODAL PROPERTIES AND SEISMIC RESPONSE OF EXISTING BUILDING RETROFITTED BY EXTERNAL BRACINGS WITH VISCOUS DAMPERS 5156
Laura Gioiella, Enrico Tubaldi, Fabrizio Gara, Andrea Dall'Asta

MS 1214: HISTORIC MASONRY STRUCTURES: MODELLING, ASSESSMENT & RETROFIT

SIMPLE CLOSED FORM HOMOGENIZATION MODEL FOR THE NON LINEAR STATIC AND DYNAMIC ANALYSIS OF RUNNING BOND MASONRY WALLS IN AND OUT OF PLANE LOADED 5172
Elisa Bertolesi, Gabriele Milani

CONSTRUCTION PHASES ANALYSIS OF UNREINFORCED MASONRY BUILDINGS THROUGH EQUIVALENT FRAME MODEL 5190
Francesco Pugi, Alessio Francioso, Giacomo Sevieri

A COMBINED EXPERIMENTAL AND NUMERICAL STUDY OF THE PULL-OUT MECHANISM OF THREADED TITANIUM BARS EMBEDDED IN MARBLE BLOCKS 5207
Stavros K. Kourkoulis, Aikaterini Marinelli, Ioanna Dakanali

FINITE-DISCRETE ELEMENT MODELLING OF MASONRY INFILL WALLS SUBJECTED TO OUT-OF-PLANE LOADS 5219
Laura Liberatore, Marta Bruno, Omar Al Shawa, Monica Pasca, Luigi Sorrentino

PALAZZO LA SAPIENZA IN PISA: STRUCTURAL ASSESSMENT AND RETROFIT OF AN HISTORICAL MASONRY BUILDING IN ITALY 5230
Silvia Caprili, Federico Mangini, Nicola Mussini, Walter Salvatore

THREE-DIMENSIONAL NONLINEAR BEHAVIOUR OF MASONRY WALLS MODELLED WITH DISCRETE ELEMENTS 5248
Daniele Baraldi, Antonella Cecchi

NUMERICAL VALIDATION OF EQUIVALENT-FRAME MODELS FOR URM WALLS 5262
Rossella Siano, Guido Camata, Vincenzo Sepe, Enrico Spacone, Pere Roca, Luca Pelà

SEISMIC ASSESSMENT OF HISTORICAL MASONRY TOWERS IN THE NORTH-EAST REGION OF ITALY 5274

A COMPUTATIONALLY EFFECTIVE FORMULATION TO FINITE ROTATIONS - SMALL STRAINS DESCRIPTION OF BEAM ELEMENTS

S. Lopez

Dipartimento di Ingegneria Civile, Università della Calabria
87030 Rende, Italy
e-mail: salvatore.lopez@unical.it

Keywords: Nonlinear three-dimensional beam analysis, finite elements, finite rotations, spatial dome structures.

Abstract. *In the context of three-dimensional elastic frame structures analysis with small strains and in the presence of large rotations we present a computationally effective model for the Euler-Bernoulli beam element. Actually, kinematical and strain measures of the beam element are completely defined by referring to boundary nodal displacements and one finite rotation parameter solely. In particular, the director along axis of the beam is defined directly by nodal positions while directors along the principal axes of the cross-section are detected by referring to the related orthogonal plane and the used rotation parameter. The definition of local rotations, required for the evaluation of torque and flexural deformation components, is obtained by imposing rotational compatibility and equilibrium conditions across inter-element boundaries. The description of the finite three-dimensional rotations is well posed under widely applicable hypotheses. The analysis of complex spatial dome structures, where matrices with large dimension and bandwidth occur, now proves a remarkable reduction of the required arithmetical operations with respect to the classical approaches.*

1 Introduction

Considerable work has been devoted to develop models for three-dimensional elastic frame structures for small strains and in the presence of large rotations. In this context the co-rotational, with minimal set parametrizations and multiplicative representations of rotations, is the most widely exploited approach. Indeed, the large-scale calculations required by these formulations have encouraged efficient treatments of the finite rotations. Then, those treatments, typically based on the rotation vector of the Euler theorem to describe finite rotations, have an economical definition of the rotated local reference system because only three parameters are used while evaluations of the coefficients in the force vector and in the tangent stiffness matrix are inexpensive. The evolution of the co-rotational approach can be traced by referring to the works of Stuelpnagel [1], Belytschko and Hsieh [2], Goldstein [3], Argyris [4], Rankin and Nour-Omid [5], Cardona and Geradin [6], Crisfield [7], Atluri and Cazzani [8], Geradin and Rixen [9], Ibrahimbegović et al. [10] and Felippa [11].

In this context here we present an alternative and computationally effective approach. Actually, kinematical and strain measures of the beam element are completely defined by referring to boundary nodal displacements and one finite rotation parameter. In particular, the director along axis of the beam is defined directly by nodal positions while directors along the principal axes of the cross-section are detected by referring to the related orthogonal plane and the only used rotation parameter. The definition of local rotations, required for the evaluation of torque and flexural deformation components, is obtained by imposing rotational compatibility and completeness conditions across inter-element boundaries. Finally, the description of the finite three-dimensional rotations is well posed under widely applicable hypotheses.

Being the infinitesimal nodal rotations computed by vectorial operations among the adjacent elements, such a formulation requires the extra storage of an integer matrix for the node - connected elements recognition. These connections, furthermore, increase the dimension of elemental force vector and tangent stiffness matrix and lead to complex programming for the imposition of rotational boundary conditions and linked applied moments. In contrast, by retaining similar approximation properties, the discretization uses one rotational unknown for each element instead of three required by the classical approaches.

As regards beam element modeling, here we use a small strain - finite displacement formulation of a two-node finite element based on the Euler-Bernoulli beam theory. The actual configuration of the element is rigidly translated and rotated, and deformed according to linear interpolations for axial displacements and quadratic interpolations for torque and flexural modes. The nonlinear motion is recovered by referring to the nodes at the boundaries of the element with three unknown displacements per node plus one unknown rotation per element. We note that boundary conditions on rotations are imposed by assuming as known the related nodal slopes or applied moments. It follows that, as will be discussed later, treatment of rotational boundary conditions and external moments proves to be more complex with respect to typical co-rotational formulations. Furthermore, the incremental rotations are restricted to the range of validity of the described formulation. Overall the use of the presented approach requires more implementation effort but less arithmetical operations with respect to the classical one.

2 Treatment of finite rotations

In the following, we denote with Greek indices the components of vectors and matrices while Latin indices are reserved to nodes and elements identification. Let $\mathbf{g}_\alpha = \{g_{\alpha\beta}\}$ and $\hat{\mathbf{g}}_\alpha = \{\hat{g}_{\alpha\beta}\}$ be, respectively, the actual and the initial configuration of three unit mutually orthogonal vectors

in the inertial reference basis $\mathbf{k}_\alpha = \{k_{\alpha\beta}\} = \{\delta_{\alpha\beta}\}$, where $\delta_{\alpha\beta}$ is the Kronecker delta. Then, matrix $\hat{\mathbf{G}} = [\hat{\mathbf{g}}_1|\hat{\mathbf{g}}_2|\hat{\mathbf{g}}_3]$ links $\hat{\mathbf{g}}_\alpha$ and $\mathbf{k}_\alpha$ vectors by $\hat{\mathbf{g}}_\alpha = \hat{\mathbf{G}}\mathbf{k}_\alpha$ while $\mathbf{G} = [\mathbf{g}_1|\mathbf{g}_2|\mathbf{g}_3]$ maps $\mathbf{k}_\alpha$ into $\mathbf{g}_\alpha$ vectors by $\mathbf{g}_\alpha = \mathbf{G}\mathbf{k}_\alpha$.

To obtain the updated treatment of rotations we refer to the $\mathbf{g}_{\alpha(k)} = \mathbf{G}_{(k)}\mathbf{k}_\alpha$, $\mathbf{G}_{(k)} = \mathbf{E}_{(k)}\bar{\mathbf{G}}_{(k)}$, expression for the actual configuration of the $\mathbf{g}_\alpha$ orthonormal triad at the k-th step. Vectors $\mathbf{e}_{\alpha(k)}$ defining $\mathbf{E}_{(k)} = [\mathbf{e}_1|\mathbf{e}_2|\mathbf{e}_3]$ represent the incremental rotation from the $\bar{\mathbf{g}}_{\alpha(k)}$ previously computed configuration. The subsequent $k+1$ step, afterward, refers to the $\bar{\mathbf{G}}_{(k+1)} = \mathbf{E}^*_{(k)}\bar{\mathbf{G}}_{(k)}$ updated configuration with the $\mathbf{e}^*_{\alpha(k)}$ established configuration of $\mathbf{e}_\alpha$. The process is initialized by $\bar{\mathbf{G}}_{(0)} = \hat{\mathbf{G}}$.

Classically, the treatment of rotations is based on the recursive composition $\mathbf{g}_{\alpha(k)} = \mathbf{E}_{(k)}\bar{\mathbf{G}}_{(k)}\hat{\mathbf{g}}_\alpha$, $\mathbf{E}_{(k)} = \mathbf{E}(\boldsymbol{\psi}_{(k)})$, where ψ_α components of $\boldsymbol{\psi}$ are the unknown rotation parameters. Following the description given before, $\mathbf{E}_{(k)}$ is the incremental rotation matrix which maps the updated frame $\bar{\mathbf{g}}_{\alpha(k)}$ into the actual frame $\mathbf{g}_{\alpha(k)}$ while $\bar{\mathbf{G}}_{(k)} = \bar{\mathbf{G}}_{(k)}(\bar{\boldsymbol{\psi}}_{(k)})$ maps the initial frame $\hat{\mathbf{g}}_\alpha$ into the updated frame $\bar{\mathbf{g}}_{\alpha(k)}$. Based on the rotation vector $\boldsymbol{\psi} = \varphi\boldsymbol{\phi}$, $\boldsymbol{\phi}^T\boldsymbol{\phi} = 1$, of the Euler theorem to describe finite rotations, a representation of rotation operators is:

$$\mathbf{G}(\boldsymbol{\psi}) = \mathbf{I} + \frac{\sin\varphi}{\varphi}\boldsymbol{\psi}_\times + \frac{1-\cos\varphi}{\varphi^2}\boldsymbol{\psi}^2_\times. \tag{1}$$

where $\mathbf{I}$ is the identity matrix. In (1) $\boldsymbol{\psi}_\times$ denotes the skew symmetric tensor obtained by the components of vector $\boldsymbol{\psi}$:

$$\boldsymbol{\psi}_\times = \mathbf{Skew}(\boldsymbol{\psi}) = \begin{bmatrix} 0 & -\psi_3 & \psi_2 \\ \psi_3 & 0 & -\psi_1 \\ -\psi_2 & \psi_1 & 0 \end{bmatrix}. \tag{2}$$

The $\boldsymbol{\psi} = \mathbf{axial}(\boldsymbol{\psi}_\times)$ is the converse operation of (2) that extracts the $\boldsymbol{\psi}$ vector from the skew symmetric tensor $\boldsymbol{\psi}_\times$.

In the use of the $\mathbf{G} = \mathbf{E}\bar{\mathbf{G}}$ composition of rotation operators, however, we stress that $\boldsymbol{\psi}_G \neq \boldsymbol{\psi} + \bar{\boldsymbol{\psi}}$ successive rotations cannot be obtained by simply adding their corresponding rotation vectors but the solution of the inverse $\boldsymbol{\psi}_G = G^{-1}(\mathbf{G})$ problem is required. Such a problem is defined as the operation of obtaining the $\boldsymbol{\psi}_G$ rotation vector based on the knowledge of the $\mathbf{G}$ rotation matrix and can be solved by the no ill-conditioning Spurrier algorithm [12]. By referring to the established configuration $\boldsymbol{\psi}^*_{(k)}$, afterwards, the updated configuration is achieved in the subsequent $k+1$ step as

$$\mathbf{G} = \mathbf{E}^*_{(k)}\bar{\mathbf{G}}_{(k)}, \quad \boldsymbol{\psi}_G = G^{-1}(\mathbf{G}), \quad \bar{\mathbf{G}}_{(k+1)} = \mathbf{G}(\boldsymbol{\psi}_G). \tag{3}$$

The process is initialized by $\bar{\mathbf{G}}_{(0)} = \mathbf{I}$.

In the presented finite rotations formulation let respectively $\overset{i}{\mathbf{u}}$ and $\overset{j}{\mathbf{u}}$ displacement vectors at the i and j boundary nodes of the element with lengh h, while discrete operators s and d rest defined by $s\mathbf{u} = (\overset{i}{\mathbf{u}} + \overset{j}{\mathbf{u}})/2$ and $d\mathbf{u} = (\overset{j}{\mathbf{u}} - \overset{i}{\mathbf{u}})/h$. Then, by evaluating the vector connecting the i and j nodes, we refer to

$$\mathbf{p}_1 = d\mathbf{u} + \hat{\mathbf{g}}_1, \quad \check{\mathbf{g}}_1 = \mathbf{p}_1/||\mathbf{p}_1|| \tag{4}$$

for the first actual vector of the orthonormal basis. By referring to the given unit vector $\bar{\mathbf{g}}_2$ we define the vectors

$$\mathbf{p}_2 = \bar{\mathbf{g}}_2 - \check{\mathbf{g}}_1 \cdot \bar{\mathbf{g}}_2 \ \check{\mathbf{g}}_1, \qquad \check{\mathbf{g}}_2 = \mathbf{p}_2/||\mathbf{p}_2|| \tag{5}$$
$$\check{\mathbf{g}}_3 = \check{\mathbf{g}}_1 \times \check{\mathbf{g}}_2$$

such that the basis $\check{\mathbf{G}} = [\check{\mathbf{g}}_1|\check{\mathbf{g}}_2|\check{\mathbf{g}}_3]$ is orthonormal and coincides with the principal axes of the beam element. The additional rotation in the reference space characterized by the angle r about the $\check{\mathbf{g}}_1$ axis

$$\mathbf{G}_r = \mathbf{I} + \sin r\check{\mathbf{g}}_{1\times} + (1-\cos r)\check{\mathbf{g}}_{1\times}^2 \tag{6}$$

completes now the definition of the rotation operator $\mathbf{G} = \mathbf{G}_r\check{\mathbf{G}}$ that links $\mathbf{g}_\alpha$ and $\mathbf{k}_\alpha$ vectors.

We note that, in the definition of the $\check{\mathbf{g}}_2$ vector in (5), the vectors $\check{\mathbf{g}}_1$ and $\bar{\mathbf{g}}_2$ have to form a linearly independent set. However this is not an actual limitation for the incremental rotation $\mathbf{E}_{(k)}$. Furthermore, rotation $\mathbf{G}_r$ defined in (6) preserves the linearity of the vector space operations because it has as axis of rotation the component $\check{\mathbf{g}}_1 = \mathbf{g}_1$ of $\mathbf{G}$.

3 Kinematics and energetic quantities of the beam element

Let ξ be the referential coordinate along the beam element centerline $-h/2 \le \xi \le +h/2$. Global displacement vector $\mathbf{u}(\xi)$ of the e element is composed of rigid and deformation components by

$$\overset{e}{\mathbf{u}}(\xi) = \overset{e}{\mathbf{u}} + (\overset{e}{\mathbf{g}}_1 - \overset{e}{\hat{\mathbf{g}}}_1)\xi + \overset{e}{\mathbf{G}}\overset{e}{\tilde{\mathbf{u}}}(\xi), \tag{7}$$

where

$$\begin{aligned}
\overset{e}{\tilde{u}}_1(\xi) &= \overset{e}{\varepsilon}\xi \\
\overset{e}{\tilde{u}}_2(\xi) &= -\frac{h^2}{8}\overset{e}{\chi}_3 - \frac{h^2}{24}\overset{e}{\gamma}_2\xi + \frac{1}{2}\overset{e}{\chi}_3\xi^2 + \frac{1}{6}\overset{e}{\gamma}_2\xi^3 \\
\overset{e}{\tilde{u}}_3(\xi) &= \frac{h^2}{8}\overset{e}{\chi}_2 + \frac{h^2}{24}\overset{e}{\gamma}_3\xi - \frac{1}{2}\overset{e}{\chi}_2\xi^2 - \frac{1}{6}\overset{e}{\gamma}_3\xi^3.
\end{aligned} \tag{8}$$

Then, local transverse rotations in the $\overset{e}{\mathbf{G}}$ basis are computed by

$$\begin{aligned}
\overset{e}{\varphi}_2(\xi) &= -\overset{e}{\tilde{u}}_{3,\xi}(\xi) = -\frac{h^2}{24}\overset{e}{\gamma}_3 + \overset{e}{\chi}_2\xi + \frac{1}{2}\overset{e}{\gamma}_3\xi^2 \\
\overset{e}{\varphi}_3(\xi) &= \overset{e}{\tilde{u}}_{2,\xi}(\xi) = -\frac{h^2}{24}\overset{e}{\gamma}_2 + \overset{e}{\chi}_3\xi + \frac{1}{2}\overset{e}{\gamma}_2\xi^2,
\end{aligned} \tag{9}$$

while local axial rotation is now defined by the expression

$$\overset{e}{\varphi}_1(\xi) = \overset{e}{\chi}_1\xi + \frac{1}{3}\overset{e}{\gamma}_1\xi^2. \tag{10}$$

By evaluating above relations for nodal coordinates we deduce that

$$\overset{e}{\varepsilon} = \overset{e}{\mathbf{g}}_1 \cdot \overset{e}{\mathbf{p}}_1 - 1 \tag{11}$$

is the expression of the axial deformation and

$$\overset{e}{\boldsymbol{\chi}} = d\overset{e}{\boldsymbol{\varphi}}, \qquad \overset{e}{\boldsymbol{\gamma}} = \frac{6}{h^2}s\overset{e}{\boldsymbol{\varphi}}, \tag{12}$$

are the expressions of torque and shear deformations as a function of nodal displacement and local rotations.

In the following, we refer to the m and p elements respectively adjacent of the current e element at the nodes i and j. Let, furthermore, $\overset{em}{\hat{\mathbf{P}}} = \overset{e}{\hat{\mathbf{G}}} \cdot \overset{m}{\hat{\mathbf{G}}}$ and $\overset{ep}{\hat{\mathbf{P}}} = \overset{e}{\hat{\mathbf{G}}} \cdot \overset{p}{\hat{\mathbf{G}}}$ rotation matrices

that carry out the representations of vector respectively in the $\overset{m}{\hat{\mathbf{g}}}_\alpha$ and $\overset{p}{\hat{\mathbf{g}}}_\alpha$ basis with respect to $\overset{e}{\hat{\mathbf{g}}}_\alpha$. By referring to the $\overset{ei}{\boldsymbol{\varphi}}$ and $\overset{ej}{\boldsymbol{\varphi}}$ nodal local rotations, nodal director components are now calculated by the vectorial operations

$$\overset{ei}{\mathbf{G}} = \overset{e}{\mathbf{G}}(\mathbf{I} + \overset{ei}{\boldsymbol{\varphi}}_\times), \qquad \overset{ej}{\mathbf{G}} = \overset{e}{\mathbf{G}}(\mathbf{I} + \overset{ej}{\boldsymbol{\varphi}}_\times). \tag{13}$$

We note that the first order accuracy of the (13) representations leads to local evaluations consistent with the small strains hypotheses. Rotational compatibility conditions at the boundary nodes, then, are obtained by imposing

$$\overset{m}{\mathbf{G}}(\mathbf{I} + \overset{mj}{\boldsymbol{\varphi}}_\times) = \overset{e}{\mathbf{G}}(\mathbf{I} + \overset{ei}{\boldsymbol{\varphi}}_\times)\overset{em}{\hat{\mathbf{P}}}, \qquad \overset{p}{\mathbf{G}}(\mathbf{I} + \overset{pi}{\boldsymbol{\varphi}}_\times) = \overset{e}{\mathbf{G}}(\mathbf{I} + \overset{ej}{\boldsymbol{\varphi}}_\times)\overset{ep}{\hat{\mathbf{P}}}. \tag{14}$$

Now we also define respectively the local rotations $\overset{em}{\boldsymbol{\theta}}$ and $\overset{ep}{\boldsymbol{\theta}}$ connecting directly the $\overset{m}{\mathbf{g}}_\alpha$ and $\overset{p}{\mathbf{g}}_\alpha$ bases with $\overset{e}{\mathbf{g}}_\alpha$ by the relations:

$$\overset{e}{\mathbf{G}} = \overset{m}{\mathbf{G}}\overset{em}{\hat{\mathbf{P}}} \cdot (\mathbf{I} + \overset{em}{\boldsymbol{\theta}}_\times), \qquad \overset{e}{\mathbf{G}} = \overset{p}{\mathbf{G}}\overset{ep}{\hat{\mathbf{P}}} \cdot (\mathbf{I} + \overset{ep}{\boldsymbol{\theta}}_\times). \tag{15}$$

Then by (14) and (15) we can evaluate at the first order:

$$\overset{mj}{\boldsymbol{\varphi}} = \overset{em}{\hat{\mathbf{P}}} \cdot (\overset{ei}{\boldsymbol{\varphi}} + \overset{em}{\boldsymbol{\theta}}), \qquad \overset{pi}{\boldsymbol{\varphi}} = \overset{ep}{\hat{\mathbf{P}}} \cdot (\overset{ej}{\boldsymbol{\varphi}} + \overset{ep}{\boldsymbol{\theta}}), \tag{16}$$

with

$$\overset{em}{\boldsymbol{\theta}}_\times = \overset{em}{\hat{\mathbf{P}}}\overset{m}{\mathbf{G}} \cdot \overset{e}{\mathbf{G}} - \mathbf{I}, \qquad \overset{ep}{\boldsymbol{\theta}}_\times = \overset{em}{\hat{\mathbf{P}}}\overset{p}{\mathbf{G}} \cdot \overset{e}{\mathbf{G}} - \mathbf{I}. \tag{17}$$

We note that rotations $\overset{em}{\boldsymbol{\theta}}$ and $\overset{ep}{\boldsymbol{\theta}}$ are in function of the assumed nodal displacements and elemental rotations unknowns. To recover expressions for the rotational deformations in (12), here we impose equilibrium equations or consistence conditions at the nodes.

Twisting and bending moments $\mathbf{m}_\alpha$ at the i node due to the e element can be expressed by the formula

$$\overset{ei}{\mathbf{m}}_\alpha = \overset{e}{H}_{\alpha\alpha}\overset{ei}{\varphi}_{\alpha,\xi}\overset{ei}{\mathbf{g}}_\alpha. \tag{18}$$

In (18) we denote with $\mathbf{H} = \mathbf{diag}[GJ_1, EJ_2, EJ_3]$ the elastic constitutive matrix of torsional and bending stiffnesses about the principal axes. Let $\overset{i}{\mathbf{m}}$ the applied vector moment at the i node, then related equilibrium equation is:

$$\overset{ei}{\mathbf{m}} = \overset{i}{\mathbf{m}} + \overset{mj}{\mathbf{m}}, \qquad \overset{ei}{\mathbf{m}} = \sum_\alpha \overset{e}{H}_{\alpha\alpha}\overset{ei}{\varphi}_{\alpha,\xi}\overset{ei}{\mathbf{g}}_\alpha, \quad \overset{mj}{\mathbf{m}} = \sum_\alpha \overset{m}{H}_{\alpha\alpha}\overset{mj}{\varphi}_{\alpha,\xi}\overset{mj}{\mathbf{g}}_\alpha. \tag{19}$$

For clarity of presentation, in the following we refer to the case $\overset{i}{\mathbf{m}} = \mathbf{0}$. Then, for the β component of equilibrium equation (19) we have

$$\overset{m}{H}_{\beta\beta}\overset{mj}{\varphi}_{\beta,\xi} = \sum_\alpha \overset{e}{H}_{\alpha\alpha}\overset{ei}{\varphi}_{\alpha,\xi}\overset{mj}{\mathbf{g}}_\beta \cdot \overset{ei}{\mathbf{g}}_\alpha. \tag{20}$$

By proceeding in a similar way for the equilibrium equation at the j node and by writing relations (20) in the matrix form we obtain

$$\overset{m}{\mathbf{H}}\overset{mj}{\boldsymbol{\varphi}}_{,\xi} = \overset{mj}{\mathbf{G}} \cdot \overset{ei}{\mathbf{G}}\overset{e}{\mathbf{H}}\overset{ei}{\boldsymbol{\varphi}}_{,\xi}, \qquad \overset{p}{\mathbf{H}}\overset{pi}{\boldsymbol{\varphi}}_{,\xi} = \overset{pi}{\mathbf{G}} \cdot \overset{ej}{\mathbf{G}}\overset{e}{\mathbf{H}}\overset{ej}{\boldsymbol{\varphi}}_{,\xi}. \tag{21}$$

By inserting compatibility conditions $\overset{ei}{\mathbf{G}}\overset{em}{\hat{\mathbf{P}}} = \overset{mj}{\mathbf{G}}$ and $\overset{ej}{\mathbf{G}}\overset{ep}{\hat{\mathbf{P}}} = \overset{pi}{\mathbf{G}}$ in the (21) relations we have:

$$\overset{m}{\mathbf{H}}\overset{mj}{\boldsymbol{\varphi}}_{,\xi} = \overset{em}{\hat{\mathbf{P}}} \cdot \overset{e}{\mathbf{H}}\overset{ei}{\boldsymbol{\varphi}}_{,\xi}, \qquad \overset{p}{\mathbf{H}}\overset{pi}{\boldsymbol{\varphi}}_{,\xi} = \overset{ep}{\hat{\mathbf{P}}} \cdot \overset{e}{\mathbf{H}}\overset{ej}{\boldsymbol{\varphi}}_{,\xi}. \tag{22}$$

In the cases of constant bending state, $\overset{e}{\boldsymbol{\gamma}} = \mathbf{0}$ and $\overset{m}{\boldsymbol{\gamma}} = \mathbf{0}$ in (12) expressions imply that $\overset{ej}{\boldsymbol{\varphi}} = -\overset{ei}{\boldsymbol{\varphi}}$ and $\overset{mi}{\boldsymbol{\varphi}} = -\overset{mj}{\boldsymbol{\varphi}}$, respectively, and

$$\overset{ei}{\boldsymbol{\varphi}}_{,\xi} = \overset{e}{\boldsymbol{\chi}} = -\frac{2}{\overset{e}{h}}\overset{ei}{\boldsymbol{\varphi}}, \qquad \overset{mj}{\boldsymbol{\varphi}}_{,\xi} = \overset{m}{\boldsymbol{\chi}} = \frac{2}{\overset{m}{h}}\overset{mj}{\boldsymbol{\varphi}}. \tag{23}$$

Finally, by (16), (22) and (23), for the i node we obtain

$$\overset{em}{\mathbf{A}}\overset{ei}{\boldsymbol{\varphi}} = -\frac{1}{\overset{m}{h}}\overset{em}{\hat{\mathbf{P}}}\overset{m}{\mathbf{H}}\overset{em}{\hat{\mathbf{P}}} \cdot \overset{em}{\boldsymbol{\theta}}, \qquad \overset{em}{\mathbf{A}} = \frac{1}{\overset{e}{h}}\overset{e}{\mathbf{H}} + \frac{1}{\overset{m}{h}}\overset{em}{\hat{\mathbf{P}}}\overset{m}{\mathbf{H}}\overset{em}{\hat{\mathbf{P}}} \cdot . \tag{24}$$

Similarly, for the j node:

$$\overset{ep}{\mathbf{A}}\overset{ej}{\boldsymbol{\varphi}} = -\frac{1}{\overset{p}{h}}\overset{ep}{\hat{\mathbf{P}}}\overset{p}{\mathbf{H}}\overset{ep}{\hat{\mathbf{P}}} \cdot \overset{ep}{\boldsymbol{\theta}}, \qquad \overset{ep}{\mathbf{A}} = \frac{1}{\overset{e}{h}}\overset{e}{\mathbf{H}} + \frac{1}{\overset{p}{h}}\overset{ep}{\hat{\mathbf{P}}}\overset{p}{\mathbf{H}}\overset{ep}{\hat{\mathbf{P}}} \cdot . \tag{25}$$

By the (24) and (25) definitions of the local rotations we can obtain the computation of the (12) element beam deformations in function of the assumed unknowns. We note that the $\mathbf{A}$ matrices are defined by fixed quantities of the problem. Then such quantities can be computed, for each node, at the preprocessing procedure.

If we want to achieve the complete consistence at the generic i node, together with (16) expressions we must impose the $\sum_\alpha \overset{ei}{\varphi}_{\alpha,\xi}\overset{ei}{\mathbf{g}}_\alpha = \sum_\alpha \overset{mj}{\varphi}_{\alpha,\xi}\overset{mj}{\mathbf{g}}_\alpha$ and $\sum_\alpha \overset{ei}{\varphi}_{\alpha,\xi\xi}\overset{ei}{\mathbf{g}}_\alpha = \sum_\alpha \overset{mj}{\varphi}_{\alpha,\xi\xi}\overset{mj}{\mathbf{g}}_\alpha$ continuity conditions that, at the first order of approximation, lead to the relations:

$$\overset{mj}{\boldsymbol{\varphi}}_{,\xi} = \overset{em}{\hat{\mathbf{P}}} \cdot \overset{ei}{\boldsymbol{\varphi}}_{,\xi} \qquad \text{and} \qquad \overset{mj}{\boldsymbol{\varphi}}_{,\xi\xi} = \overset{em}{\hat{\mathbf{P}}} \cdot \overset{ei}{\boldsymbol{\varphi}}_{,\xi\xi} \tag{26}$$

respectively, while for the j node

$$\overset{pi}{\boldsymbol{\varphi}}_{,\xi} = \overset{ep}{\hat{\mathbf{P}}} \cdot \overset{ej}{\boldsymbol{\varphi}}_{,\xi} \qquad \text{and} \qquad \overset{pi}{\boldsymbol{\varphi}}_{,\xi\xi} = \overset{ep}{\hat{\mathbf{P}}} \cdot \overset{ej}{\boldsymbol{\varphi}}_{,\xi\xi}. \tag{27}$$

After algebraic manipulations by the above expressions the following relations are obtained:

$$-\frac{2\overset{m^2}{h} + 3\overset{m}{h}\overset{e}{h} + \overset{e^2}{h}}{\overset{e^2}{h}}s\overset{e}{\boldsymbol{\varphi}} + \frac{\overset{m}{h} + \overset{e}{h}}{2}d\overset{e}{\boldsymbol{\varphi}} = \overset{em}{\boldsymbol{\theta}}, \qquad -\frac{2\overset{p^2}{h} + 3\overset{p}{h}\overset{e}{h} + \overset{e^2}{h}}{\overset{e^2}{h}}s\overset{e}{\boldsymbol{\varphi}} - \frac{\overset{p}{h} + \overset{e}{h}}{2}d\overset{e}{\boldsymbol{\varphi}} = \overset{ep}{\boldsymbol{\theta}}. \tag{28}$$

Also here, by the (28) definitions of the local rotations, we can achieve the computation of the element beam deformations in function of the assumed unknowns.

4 Boundary conditions, multiple connections and solution scheme

Boundary conditions imposition implies a case depending implementation of the solution process. In effect, conditions involving rotations and moments given at boundary nodes are imposed by specializing related elements by following the formulation described in Section

3 because we have worked with global rotation and curvature definitions. Furthermore, we remark that only the external work of forces can be defined in the described formulation so that moments can be modelled as forces following the motion of points of the beam element. In particular, let vector $\overset{n}{\mathbf{m}}$ be the spatially fixed moment applied in the n node of the e element and $\overset{en}{\mathbf{g}}_\alpha$ the related nodal basis. As described in [13], we refer to three force vectors $\mathbf{p}_{(\alpha)}$ applied to n and compute the external work as

$$W_{\mathbf{m}} == \sum_\alpha \mathbf{p}_{(\alpha)} \cdot (\overset{en}{\mathbf{g}}_\alpha - \overset{en}{\hat{\mathbf{g}}}_\alpha). \tag{29}$$

The variation of the functional $W_{\mathbf{m}}$ is carried out on the $\overset{en}{\mathbf{g}}_\alpha$ vectors by considering $\mathbf{p}_{(\alpha)}$ as constants. Then, after variation of (29), we define the $\mathbf{p}_{(\alpha)}$ force vectors by

$$\mathbf{p}_{(\alpha)} = -\frac{1}{2}\sum_{\beta\kappa} e_{\alpha\beta\kappa} p_\beta \overset{en}{\mathbf{g}}_\kappa, \qquad \sum_\alpha \overset{en}{\mathbf{g}}_\alpha \times \mathbf{p}_{(\alpha)} = \overset{n}{\mathbf{m}}. \tag{30}$$

As can be observed in (30), applied forces are such that the resulting moment in the n node is the given $\overset{n}{\mathbf{m}}$ vector. Simple algebraic manipulations, finally, lead to the $p_\alpha = \overset{n}{\mathbf{m}}^T \overset{en}{\mathbf{g}}_\alpha$ components. We note that, the definitions given in (29) and (30) imply that the external force vectors are a function of the assumed unknowns.

In the case of more elements connected to the i node, the relations in (19) of the (*EF*) equilibrium based formulation become

$$\overset{ei}{\mathbf{m}} = \overset{i}{\mathbf{m}} + \sum_m \overset{mj}{\mathbf{m}}, \quad \text{or} \quad \sum_\alpha \overset{e}{H}_{\alpha\alpha} \overset{ei}{\varphi}_{\alpha,\xi} \overset{ei}{\mathbf{g}}_\alpha = \overset{i}{\mathbf{m}} + \sum_m \sum_\alpha \overset{m}{H}_{\alpha\alpha} \overset{mj}{\varphi}_{\alpha,\xi} \overset{mj}{\mathbf{g}}_\alpha. \tag{31}$$

Being $\overset{ei}{\mathbf{G}}\overset{em}{\hat{\mathbf{P}}} = \overset{mj}{\mathbf{G}}$, $\forall m$ and by assuming $\overset{mi}{\boldsymbol{\varphi}} = -\overset{mj}{\boldsymbol{\varphi}}$, $\forall m$ we obtain:

$$\overset{em}{\mathbf{A}}\overset{ei}{\boldsymbol{\varphi}} = -\sum_m \frac{1}{\overset{m}{h}} \overset{em}{\hat{\mathbf{P}}} \overset{m}{\mathbf{H}} \overset{em}{\hat{\mathbf{P}}} \cdot \overset{em}{\boldsymbol{\theta}}, \qquad \overset{em}{\mathbf{A}} = \frac{1}{\overset{e}{h}} \overset{e}{\mathbf{H}} + \sum_m \frac{1}{\overset{m}{h}} \overset{em}{\hat{\mathbf{P}}} \overset{m}{\mathbf{H}} \overset{em}{\hat{\mathbf{P}}} \cdot, \tag{32}$$

and the analogous for the j node. From the implementation point of the view, at the current e element, multiple connections are carried out by repeating m times the assembling of internal force vectors and stiffness matrices for each connected element. For the (*CF*) consistence based formulation, instead, a master element must be assigned at the multiply connected node as reference of related continuity conditions.

The definition of equilibrium equations is based on the classical stationary problem for the energy functional. Because a multiplicative approach is here exploited, admissible variational formulation and linearization must be carried out at the solution point in the respect of the $\delta\mathbf{G} = \delta\boldsymbol{\varphi}_\times \mathbf{G}$ consistent condition, where $\delta\boldsymbol{\varphi}$ is the spatial component of the angular variation. A predictor-corrector scheme as described in [14] for the equilibrium path individualization is used in the analysis. It is characterized by a predictor step obtained by the linear extrapolation of the previously computed two solution points when $k > 0$, while the first order asymptotic extrapolation is used when $k = 0$. Furthermore, the corrector is accomplished by a Newton method based corrector scheme with minimization of the distance between the approximate and equilibrium points as a constraint equation.

5 Numerical examples

Equilibrium curve of the framed dome shown in Figure 1 and analyzed in Battini [15], Kouhia and Tuomala [16], was calculated with both *EF* and *CF* approaches. By assuming ε=0 or ε=0.0001 two different behaviours of the structure have been considered. The dome has been modelled by using N_{mb}=4,8 elements for each member, i.e. totally 18N_{mb} elements.

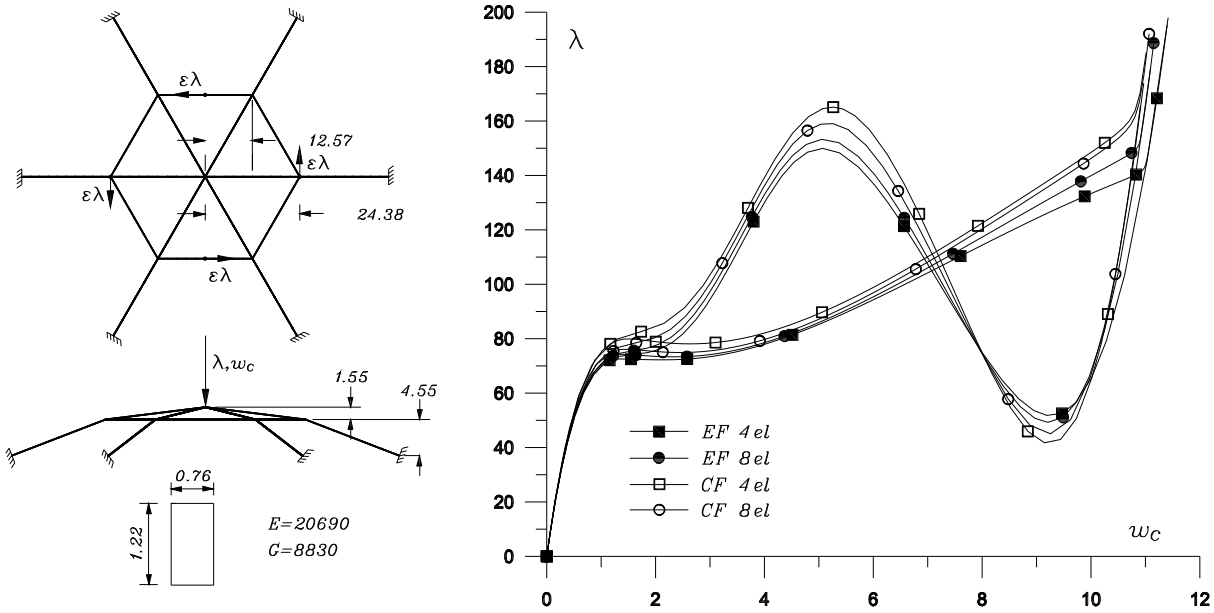

Figure 1: Framed dome: problem definition and equilibrium paths.

In Figure 1 the fundamental path and the secondary path branching out at the lowest bifurcation point are also displayed. Significant deformed configurations are shown in Figure 2 for both loadings. In particular, the perfect case (a) is characterized by a symmetric behaviour while the post-buckling mode (b) is a rotation around the central vertical axis. The detected computational performances indicate that the presented formulation requires more implementation effort but less arithmetical operations with respect to the classical rotation vector based approach.

6 Conclusions

In the hypothesis of large displacements and rotations and small strains, a technique to analyze the behaviour of three-dimensional finite element beam frames has been presented. The approach is based on an updated Lagrangian description of rotations and the presented formulations do not use angle measures. By adopting the Euler-Bernoulli beam model, a computationally effective beam element is obtained because kinematical and strain measures are completely defined by referring to boundary nodal displacements and one finite rotation parameter solely. The treatment of rotational boundary conditions and external moments proves to be more complex with respect to the co-rotational formulations. Nevertheless, the description of the finite three-dimensional rotations is well posed under widely applicable hypotheses, while the analysis of complex spatial dome structures, where matrices with large dimension and bandwidth occur, now proves a remarkable reduction of the required arithmetical operations with respect to the classical approaches.

Keywords: Corotational finite elements, cable dynamics, hysteretic bending, friction.

Abstract. *A new formulation to model the mechanical response of metallic strands undergoing a combination of axial load and planar bending is developed. Each wire of the strand is modeled as an elastic curved thin rod. A kinematic model is then introduced to relate the generalized strain variables of the strand to those of the wires. The stress-strain state of the wires is evaluated starting from the analysis of the internal contact conditions. Friction is modeled through the classic Amontons-Coulomb law and the elastic tangential compliance of contact patches is accounted for. A non-holonomic material constitutive law in terms of the cross sectional generalized stresses and strains of the Euler-Bernoulli beam theory is obtained and implemented within a corotational beam element explicitly conceived for nonlinear static and dynamic analyses of flexible structures. Numerical applications are presented to highlight the role of the tangential compliance mechanism on the hysteretic bending behavior of a typical steel strand.*

1 INTRODUCTION

Metallic strands can be regarded as composite elements which are made of helical wires twisted around a straight core and grouped in concentric layers. They are widespread structural members, used in many engineering applications, e.g. overhead electrical lines, tensile structures, guyed masts and towers.

When a strand is bent, wires tend to slip relatively one to each other, as a consequence of the axial force gradient generated along their length. The relative displacements are contrasted by friction forces, which are a function of the geometry of the internal structure, the material properties of the wires and the intra- and inter-layer contact pressures. If the forces which tend to activate sliding are greater than the friction ones, then a generic wire can experience relative displacements with respect to the neighbors. Interwire sliding phenomena makes the bending behavior of strands inherently non-linear and can significantly affect both the local response of the elements under cyclic loading (e.g. leading to the occurrence of fretting fatigue and wear [11, 18]) as well as the overall structural response. In fact, bending vibrations of metallic strands are characterized by an hysteretic damping mechanism, as it can be inferred from both quasi-static [17] as well as dynamic tests [21].

In the present paper, a new formulation to model the mechanical response of metallic strands undergoing a combination of axial load and planar bending is developed. Each wire of the strand is modeled as an elastic curved thin rod. A kinematic model is then introduced to relate the generalized strain variables of the strand to those of the wires. The stress-strain state of the wires is then evaluated starting from the analysis of the internal contact conditions. Friction is modeled through the classic Amontons-Coulomb law and the elastic tangential compliance of contact patches is accounted for, aiming at extending a previous authors' model taking into account the gross sliding only [3, 5, 7-9]. A non-holonomic material constitutive law in terms of the cross sectional generalized stress and strains of the Euler-Bernoulli beam theory is obtained, which can be exploited to describe cables as structural members reacting to a generic combination of axial force and bending. The sectional constitutive law is then implemented within a corotational beam element, previously developed and able to deal with large displacements and rotations and explicitly conceived for the nonlinear static and dynamic analysis of flexible structures [3, 6, 10].

The new mechanical model developed in this work is presented with reference to a simple strand made of a single layer of wires, in order to focus on the most important aspects of the proposed approach, while avoiding additional difficulties and cumbersome calculations stemming from a more complex internal geometry.

Numerical applications of the proposed cross sectional and finite element formulations are then presented for the case of a well documented steel strand, extensively studied in literature both for a combination of axial-torsional loads [4, 15, 16, 19, 20] as well as under the combined action of axial load and planar bending [9].

Within this context, systematic comparisons are carried out among the predictions of the new formulation and those of the model previously developed by the author and neglecting the interwire tangential contact compliance. The aim is to assess the effects of the tangential contact compliance on the hysteretic bending behavior of the strand. The latter, in turn, plays a key role in the modeling of the flexural vibrations of metallic strands.

2 GEOMETRY OF THE STRAND

A strand made of a single layer of six round wires, wrapped around an initially straight core wire, is considered in this work (Figure 1). The core and external wires have diameters d_0 and d_1, respectively. Each wire can be described as a curved thin rod, defined by the position of the centerline within a reference system attached to the strand centerline (axes $\{x_i\}$ (i=1, 2, 3)) as depicted in Figure 1. The centerline of the external wires is a circular helix spanned by the position vector:

$$\mathbf{x}(\theta) = \frac{R}{\tan(\alpha)}(\theta - \theta_0)\mathbf{e}_1 + R\cos(\theta)\mathbf{e}_2 + R\sin(\theta)\mathbf{e}_3 \tag{1}$$

where: $\{\mathbf{e}_i\}$ are the unit vectors of the axes $\{x_i\}$, R is the *helix radius*, i.e. the distance measured on the plane (x_2, x_3) from the centroid of the wire to that of the strand, α is the lay angle, i.e. the constant angle which the tangent vector to the helix defines with the strand centerline (axis x_1), and θ is the *swept angle*, i.e. the angle which the projection of the position vector $\mathbf{x}$ on the plane x_1=0 makes with the axis x_1 (see Figure 1(b)). The symbol θ_0 is adopted to denote the value of the swept angle at the strand cross section identified by the coordinate: x_1=0.

The external wires are assumed in contact with the core, but not among them. This condition, commonly referred to as *radial contact* condition (e.g. [1]), is typical of metallic strands.

As a consequence the helix radius in the reference (undeformed) configuration of the strand is the sum of the wire radii: R=0.5(d_0+d_1). The lay angle must be smaller than the maximum value α_{max}, that causes contact among the wires of a layer (see e.g. [2]).

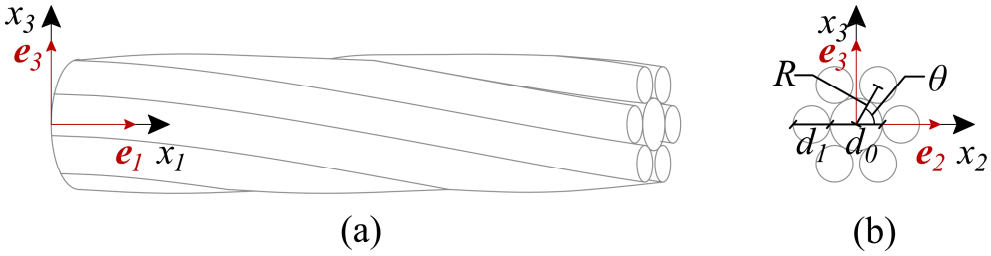

Figure 1: Geometry of the strand. (a) Side view. (b) Cross section.

3 MECHANICAL MODEL OF THE STRAND

The response of the strand to a constant axial force F_s and bending moment distribution M_s is first studied. The geometric nonlinearities, which typically affect the behavior of such slender structural elements, then, are fully considered within the framework of the corotational beam element formulation.

A “two-stage” approach is adopted in this work to tackle the axial-bending problem. As outlined e.g. in [1], the solution of the bending problem is superimposed on the initial state of stress and deformation due to the axial load. The axial force in a generic wire of the layer (tangent to the wire centerline), hence, can be expressed through the sum of a first contribution due to the axial load ($F_{w1,a}$) and a second one due to the bending of the strand ($F_{w1,b}$):

$$F_{w1} = F_{w1,a} + F_{w1,b} \tag{2}$$

3.1 Solution of the axial problem

The axial response of small-diameter metallic strands is substantially linear for a broad range of loads corresponding to typical service conditions (see e.g. the experimental results in [19] and the numerical simulations in [4, 9]). Accordingly, geometric nonlinearities due to the variation of the internal strand geometry, such as the contraction of the wire diameters (Poisson's effect) and the wire flattening (normal deformation of internal contact surfaces), can be practically neglected without significantly affecting the results.

A model for the linear coupled axial-torsional response of strands has been presented in [3, 9]. Whenever an axial load F_s is applied to the simple strand considered in the present paper, the axial elongation of the strand can be evaluated (under the assumption of zero torsional rotations of the cross sections) as:

$$\varepsilon_s = \frac{F_s}{EA_s} \tag{3}$$

where EA_s is the direct axial stiffness of the strand. By denoting as EA_0 and EA_1 the axial stiffness of the core and external wires, respectively, the strand stiffness EA_s is given by:

$$EA_s = EA_0 + 6EA_1 \cos^3(\alpha) \tag{4}$$

The axial force in the wires of the layer, then, can be expressed as:

$$F_{w1,a} = \cos^2(\alpha)\frac{EA_1}{EA_s}F_s \tag{5}$$

The axial force $F_{w1,a}$ is the same for all wires of the layer and constant along their length.

3.2 The contact model

The external wires are in contact with the core along a continuous helix (linear contact) with the same pitch of the wire centerline (see [8, 9] for more details). A system of radial (P) and tangential (T) forces per unit length of the wire centerline is first defined to model the interaction between a generic wire and the core, as shown in Figure 2. Then, the indefinite equilibrium equations of the wire in radial and tangential direction are written as:

$$\begin{cases} \dfrac{F_{w1,a} + F_{w1,b}}{\rho} - P = 0 \\ \dfrac{dF_{w1,b}}{dS} - T = 0, \ \text{ with: } \ T \le \mu P \end{cases} \tag{6a, b}$$

where ρ is the curvature radius of the wire centerline, which can be evaluated starting from equation (1) as: $\rho = R/\sin^2(\alpha)$ and μ is the friction coefficient of the contact interface.

The radial contact force P can be obtained by solving equation (6a). By neglecting the contribution $F_{w1,b}/\rho$ due to the bending of the strand, the following expression is obtained:

$$P \simeq \frac{F_{w1,a}}{\rho} \tag{7}$$

While introducing a great simplification in the analysis of the interwire contact conditions, the approximation introduced in (7) doesn't affect significantly the solution of the bending problem, as it has been shown numerically in [3] and analytically in [8] for the more general case of multi-layer metallic strands.

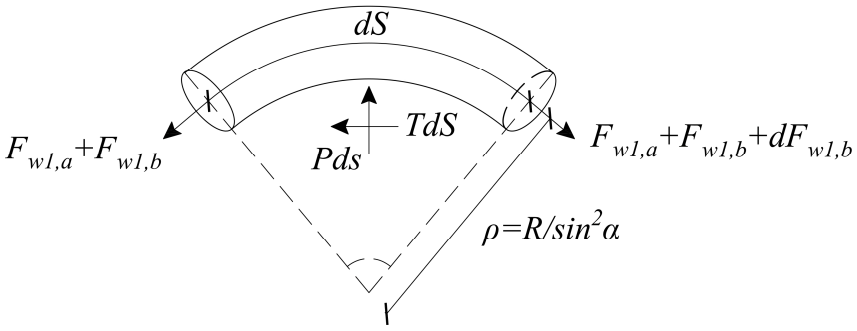

Figure 2: Equilibrium of an infinitesimal segment of the wire.

The tangential force T is related to the gradient of the wire axial force through the tangential equilibrium equation (6b). Since the term $F_{w1,a}$ stemming from the solution of the axial problem is constant along the length of the wire (see equation (5)), only the gradient of the bending contribution $F_{w1,b}$ to the total wire axial force is present in (6b).

The axial force gradient gives the wires the trend to slip with respect to the underlying core. This relative displacement is contrasted by the tangential contact force T, whose values are bounded by the Amontons-Coulomb inequality: $T \leq \mu P$. As long as $T < \mu P$, the sliding between the wire and the core is prevented (*no-sliding regime*). Relative displacements between the wire centerline (which will be denoted in the following as u_t) and the core, however, are present also in the no-sliding regime because of the tangential compliance of the contact surface. Goudreau et al. [12] studied the tangential compliance mechanism between the external wires and the core of a strand by exploiting the solution of the Hertzian contact problem for two parallel cylinders, made of the same material and pressed together. Accordingly, they introduced a non-linear relation between the relative displacement u_t and the tangential force per unit length T, herein re-stated as follows:

$$u_t = u_t^{gs}(P)\left(1-\left(1-\frac{T}{\mu P}\right)^{\frac{2}{3}}\right), \quad \text{with: } T \leq \mu P \tag{8}$$

where $u_t{}^{gs}(P)$ is the value of the relative displacement at the onset of gross sliding. The displacement $u_t{}^{gs}$ is a function of the normal contact force P. By denoting as $C_{Ti}(P)$ the initial value of the tangential compliance of the contact surface, $u_t{}^{gs}$ can be expressed as:

$$u_t^{gs} = \frac{3C_{Ti}(P)}{2\mu P} \tag{9}$$

The initial tangential compliance, in turn, depends upon the normal contact compliance $C_n(P)$ of the surface, according to the following relation, first proposed by Hobbs and Raoof [13] and later adopted also by Goudreau et al.:

$$C_{Ti}(P) = \frac{C_n(P)}{2(1-\nu)} \tag{10}$$

where ν is the Poisson coefficient of the material. A closed-form expression of the normal contact compliance $C_n(P)$ has been also derived by Goudreau et al. for the special case of ν=0.3, herein re-written, by denoting as E the Young modulus of the material, as:

$$C_n(P) = \frac{1}{E}\left(0.068505 + 1.1586 \ln\left(\sqrt{0.54945 \frac{E d_0}{P}\left(1 + \frac{d_1}{d_0}\right)}\right)\right) \tag{11}$$

A linear approximation of the model by Goudreau et al. is adopted in this work to characterize the tangential compliance between wires and core in the no-sliding regime. Based on the initial value of the tangential compliance, the following relation is introduced:

$$T \simeq \frac{1}{C_{Ti}(P)} u_t \leq \mu P \tag{12}$$

3.3 Solution of the bending problem

The nonlinear bending of multilayer strands has been studied in [3, 5, 7-9], starting from a description of the wire kinematics which accounts for the possible activation of gross-sliding phenomena, but neglects the effects of the tangential contact compliance. The aforementioned kinematic model will be augmented to account for the tangential compliance with the core wire.

By recalling equation (1) and assuming all wires as linearly elastic, the axial strain of a generic wire, ε_{w1}, can be expressed as the sum of the strain due to the axial load and to the bending, i.e.:

$$\varepsilon_{w1} = \frac{F_{w1}}{EA_1} = \frac{F_{w1,a}}{EA_1} + \frac{F_{w1,b}}{EA_1} = \varepsilon_{w1,a} + \varepsilon_{w1,b} \tag{13}$$

Two limit kinematic hypothesis can be introduced to evaluate $\varepsilon_{w1,b}$, which will be referred in the following as: *full-stick* and *full-slip* assumption. In the first case the tangential force T, due to the friction between the wire and the core, is assumed to be large enough to prevent the gross-sliding and the effect of the tangential compliance is neglected. As a consequence, the wire behaves as a part of an ideal planar cross section and the term $\varepsilon_{w1,b}$ can be simply evaluated according to the well-known Euler-Bernoulli kinematic model:

$$\varepsilon_{w1,b}^{full-stick} = \cos^2(\alpha) R \sin(\theta) \chi_s \tag{14}$$

where χ_s is the bending curvature with respect to the axis x_2 (see Figure 1).

In the second case, instead, the wire is free to slide with respect to the core and can be considered as individually bent. Under the full-slip assumption, hence, the term $\varepsilon_{w1,b}$ is identically equal to zero. By neglecting the tangential compliance, hence, the following incremental alternatives can be introduced to account for the possible transition between the no-sliding and the gross-sliding regime:

$$\dot{\varepsilon}_{w1,b} = \begin{cases} \dot{\varepsilon}_{w1,b}^{no-sliding} = \dot{\varepsilon}_{w1,b}^{full-stick} \\ \dot{\varepsilon}_{w1,b}^{gross-sliding} = 0 \end{cases} \tag{15a, b}$$

where a dot is adopted to denote the derivative with respect to a time variable t.

Equation (15a) can be modified in order to account for the effect of the tangential compliance between the external wires and the core, based on the solution of the bending problem in no-sliding regime which will be detailed in the following.

By recalling the definition of the relative displacement u_t introduced in Section 3.2, the term $\varepsilon_{w1,b}$ can be evaluated as:

$$\varepsilon_{w1,b}^{no-sliding} = \varepsilon_{w1,b}^{full-stick} + \frac{du_t}{dS} \tag{16}$$

By observing that $\sin(\alpha)\mathrm{d}S = R\mathrm{d}\theta$ (see e.g. [8]), from equations (6b), (12), (13) and (16) it's easy to derive the following equation for the axial force $F_{w1,b}$ in the *no-sliding* regime:

$$\frac{d^2 F_{w1,b}^{no-sliding}(\theta)}{d\theta^2} - \frac{R^2}{C_{Ti} EA_1 \sin^2(\alpha)} F_{w1,b}^{no-sliding}(\theta) = -\frac{R^3 \cos^2(\alpha)\chi_s}{C_{Ti}\sin^2(\alpha)}\sin(\theta) \tag{17}$$

The equation above can be easily solved under the assumption of constant curvature of the strand. The following expression is obtained:

$$F_{w1,b}^{no-sliding}(\theta) = \frac{\cos^2(\alpha) R\, EA_1\, \chi_s}{1 + \dfrac{C_{Ti}(P) EA_1 \sin^2(\alpha)}{R^2}}\sin(\theta) \tag{18}$$

Once the function $F_{w1,b}^{no-sliding}(\theta)$ is known, the corresponding axial strain can be evaluated and used in (15, a).

A numerical strategy to evaluate the wire axial force $F_{w1,b}(\theta)$, accounting for the possible transition between *no-sliding* and *gross-sliding* regime has been developed by the author in [3, 5, 7-9] and is adopted also in this work. The numerical procedure is based on a classic *Return-Map algorithm*, based on a "*no-sliding* prediction" and a "*gross-sliding* correction" (according to the alternative kinematic equations previously discussed). The Return-Map algorithm delivers the value of the gradient of the wire axial force which satisfies equation (16b), over a discrete set of control points defined along the pitch of the wire. Then, the wire axial force is obtained through numerical integration along the wire length.

Finally, starting from the knowledge of the wire axial force in all the wires of the layer the cross sectional moment of the strand can be evaluated, through simple equilibrium considerations, as:

$$M_s = M_s^{ind} + M_s^{add} = EI_{\min}\chi_s + M_s^{add} \tag{20}$$

The first term, M_s^{ind}, in (20) is linear and stems from the individual bending of the wires. It can be simply calculated as the product of the strand curvature and the minimum bending stiffness of the strand $EI_{\min}$. The latter can be evaluated by modeling the strand as a bundle of elastic curved thin rods, individually bent. The following expression can be obtained from [8]:

$$EI_{\min} = EI_0 + 6\cos^3(\alpha) EI_1 \tag{21}$$

The second term in (20), instead, accounts for the additional moment due to the bending contribution $F_{w1,b}(\theta)$ to the total axial force of the wires and can be evaluated (see e.g. [8]) as:

$$M_s^{add} = \sum_{i=1}^{6} R\cos(\alpha) F_{w1,b}(\theta_i)\sin(\theta_i) \tag{22}$$

3.4 The corotational beam element

The equations (3) and (20) fully define the relation between generalized stress and strain variables of the strand cross section, herein regarded as a plane Euler-Bernoulli beam. The proposed constitutive equations have been implemented within a corotational beam element

previously developed [3, 6, 10] to study the static and dynamic response of flexible structures taking into account geometrical and material nonlinearities.

4 NUMERICAL APPLICATION

The proposed strand mechanical model and beam finite element formulation are applied in this section to investigate the bending response of a strand made of steel wires, already studied in [9]. The geometric and material properties of the element are listed in Table 1.

d_0 (mm)	d_1 (mm)	α (deg)	E (GPa)	ν (-)
3.94	3.73	11.8	188	0.3

Table 1: Geometric and material parameters from [15].

The wire axial force in the no-sliding regime is shown in Figure 3 in terms of the amplification factor q_F of the force equivalent to $F_{w1,b}^{no-sliding}$ but obtained (under the full-stick assumption) by neglecting the tangential compliance. The factor q_F is plotted in Figure 3 as a function of the non-dimensional axial load parameter η, defined as the ratio between the axial load F_s and the Rated Tensile Strength of the element (here 137 kN – see [19]). From Figure 3, it can be observed that the inclusion of the tangential compliance mechanism in the strand mechanical model leads to a reduction of 10% of the maximum value which can be attained by the wire axial force $F_{w1,b}$ in the no-sliding regime with respect to the full-stick solution. The value of q_F depends on the non-dimensional loading parameter η. By increasing the axial load, indeed, the tangential compliance is reduced, as predicted by equations (10) and (11). As a consequence the axial force $F_{w1,b}$ tends toward the full-stick solution $F_{w1,b}^{full-stick}$ for increasing values of axial load. However, it's worth noting that the ratio q_F: (a) doesn't reach the unit value, even for very large values of the axial load, close to the RTS of the strand (for which, however, the assumption of linearly elastic material adopted in the proposed formulation ceases to be valid), and (b) is only slightly dependent on the axial load for the particular strand under consideration (variations of q_F are in the order of 3% for axial loads ranging from zero to the RTS value).

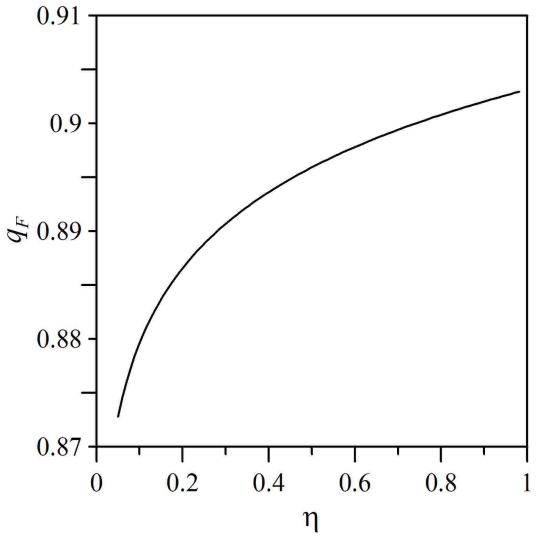

Figure 3: Ratio q_F vs. the non-dimensional axial load η.

Figure 4 shows a comparison among the moment-curvature diagrams of the strand cross section obtained with the proposed formulation, accounting for the tangential compliance of the internal contact surfaces, and those obtained by considering a full-stick initial behavior of the wires. Results are plotted for different values of the axial load parameter η in the range 0.1-0.25 (Figure 4(a)) and for different values of the friction coefficient μ in the range 0.3-0.7 (Figure 4(b)), in order to cover the interval of values typically considered in literature (e.g.: [8, 9, 14, 17]).

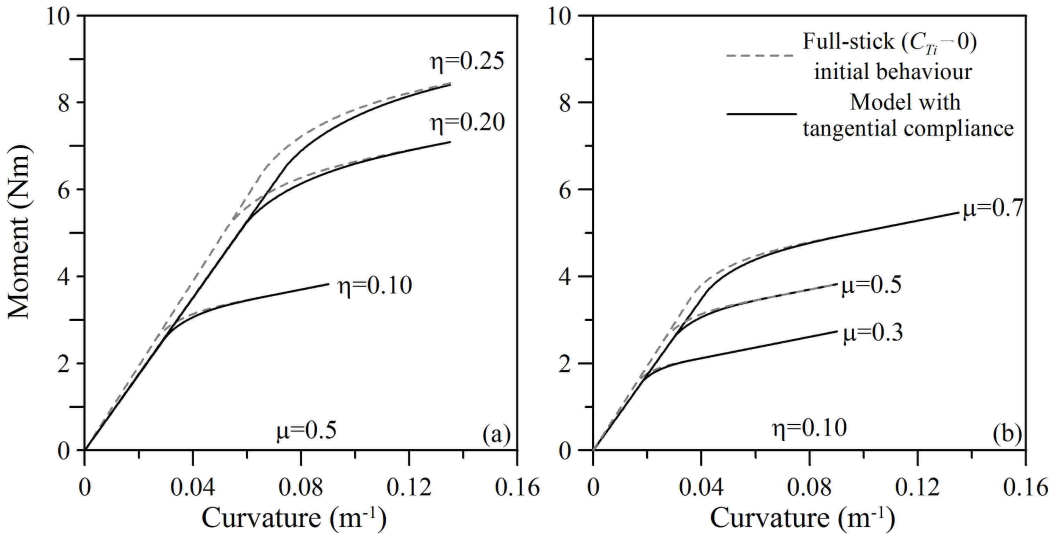

Figure 4: Moment-curvature diagrams. (a) Variation of the non-dimensional axial load η. (b) Variation of the friction coefficient μ.

The moment-curvature diagrams obtained with or without accounting for the tangential compliance mechanism are very similar, for the special strand considered in this work. In particular, the two models exhibit a similar dependency on the axial loading parameter η and on the friction coefficient μ. These parameters strongly influence the hysteretic bending behavior of metallic strands, as it has been extensively discussed e.g. in [8, 9]. The major effect of the tangential compliance between the core and the external wires is recognized in a reduction of about 10% of the value of the initial bending stiffness (i.e. the maximum bending stiffness of the strand section: $EI_{\max}$) of the cross section.

A typical experimental test setup for the characterization of the hysteretic bending behavior of metallic strands has been numerically simulated, in order to investigate the effect of the tangential contact compliance on the overall behavior of a strand specimen. A schematic representation of the numerical test setup is reported in Figure 5. The specimen is first loaded in the axial direction and then subjected to a transverse quasi-static load F. A mesh of 32 equally spaced corotational beam finite elements is adopted to represent the strand. Mesh refinements have been also considered in preliminary calculations to check the accuracy of the numerical model. A friction coefficient equal to 0.5 has been assumed in all the analyses.

Figures 6(a) and 6(b) show the load-displacement curves of the strand for a monotonically increasing vertical load and two different values of axial load, namely: η=0.1 (Figure 6(a)) and η=0.2 (Figure 6(b)). The load-displacement curves obtained both with and without considering the tangential compliance are plotted in Figures 6(a) and 6(b), together with the reference elastic solutions (plotted with red dashed lines) calculated under the full-stick ($EI_{\max}^{full-stick}$) and the full-slip ($EI_{\min}$) kinematic assumptions. The main effect of the tangential

compliance mechanism can be recognized in a reduction of the initial stiffness of the load-displacement curves, of about 10% for the slacker strand (η=0.1) and 1% in the other case (η=0.2). The influence of the tangential compliance mechanism on the specimen behavior, hence, is similar to the influence on the cross sectional response. However, a more pronounced dependency on the value of the axial load is observed for the overall specimen response than for the individual cross section behavior.

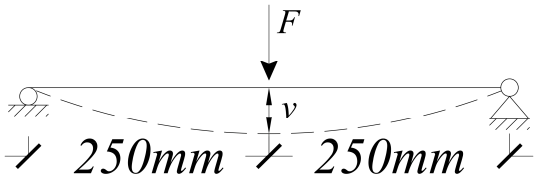

Figure 5: Structural scheme of the setup.

Additional numerical tests under cyclic vertical loading have shown that, for the special strand considered in this paper, the tangential compliance mechanism affects very slightly both the shape as well as the area of the hysteresis loops.

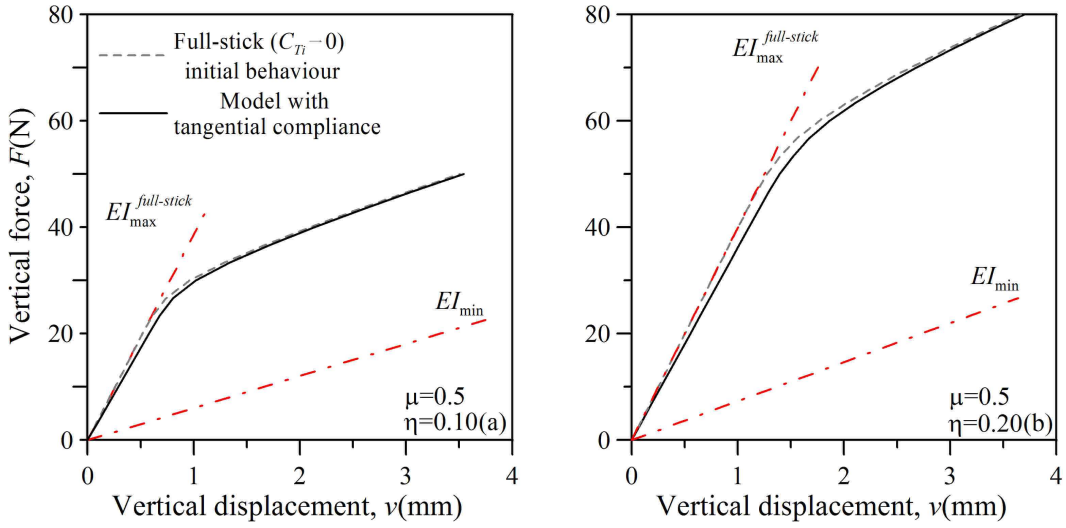

Figure 6: Bending behavior of the strand. (a) Monotonic loading. Load vs. displacement curve, μ=0.5 and η=0.10. (b) Monotonic loading. Load vs. displacement curve, μ=0.5 and η=0.20.

5 CONCLUSIONS

A new mechanical model to study the mechanical response of metallic cables undergoing a combination of axial load and planar bending has been developed for a single-layer strand. The proposed formulation is based on a detailed analysis of the internal contact conditions between the external wires and the core of the strand. Friction is modeled through the classic Amontons-Coulomb law and the elastic tangential compliance of contact patches is accounted for, aiming at extending a previous authors' model taking into account the gross sliding only. A nonlinear and non-holonomic relation between the sectional generalized stress and strains of the Euler-Bernoulli beam theory is formulated and implemented in a corotational beam element suitable for nonlinear static and dynamic analyses of flexible structures.

The proposed strand mechanical model and finite element formulation have been applied to characterize the hysteretic bending behavior of a common structural steel strand. Numerical

analyses have been carried out to show the influence of the tangential contact compliance mechanism between the external wires and the core, both on the cross sectional behavior as well as on the overall response of a strand specimen tested on a typical experimental test rig.

For the particular strand considered in this work, it is found that the tangential contact compliance mainly influence the initial bending stiffness of the strand, while it has only a small effect on the shape of the cross sectional moment-curvature diagrams and on the overall hysteretic behavior. Ongoing research is devoted to the extension of the proposed formulation to other strand geometries, including the case of multi-layer elements.

Abstract. *The paper discusses the application of a 2-node, three-dimensional (3D) beam-column finite element with an enhanced fiber cross-section model to the inelastic response analysis of concrete members. The element accounts for the local distribution of strains and stresses under the coupling of axial, flexural, shear, and torsional effects with an enriched kinematic description that accounts for the out-of-plane deformations of the cross-section. To this end the warping displacements are interpolated with the addition of a variable number of local degrees of freedom. The material response is governed by a 3D nonlinear stress-strain relation with damage that describes the degrading mechanisms of typical engineering materials under the coupling of normal and shear stresses. The element formulation is validated by comparing the numerical results with measured data from the response of two prismatic concrete beams under torsional loading and with standard beam formulations.*

1 INTRODUCTION

Beam-column finite elements are widely used for describing the inelastic response of structural members in large scale simulations, because of the optimal balance between accuracy and computational efficiency they offer.

Among the different beam finite element models *force-based* and *mixed* formulations [1, 2, 3, 4] have proven superior to the classical *displacement-based* models under large inelastic, cyclic deformations, even with the slight increase in computational cost for the element state determination. In this framework, many researchers focused their efforts on the development of an efficient, discrete *fiber cross-section model* [5, 6] for effectively capturing the multi-axial coupling of the beam stress resultants under general constitutive material relations. While classical Euler-Bernoulli beam formulations assume that plane sections remain plane and normal to the axis and are unable to capture the effect of shear and torsion, recent studies have proposed enhanced models that account for these effects [7, 8, 9, 10]. Nonetheless, no existing model appears to give a complete and realistic representation of the cross-section warping with the resulting shear stresses and strains. According to [11] existing models fail to reproduce accurately the interaction of the shear and normal stresses along the beam axis, the local response near the boundaries, and the shear lag phenomenon.

This paper extends the 2-node 3D beam-column finite element (FE) in [12] to reinforced concrete beams. The formulation by LeCorvec is based on a modified Hu-Washizu variational potential that leads to the definition of a four-field mixed formulation. With respect to the standard Hu-Washizu mixed formulation with only three independent fields, LeCorvec's formulation introduces as fourth additional field the out-of-plane displacements due to warping of the element cross-section [12]. These displacements are interpolated at two independent levels: along the axis and over the cross-section. The degrees of freedom associated with the resulting interpolation functions constitute additional independent variables of the element allowing it to capture the evolution of the warping displacements during the loading process, and the coupling between the shear and torsion with the normal stress components.

To correctly reproduce the nonlinear behavior of the cross-section, a fiber discretization is introduced. Hence, stress and strain variables are determined at each discrete fiber and then integrated over the area to obtain the generalized section quantities. To describe the damaging mechanisms typical of brittle-like engineering materials, the isotropic 3D damage model in [15] is adopted. This considers the non-symmetric response, in tension and compression, and the unilateral effect, observed during cyclic load patterns for this material type.

The proposed FE is validated by comparing the numerical results of plain concrete (PC) and reinforced concrete (RC) beams under end torque with experimental measurements and by confronting these results with those of standard FE beam models.

2 FINITE ELEMENT FORMULATION

This section summarizes the salient features of the 3D beam-column FE formulation in [12] with the description of the warping displacements for the cross section under inelastic nonlinear material response.

The FE element formulation is based on the assumption of small end node displacements and small strains, because nonlinear geometry effects are accounted for with the corotational formulation during the transformation of the nodal response variables.

Figure 1 shows the global FE reference system (O, X, Y, Z) together with the nodal displacement vector components. These are the twelve degrees of freedom (DOFs) of a standard 3D

beam-column element, that is three translations (listed in the vectors $\mathbf{u}_{I/J}$) and three rotations (listed in the vectors $\boldsymbol{\theta}_{I/J}$) at each node:

$$\mathbf{u} = \left\{\mathbf{u}_I^T \;\; \boldsymbol{\theta}_I^T \;\; \mathbf{u}_J^T \;\; \boldsymbol{\theta}_J^T\right\}^T \tag{1}$$

The corresponding nodal force components are collected in the vector:

$$\mathbf{p} = \left\{\mathbf{p}_I^T \;\; \mathbf{m}_I^T \;\; \mathbf{p}_J^T \;\; \mathbf{m}_J^T\right\}^T \tag{2}$$

with $\mathbf{p}_{I/J}$ and $\mathbf{m}_{I/J}$ being the force and moment vectors at node I/J.

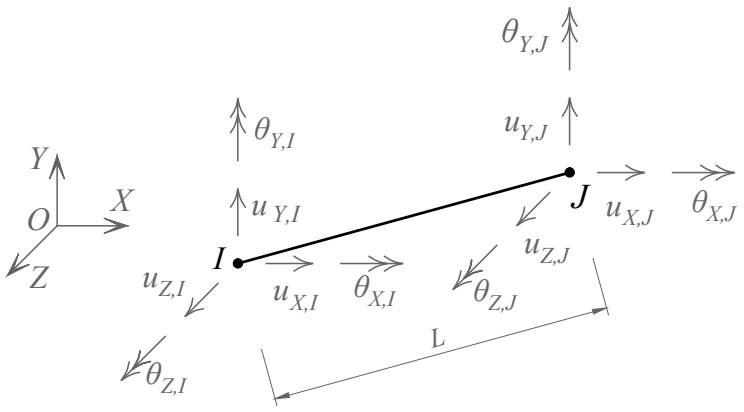

Figure 1: Global FE reference system (undeformed configuration): nodal traslation and rotation components.

By restraining the rigid body motions of the element, the basic reference system (I, x, y, z) is introduced (Figure 2), with x parallel to the axis directed from node I to node J and y and z lying in the plane of the element cross-section. Hence, the basic displacement vector $\mathbf{v}$, also called the element deformation vector, can be defined:

$$\mathbf{v} = \{u_{x,J} \quad \theta_{z,I} \quad \theta_{z,J} \quad \theta_{x,J} \quad \theta_{y,I} \quad \theta_{y,J}\}^T \tag{3}$$

where $u_{x,J}$ is the translation of node J parallel to the local axis x, $\theta_{z,I/J}$ and $\theta_{y,I/J}$ are the rotations at node I/J about the z and y–axis, respectively, and $\theta_{x,J}$ is the rotation at node J about the x–axis. The basic displacement vector $\mathbf{v}$ is obtained from the global vector $\mathbf{u}$ according to:

$$\mathbf{v} = \mathbf{a}_g\,\mathbf{u} \quad with \quad \mathbf{a}_g = \begin{bmatrix} -1 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1/L & 0 & 0 & 0 & 1 & 0 & -1/L & 0 & 0 & 0 & 0 \\ 0 & 1/L & 0 & 0 & 0 & 0 & 0 & -1/L & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & -1 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & -1/L & 0 & 1 & 0 & 0 & 0 & 1/L & 0 & 0 & 0 \\ 0 & 0 & -1/L & 0 & 0 & 0 & 0 & 0 & 1/L & 0 & 1 & 0 \end{bmatrix} \tag{4}$$

where $\mathbf{a}_g$ is the kinematic matrix and L is the undeformed element length. The basic force vector $\mathbf{q}$, corresponding to the deformation vector $\mathbf{v}$, is defined as:

$$\mathbf{q} = \{p_{x,J} \quad m_{z,I} \quad m_{z,J} \quad m_{x,J} \quad m_{y,I} \quad m_{y,J}\}^T \tag{5}$$

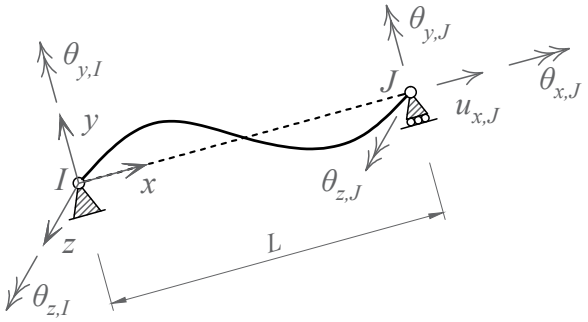

Figure 2: Basic FE reference system (deformed configuration): basic displacement components.

where $p_{x,J}$ is the force at node J in the direction of the local x–axis, $m_{z,I/J}$ and $m_{y,I/J}$ are the moments at node I/J about the z and y–axis, respectively, and $m_{x,J}$ is the moment at node J about the x–axis.

Because of the virtual work equivalence, the element stiffness matrix $\hat{\mathbf{k}}$ and the element force vector $\mathbf{p}$ in the global system can be defined through the transpose of the matrix $\mathbf{a}_g$, [2]:

$$\hat{\mathbf{k}} = \mathbf{a}_g^T \, \mathbf{f}^{-1} \, \mathbf{a}_g \qquad \text{and} \qquad \mathbf{p} = \mathbf{a}_g^T \, \mathbf{q} \tag{6}$$

where $\mathbf{f}$ is the element basic flexibility matrix, whose derivation is discussed next.

Under the assumption of the cross-section remaining rigid in plane and out of plane, the generalized section displacement vector $\mathbf{u}_s(x)$ is defined in the basic coordinate system as:

$$\mathbf{u}_s(x) = \{u(x) \quad \theta_z(x) \quad v(x) \quad \theta_x(x) \quad \theta_y(x) \quad w(x)\}^T \tag{7}$$

where $u(x)$, $v(x)$ and $w(x)$ are the translation components of the beam axis, and $\theta_x(x)$, $\theta_y(x)$ and $\theta_z(x)$ are the rotations of the cross-section (Figure 3(a)).

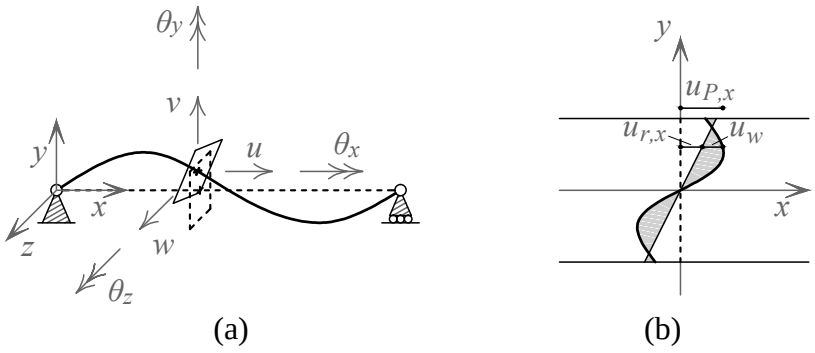

Figure 3: Cross-section rigid (a) and warping (b) displacements.

To describe the warping of the cross-section, the assumption of a rigid cross section is partially removed, by accounting for the out-of-plane deformations of the cross section, which still remains rigid in its plane. Hence, the displacement $\mathbf{u}_P(x, y, z)$ at the generic point P is expressed as the composition of the rigid part $\mathbf{u}_r(x, y, z) = \mathbf{a}_s(y, z) \, \mathbf{u}_s(x)$ and the displacement

$\mathbf{u}_w(x,y,z)$ due to the warping (Figure 3(b)):

$$\mathbf{u}_P(x,y,z) = \left\{ \begin{array}{c} u_{P,x}(x,y,z) \\ u_{P,y}(x,y,z) \\ u_{P,z}(x,y,z) \end{array} \right\} = \mathbf{a}_s(y,z)\,\mathbf{u}_s(x) + \mathbf{u}_w(x,y,z) \tag{8}$$

where $\mathbf{a}_s(y,z)$ is the compatibility operator, defined as:

$$\mathbf{a}_s(y,z) = \left[\begin{array}{cccccc} 1 & -y & 0 & 0 & z & 0 \\ 0 & 0 & 1 & -z & 0 & 0 \\ 0 & 0 & 0 & y & 0 & 1 \end{array} \right] \tag{9}$$

By applying the same operator, the strain vector is also evaluated as the sum of the rigid part $\boldsymbol{\epsilon}_r(x,y,z) = \mathbf{a}_s(y,z)\,\mathbf{e}(x)$ and that associated to the warping $\boldsymbol{\epsilon}_w(x,y,z)$:

$$\boldsymbol{\epsilon}(x,y,z) = \left\{ \begin{array}{c} \epsilon_x(x,y,z) \\ \gamma_{xy}(x,y,z) \\ \gamma_{xz}(x,y,z) \end{array} \right\} = \mathbf{a}_s(y,z)\,\mathbf{e}(x) + \boldsymbol{\epsilon}_w(x,y,z) \tag{10}$$

The generalized section deformation vector $\mathbf{e}(x)$ is:

$$\mathbf{e}(x) = \left\{ \begin{array}{c} \epsilon_G(x) \\ \chi_z(x) \\ \gamma_y(x) \\ \chi_x(x) \\ \chi_y(x) \\ \gamma_z(x) \end{array} \right\} = \left\{ \begin{array}{l} u'(x) \\ \theta'_z(x) \\ v'(x) - \theta_z(x) \\ \theta'_x(x) \\ \theta'_y(x) \\ w'(x) + \theta_y(x) \end{array} \right\} \tag{11}$$

where $\epsilon_G(x)$ is the axial strain, $\chi_z(x)$ and $\chi_y(x)$ are the curvatures, $\chi_x(x)$ the torsion rate of twist, and $\gamma_y(x)$ and $\gamma_z(x)$ the shear strains. As a consequence of the assumption that the section remains rigid in its plane, the warping displacement field has non-zero values only in the x direction, i.e.

$$\mathbf{u}_w(x,y,z) = \left\{ u_w(x,y,z) \quad 0 \quad 0 \right\}^T$$

Hence, the vector $\boldsymbol{\epsilon}_w(x,y,z)$ of the strains due to the warping displacements $u_w(x,y,z)$ becomes:

$$\boldsymbol{\epsilon}_w(x,y,z) = \left\{ \begin{array}{ccc} \frac{\partial u_w(x,y,z)}{\partial x} & \frac{\partial u_w(x,y,z)}{\partial y} & \frac{\partial u_w(x,y,z)}{\partial z} \end{array} \right\}^T \tag{12}$$

The stress components that are work conjugate with the strain quantities in $\boldsymbol{\epsilon}(x,y,z)$ are collected in the stress vector $\boldsymbol{\sigma}(x,y,z) = \left\{ \sigma_x(x,y,z) \quad \tau_{xy}(x,y,z) \quad \tau_{xz}(x,y,z) \right\}^T$, where σ_x is the normal stress along the beam axis direction, and τ_{xy} and τ_{xz} are the shear stresses in the plane of the cross-section parallel to the y and z–axis, respectively. With the virtual work equivalence the generalized stress vector $\mathbf{s}(x)$ is:

$$\mathbf{s}(x) = \int_A \mathbf{a}_s^T(y,z)\,\boldsymbol{\sigma}(x,y,z)\,dA = \left\{ \begin{array}{c} N(x) \\ M_z(x) \\ T_y(x) \\ M_x(x) \\ M_y(x) \\ T_z(x) \end{array} \right\} \tag{13}$$

where A is the cross-section area, $N(x)$ the axial stress, $M_z(x)$ and $M_y(x)$ are the bending moments, $M_x(x)$ the torsional moment, and $T_y(x)$ and $T_z(x)$ the generalized shear stresses.

From the element equilibrium in the undeformed configuration the stress vector $\mathbf{s}(x)$ can be expressed in terms the basic element force vector $\mathbf{q}$:

$$\mathbf{s}(x) = \mathbf{b}(x)\,\mathbf{q} + \mathbf{s}_p(x) \quad , \quad \mathbf{b}(x) = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & \frac{x}{L}-1 & \frac{x}{L} & 0 & 0 & 0 \\ 0 & -\frac{1}{L} & -\frac{1}{L} & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{x}{L}-1 & \frac{x}{L} \\ 0 & 0 & 0 & 0 & \frac{1}{L} & \frac{1}{L} \end{bmatrix} \tag{14}$$

where $\mathbf{b}(x)$ is the equilibrium matrix and $\mathbf{s}_p(x)$ the generalized section stresses under element loading. In addition to these forces, the force field $p_w(x, y, z)$ is work conjugate with the warping displacement $u_w(x, y, z)$ and arises at cross-sections with constrained warping displacements. In the element formulation in [12] the warping displacements u_w are treated as internal DOFs that are condensed out during the element state determination, as described in the next section. Consequently, only the standard twelve DOFs in (1) are associated with the global DOFs of the structural model.

2.1 Warping displacement interpolation

The study in [12] interpolates the warping displacement field $u_w(x, y, z)$ along the element axis x independently from the interpolation over the cross-section. The Gauss-Lobatto integration rule is used along the element axis using n_w points and 1D Lagrange polynomials $\mathrm{N}_i(x)$. At each Gauss-Lobatto point x_i, the warping displacements are interpolated over the cross-section by subdividing it into several rectangular patches with a regular distribution of interpolation points in each, for a total of s_w points (Figure 4). This approach defines a set of m_w 2D interpolation functions $\mathrm{M}_j(y, z)$ for the warping DOFs.

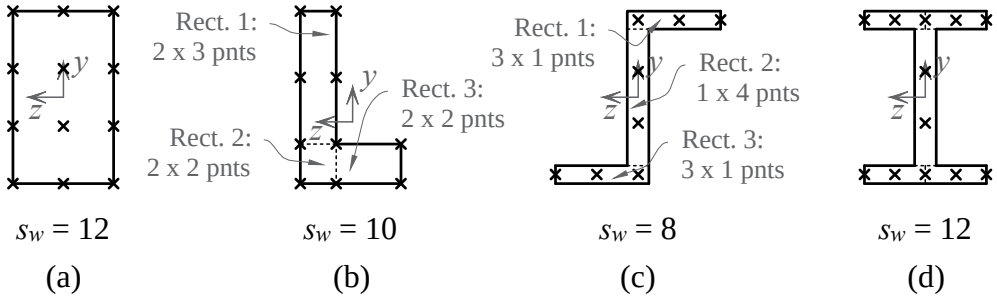

Figure 4: Warping interpolation points over the element cross-section.

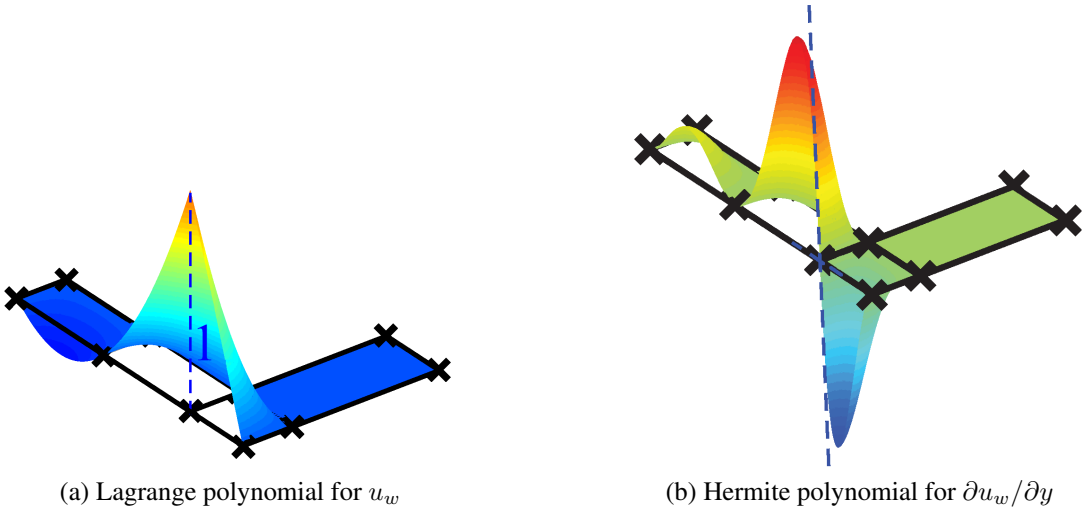
This study explores the use of Hermite polynomials for the warping displacements in addition to the Lagrange polynomials used in [12]. For the Lagrange polynomials only one internal DOF is required at each integration point of the warping displacement u_w (Figure 5(a)) and the total number m_w of warping DOFs is equal to the number s_w of integration points. In contrast, Hermite polynomials required three internal DOFs at each integration point, one for the warping displacement u_w, and two for the derivatives $\partial u_w/\partial y$ and $\partial u_w/\partial z$ (Figure 5(b)). In this

case the total number m_w of warping DOFs is equal to three times the number s_w of integration points, $m_w = 3\,s_w$.

Henceforth, $u_{w,ij}$ denotes the generic j-th warping DOF at section x_i, coinciding with the displacements u_w for Lagrange polynomials, and with the displacements u_w and their derivatives for Hermite polynomials:

$$\begin{aligned} \{u_{w,1}, \quad u_{w,2}, \quad u_{w,3}, \ldots\} &= \{u_w^{pnt\,1}, \quad u_w^{pnt\,2}, \quad u_w^{pnt\,3}, \ldots\} \quad Lagrange \\ \{u_{w,1}, \quad u_{w,2}, \quad u_{w,3}, \ldots\} &= \{u_w^{pnt\,1}, \quad \tfrac{\partial u_w^{pnt\,1}}{\partial y}, \quad \tfrac{\partial u_w^{pnt\,1}}{\partial z}, \ldots\} \quad Hermite \end{aligned} \tag{15}$$



(a) Lagrange polynomial for u_w (b) Hermite polynomial for $\partial u_w/\partial y$

Figure 5: Example of polynomial interpolation function in a cross-section composed by a set of rectangular portions: L-shaped section of Figure 4(b), $m_w = 10$ for Lagrange and $m_w = 30$ for Hermite.

The interpolation of the warping displacement field $u_w(x, y, z)$ thus is:

$$u_w(x, y, z) = \sum_{i=1}^{n_w} \mathrm{N}_i(x)\, u_{w,i}(x_i, y, z) = \sum_{i=1}^{n_w} \mathrm{N}_i(x)\, \mathbf{M}(y, z)\, \mathbf{u}_{w,i} \tag{16}$$

with the following expression for the interpolation of $u_{w,i}(x_i, y, z)$ at section i:

$$u_{w,i}(x_i, y, z) = \sum_{j=1}^{m_w} \mathrm{M}_j(y, z)\, u_{w,ij} = \mathbf{M}(y, z)\, \mathbf{u}_{w,i} \tag{17}$$

$\mathbf{u}_{w,i}$ is a column vector with all m_w warping DOFs $u_{w,ij}$ at section i (following the order in Equation (15)) and $\mathbf{M}(y, z)$ is a row vector with all m_w shape functions $M_j(y, z)$ defined over the cross-section.

It is important to point out the following difference between Lagrange and Hermite polynomials. Because for the Lagrange polynomials all warping DOFs correspond to warping displacement values the condition of warping restraint $u_{w,ij} = 0$ can be applied to each polynomial separately, so that even a single point or a specific portion of the cross-section can be restrained. In contrast, for the Hermite polynomials some of the warping DOFs are the derivatives of the warping displacement field in the cross-section. This requires the restraint of all displacements of the particular cross-section at the same time, thus ensuring that $u_w = \partial u_w/\partial y = \partial u_w/\partial z = 0$ is satisfied on the cross-section.

The vector $\mathbf{p}_{w,i}$ collecting the warping forces $p_{w,i}$ at the points located on the i-th section can be defined, which is work conjugated with $\mathbf{u}_{w,i}$.

2.2 Element variational formulation

This section describes the main aspects of the element formulation and focuses on the role played by the warping DOFs in the governing equations.

The equations governing the element state determination are derived on the basis of a modified Hu-Wahizu variational principle, depending on the four independent fields $\mathbf{u}_s(x)$, $\mathbf{e}(x)$, $\boldsymbol{\sigma}(x,y,z)$ and $u_w(x,y,z)$ [12]:

$$\Pi(\mathbf{u}_s, \mathbf{e}, \boldsymbol{\sigma}, u_w) = \int_V \boldsymbol{\sigma}^T \mathbf{a}_s \left[\mathbf{e}(\mathbf{u}_s) - \mathbf{e}\right] dV + \int_V W(\mathbf{e}, \boldsymbol{\epsilon}_w)\, dV - \mathbf{u}^T \mathbf{p} - \int_0^L \mathbf{u}_s^T \mathbf{p}_s\, dx \quad (18)$$

where $W(\mathbf{e}, \boldsymbol{\epsilon}_w)$ is the internal potential energy and $\mathbf{p}_s$ denotes the loads along the element axis. The stationarity of Π with respect to the four independent fields gives the following governing equations:

Stationarity with respect to:	Governing equation:	
$\mathbf{u}_s(x)$	$\mathbf{a}_g^T \mathbf{q} = \mathbf{p} + \mathbf{p}_{rp}$	(19a)
$\mathbf{e}(x)$	$\boldsymbol{\sigma}(x,y,z) = \hat{\boldsymbol{\sigma}}[\boldsymbol{\epsilon}(x,y,z)]$	(19b)
$\boldsymbol{\sigma}(x,y,z)$	$\mathbf{v} = \int_0^L \mathbf{b}^T(x)\, \mathbf{e}(x)\, dx$	(19c)
$u_w(x,y,z)$	$\mathbf{p}_{w,i} = \int_0^L \frac{\partial \mathrm{N}_i}{\partial x} \mathbf{s}_w^x\, dx + \int_0^L \mathrm{N}_i\, \mathbf{s}_w^{yz}\, dx$	(19d)

The first three (19a), (19b) and (19c) are the equations of the standard three-field mixed formulation [4], and govern the element equilibrium, the material constitutive law and the element compatibility, respectively. The vector $\mathbf{p}_{rp}$ collects the nodal forces under element loading. Equation (19d), represents the section equilibrium equation under warping displacements. The stresses $\mathbf{s}_w^x$ and $\mathbf{s}_w^{yz}$ are the generalized stresses due to section warping, as defined by the integral of the material stresses $\boldsymbol{\sigma}(x,y,z)$ over the cross-section:

$$\mathbf{s}_w(x) = \left\{ \begin{array}{c} \mathbf{s}_w^x(x) \\ \mathbf{s}_w^{yz}(x) \end{array} \right\} = \left\{ \begin{array}{c} \int_A \left[\mathbf{a}_w^x(y,z)\right]^T \boldsymbol{\sigma}(x,y,z)\, dA \\ \int_A \left[\mathbf{a}_w^{yz}(y,z)\right]^T \boldsymbol{\sigma}(x,y,z)\, dA \end{array} \right\} \quad (20)$$

with $\mathbf{a}_w^x(y,z)$, $\mathbf{a}_w^{yz}(y,z)$ being $3 \times m_w$ matrices of the following form:

$$\mathbf{a}_w^x(y,z) = \left[\begin{array}{c} \mathbf{M}(y,z) \\ \mathbf{0} \\ \mathbf{0} \end{array} \right] \quad , \quad \mathbf{a}_w^{yz}(y,z) = \left[\begin{array}{c} \mathbf{0} \\ \frac{\partial \mathbf{M}(y,z)}{\partial y} \\ \frac{\partial \mathbf{M}(y,z)}{\partial z} \end{array} \right] \quad (21)$$

The nonlinear system of equations (19) are solved by iteration of their linearized form [12].

3 CORRELATION STUDIES

This section discusses the correlation study of two specimens for validating the 3d beam formulation. The Matlab toolbox FEDEASLab [16] is used for investigating the capability of the

model to represent the damage evolution of frame members when relevant warping deformations arise. To this end, two different prismatic beams under end torsional loads are considered, from the experimental tests of plain concrete specimens by [17] and of RC specimens by [18]. In this framework, advantages and disadvantages of the use of Hermite polynomials vs. Lagrange polynomials for the warping interpolation functions are discussed.

The Gauss-Lobatto integration rule is adopted for the integrals along the element axis together with a fiber discretization of the cross-section using the mid-point rule [6]. The nonlinear material relation of the following section is used for each concrete fiber and the classical J2 plasticity model is used for the steel bars.

3.1 Damage model

In this study the constitutive behavior of concrete is described with the damage material model in [15]. The model uses a scalar damage variable D to define the relation between the strain tensor $\mathbf{E}$ and the stress tensor $\mathbf{\Sigma}$:

$$\mathbf{E} = \frac{(1+\nu)\mathbf{\Sigma} - \nu\,\mathrm{tr}(\mathbf{\Sigma})\,\mathbf{I}}{E(1-D)} \tag{22}$$

where E in the material Young modulus and ν the Poisson ratio, and $\mathbf{I}$ is the second order identity tensor. The damage variable D, bounded in the range $[0 \quad 1]$, where $D = 0$ correponds to initial undamaged state and $D = 1$ to the complete degraded state, is a function of a single variable Y, which is the combination of two strain measures Y_t and Y_c for cracking (tensile state) and crushing (compressive state), respectively. The combination gives:

$$Y = r\,Y_t + (1-r)\;Y_c \qquad \text{with} \quad r = \frac{\sum \left\langle \hat{\bar{\sigma}}_i \right\rangle_+}{\sum |\hat{\bar{\sigma}}_i|} \in [0;1] \tag{23}$$

where $\hat{\bar{\sigma}}_i$ are the principal effective stresses.

The evolution law for D is defined by the following exponential relation:

$$D = 1 - \frac{Y_0(1-A)}{Y} - A\,e^{-B(Y-Y_0)} \tag{24}$$

where $Y_0 = r\,\epsilon_{0,t} + (1-r)\;\epsilon_{0,c}$ is the initial threshold for Y and A and B are material parameters, also defined from the combination of the tensile and compressive parameters, $A_{t/c}$ and $B_{t/c}$, respectively according to:

$$A = A_t\left(2\,r^2\,(1-2k) - r\,(1-4k)\right) + A_c\left(2\,r^2 - 3\,r + 1\right) \tag{25}$$

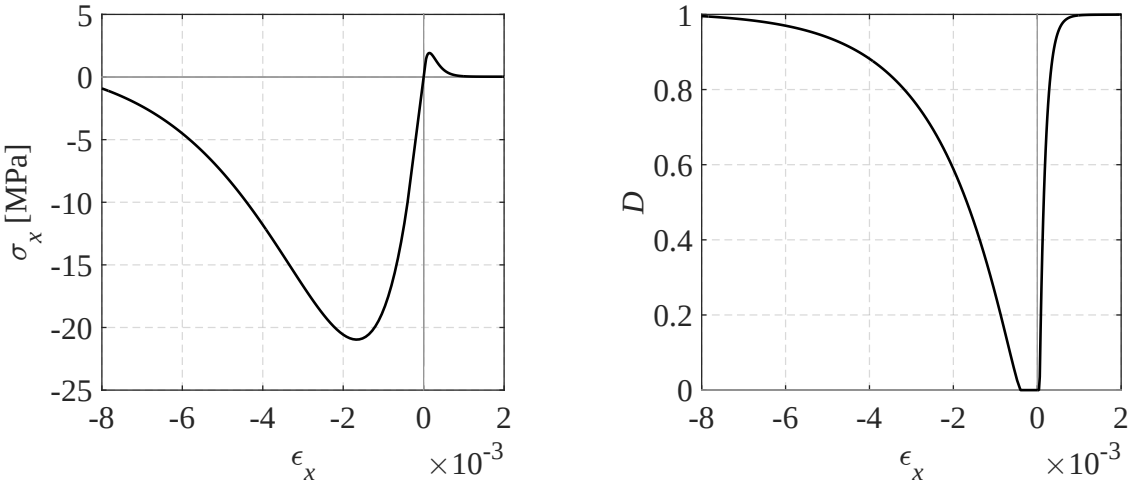
$$B = r^q B_t + (1-r^q)\,B_c \qquad \text{with} \quad q = r^2 - 2r + 2 \tag{26}$$

k is a parameter for calibrating the asymptotic stress value at large shear deformations and is set equal to 0.7 throughout the following simulations.

Figure 6(a) and 6(b) shows the resulting stress-strain constitutive relation and the damage evolution law with the material parameters in the first row of Table 1.

3.2 Plain concrete and RC beams subjected to end torsional loads

Two prismatic beams under pure torsion are used for the validation of the 3d beam formulation. Both specimens have a total length of 160 cm, and are divided into three parts: two end



(a) Uniaxial stress-strain relation. (b) Damage evolution law.

Figure 6: Damage constitutive law for concrete.

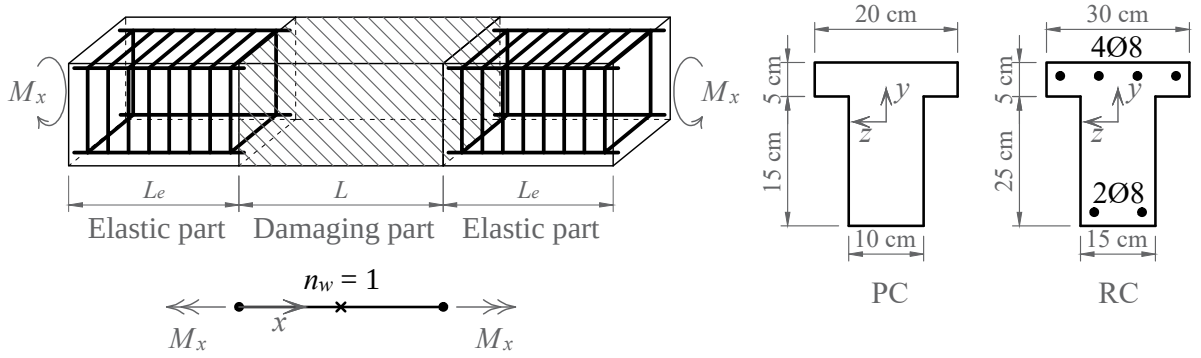


Figure 7: Beams subjected to end torsional loads: specimens geometry.

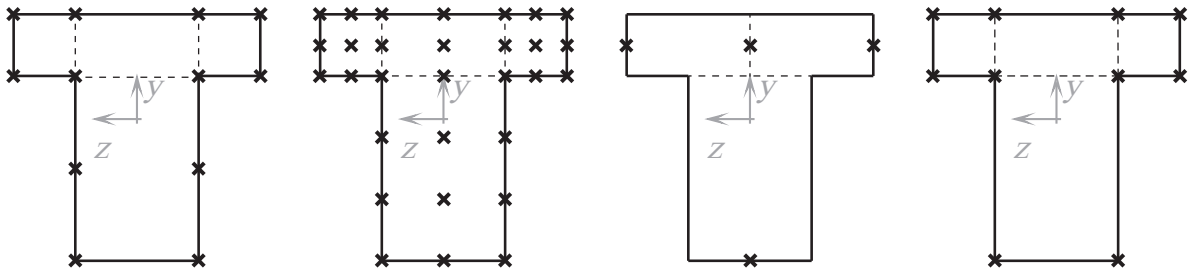
regions of length L_e, reinforced so as to remain elastic, and a middle part of length L undergoing cracking and damage (Figure 7). For pure torsion a torsional moment M_x is applied at both ends with a particular arrangement that allows the beam cross-sections to undergo warping.

The plain concrete (PC) and the reinforced concrete (RC) cross-section in Figure 7 are considered for the central damaging part of the beam. The geometrical parameters are: $L = 60$ cm for the former one ($L_e = 50$ cm) and $L = 100$ cm for the latter one ($L_e = 30$ cm). Only the middle part is modeled in the numerical analysis, using one FE with one warping interpolation point located along the axis, $n_w = 1$ (Figure 7), as a uniform warping distribution is expected in this direction. Three Gauss-Lobatto quadrature points are used for the integration along the FE with a uniform fiber discretization made of 86 fibers at each point. The material parameters are given in Table 1. Modulus E is not specified in the two reference papers, thus it is adjusted to reproduce the measured initial stiffness. For the steel bars, which are modeled as additional fibers, the following material parameters are used: Young modulus $E = 210000\,\mathrm{MPa}$, Poisson coefficient $\nu = 0.3$, yield stress $f_y = 560\,\mathrm{MPa}$, isotropic hardening $H_i = 0.001\,E$ and kinematic hardening $H_k = 0.01\,E$.

Four different warping DOFs distributions in Figure 8 are considered. The first two adopt Lagrange polynomials, L1(12) and L2(30) and the other two use Hermite polynomials, H1(12) and H2(30) with the total number of internal DOFs in parentheses.

	E [MPa]	ν	$\varepsilon_{0,t}$	A_t	B_t	$\varepsilon_{0,c}$	A_c	B_c
PC	25 000	0.20	0.000055	0.98	7 000	0.000200	1.30	600
RC	30 000	0.20	0.000100	0.98	11 000	0.000200	1.50	600

Table 1: Beams subjected to end torsional loads: material parameters for concrete.



(a) L1(12) (b) L2(30) (c) H1(12) (d) H2(30)

Figure 8: Warping DOFs distribution over the cross-section of the T-shaped beams ("L" = Lagrange interpolation functions, "H" = Hermite interpolation functions and the number in the parentheses indicates the total number m_w of warping DOFs).

Figure 9(a) compares the global response for the four warping distributions with the experimental results for the plain concrete beam. The H2(30) model gives the best solution, since it adopts cubic interpolation functions in the y and z direction. The L2(30) model uses the same number of warping DOFs and, although it provides parabolic interpolation functions (cubic only in the y direction for the web), it gives a solution that agrees very well with the solution of the H2(30) model. The L1(12) model with linear interpolation functions, slightly overestimates the element strength, with a significantly smaller number of warping DOFs. Finally, the H1(12) model, which uses the same number of warping DOFs with linear interpolation functions as the L1(12) model, underestimates both the stiffness and the strength of the element. These results lead to the conclusion that Lagrange polynomials are a good compromise between accuracy and computational efficiency. In fact, with a small number of warping DOFs these interpolation functions give satisfactory solutions, whereas for the Hermite polynomials high order interpolation polynomials are required over the cross section. For sections composed of thin rectangular segments, as is the case for the commercial steel profiles, linear Lagrange polynomial prove computationally superior (see [12]) to the Hermite polynomials which require many warping DOFs for good results.

Figure 9(b) compares the results of the H2(30) model with the experimental results in [17] and with the analytical results of the same study under the assumption of a rigid cross-section. The response under the assumption of a rigid cross-section results from a value of $J = 6\,774\,\mathrm{cm}^4$ for the polar moment of area based on the semi-analytical solution with Fourier series.

Figure 9(b) shows that the rigid section assumption overestimates the peak load, since the damage distribution over the cross-section is not captured correctly. In fact, Figure 10 shows that the distribution of damage variable D is similar to that for a circular section where warping is not possible. Instead, in the presence of warping the damage distribution is much more diffused over the whole cross-section. Figure 11 shows the γ_{xy} distribution. Note that the section warping gives rise to parabolic distributions of the shear strains γ_{xy} and γ_{xz} over the section. In contrast, the rigid section assumption is associated with in a linear distribution of

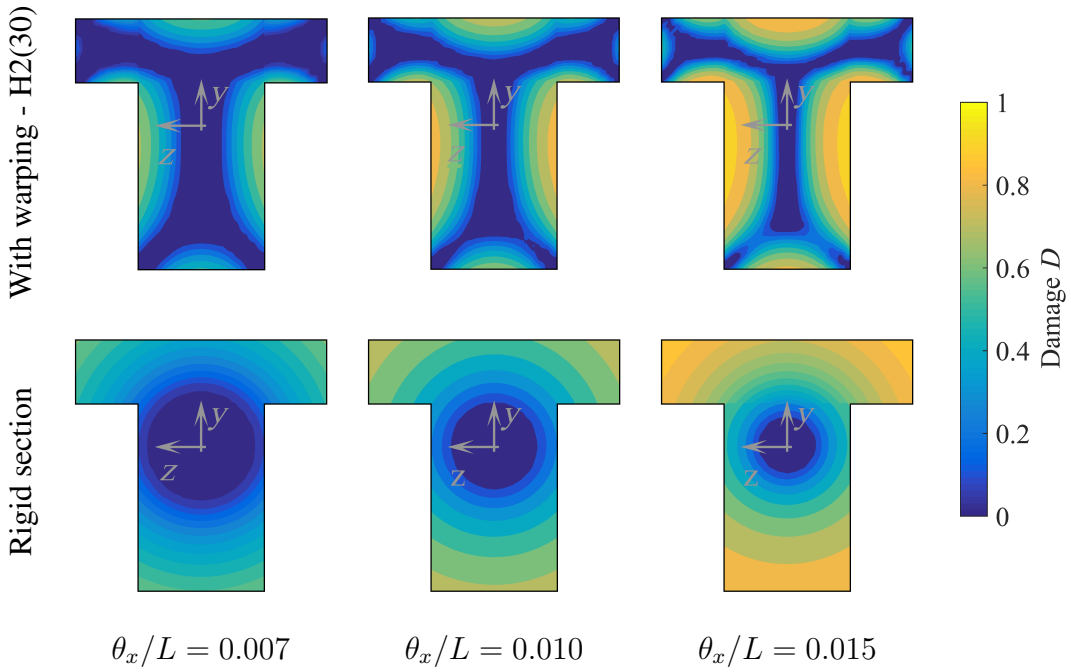

Figure 10: Evolution of the damage over the plain concrete T-shaped cross-section with and without warping.

these strains in the y and z direction.

Similar observations result for the RC beam whose global response is shown in Figure 12. The response under the assumption of a rigid cross-section results from a value of $J = 32\,642\,\mathrm{cm}^4$ for the polar moment of area based on the semi-analytical solution with Fourier series. The response of the plain concrete beam with the H2(30) model is superimposed on the same figure for contrast. The comparison shows that the reinforcing bars increase the member strength slightly under high values of torsional deformation, when the concrete is completely damaged. The experimental response shows greater strength under intermediate deformations, as the beam transitions from the uncracked to the fully cracked state, but this transitory behavior

due to rough cracks and dowel action is not accounted for in the present numerical model.

4 CONCLUSIONS

- The paper extends an existing 3d enhanced fiber beam element formulation with warping degrees of freedom to the analysis of concrete beams under torsion with warping by incorporating a constitutive material law with damage.
- Two examples demonstrate the capabilities of the element for describing the inelastic response of plain concrete and RC members under torque, as well as the resulting shear strain-stress and damage distributions over the cross-section.
- The numerical analyses show the importance of the interaction between the warping deformations and the damage progression. In fact, the standard elements, that account for the torsional effects in a simplified way, give unrealistic results and overestimate both the strength and the ductility of the structure.
- The 3d enhanced fiber beam element proves to be robust and accurate and has significantly lower computational cost than shell and brick finite elements, while delivering results of excellent accuracy for the local response of the structural members.

Singularly Perturbed Problems in Mechanics (some fundamental aspects of designing and computing)

Lyudmila K.Kuzmina
KNRTU - KAI
RUSSIA
Lyudmila.Kuzmina@kpfu.ru

Abstract. It is important study, that is concerned with the development of the concepts and methods of classical stability theory in reference to the problems of designing and computing for singularly perturbed class systems , generated by engineering practice. The various aspects of complex systems dynamics are considered. Methods of the modelling and analysis on the generalized methodology base, coupling the stability theory ideas and asymptotic theory manners, are elaborated. Non-traditional, extended approach, formed on A.M.Lyapunov's theory methods, on brilliant ideas of N.G.Chetayev, P.A.Kuzmin, V.V. Rumyantsev, K.P.Persidskiy, is worked out. It gives universal tool that makes it possible to come near to the solving of fundamental problems in general modelling theory, in designing/computing. The effective algorithm of engineering level is constructed, which is perspective for multidisciplinary systems. Besides all investigated objects are interpreted from unified positions as singular ones; effectual non-traditional technology of modelling, that uses *principally non-linear approach*, is established; the simple schemes of *decomposition of original systems (models) and of dynamic properties* are worked out; *the generalization of the reduction principle,* well-known in stability theory, is got for general qualitative analysis. This manner is permitting to construct the hierarchical sequence of simplified systems (and models) as comparison ones; to determine the conditions of the qualitative equivalence between original and shortened systems; to find the areas of their acceptability for analytical or computer- analytical analysis in designing of engineering objects.

Keywords: Complex Systems, Stability Theory, Singularity, Modelling.

1 INTRODUCTION

The first fundamental rigorous results in this direction were obtained by H.Poincare and by A.M.Lyapunov. In classical works of A.M.Lyapunov the comparison method (general method of qualitative analysis) was developed with the strong justification for the solving of stability problems. This method led to the reduction principle, well-known one in stability theory (A.M.Lyapunov, K.P.Persidskiy,…), and to the comparison principle (R.Bellman-V.Matrosov).

There is the direct methodological connection between stability theory and singular perturbations theory (I.S.Gradstein, N.G.Chetayev); between modelling problems and parametric stability theory (N.G.Chetayev, P.A.Kuzmin). With reference to Mechanics problems, formulated here, it leads to the singularly perturbed problems, with various singularities types, with specific critical cases. This research is formed on accepted here basic proposition about global, in-depth fundamental, connection between the singularly perturbed problems (and modelling problems in Mechanics) and the stability methods of Lyapunov's theory. Such tenet is ascending to well-known stability postulate (N.G.Chetayev), and singularity postulate (L.K.Kuzmina), with the extending statement about stability with parametric perturbations on singular case. All original objects may be treated from unified

view point of systems of singularly perturbed class. The object state may be described by the equations with small (or big) parameters. The original mathematical model (as example, in Lagrange's form) may be represented in standard form, as singular model, with small parameters in different powers. For this it is necessary to construct the corresponding non-linear, non-singular, evenly-regular transformation of variables. It is postulated (L.K.Kuzmina), that such suitable transformation exists always, and it may be constructed by special, non-formal manners. Besides the original dynamic problems are solved as singular ones; shortened (approximate) systems are introduced as subsystems of *s*-level (*s*-systems); *reduced models are obtained as asymptotic s-models*. Here these *s*-systems are also singularly perturbed ones. It is non-traditional approach, combining the methods of stability theory and perturbations theory that allows to come near to the solving fundamental problem of modelling ,designing, computing in Mechanics via understanding it as problem of singularly perturbed class.

Following to ideas of N.G.Chetayev's, in accordance with Lyapunov's methods, the singular problems may be solved (stability, proximity, optimality, quickness,…) both for non-critical and for critical cases; with simple and multiple roots;… Also for singular systems with the peculiarities (critical spectrums) the reduction conditions may be determined. In these cases the direct use of known results of singular perturbations theory (A.N.Tikhonov, A.Naifeh,…) is non-suitable: eigen-values of corresponding matrices are zero- and imaginary ones. Mechanical systems, modelling the technical objects, are "quasi-Tikhonov's systems" (N.N.Moiseev). *Therefore special, novel, manners are necessary*. Methods, based on Lyapunov's methodology, Chetayev's ideas, elaborated here, give powerful tool; bring new interesting results, perspective both for perturbations theory (singular problems in specific, critical cases are solvable) and for applications to Mechanics, for general modelling theory.

2 INITIAL GENERAL PRINCIPLES OF METHODOLOGY

It is well known [1-16], many applied investigations lead to the mathematical problems, having important general features: the reduction of the order of the differential equations, the loss of continuity, boundary condition. We shall call the singular systems such ones, when the transition to the reduced system is accompanied by the lowering of the model order, with the structural change. For these systems the initial mathematical model may be presented in standard form of system with the singular perturbations. It enables to consider the original objects on typical scheme, to construct by regular manners the "idealized" mechanical-mathematical models, that are interesting for engineering applications, to get strict conditions of their acceptability in dynamics.

For singularly perturbed objects a motion consists of components of various multi-scale classes, from fast to slow, and their differential equations (mathematical models) can be led to the form of equations with small parameters before higher derivatives. Therefore in practice for analysis of such systems the reduced models of lower order are being used as working models. Let the differential equations of the perturbed motion of considered system can be led to a form (let consider the systems with the steady states set)

$$M(m)\frac{dy}{dt} = Y(t, m, y) \tag{1}$$

where $y = \|z, x\|^T$, z, x are m-, n-dimensional vectors; $m > 0$ is a small dimensionless parameter; $M(m) = \|M_{i,j}(m)\|$; $Y(t,m,y) = \|Z(t,m,y); P(m)x + X(t,m,y)\|^T$; $P(m) = \|P_{i,j}(m)\|$;

$M_{i,j}$, $P_{i,j}$ are submatrices of the appropriate sizes; $Z(t, m, y)$, $X(t, m, y)$ are non-linear vector-functions, holomorphic (in appropriate domain) on the totality of variables z, x, in which coefficients are continuous, limited functions of t, m; $Z(t, m, z, 0)= 0$, $X(t, m, z, 0)= 0$; $M_{i,j}(m) = m^{a_i} I$, $0 \le a_i \le r$; I are identity matrices. We shall be able to consider the critical cases of system (1), where z are critical variables [1]. Taking into consideration in (1) only members containing m in power not more than s, $s < r$, we shall receive the shortened approximate system of type

$$M_s(m)\frac{dy}{dt} = Y_s(t, m, y) \tag{2}$$

We shall call (2) the shortened system of s-level, s-system (s-approximation on m). For singularly perturbed systems that are considered here, the order of system (2) is lower than order of full system (1). In applications to mechanics this shortened system leads to the reduced model as the asymptotic model of s-level. From the point of view of mechanics a transition to the reduced model is accompanied by a decrease of freedom degrees number. The system (2) is system of differential-algebraic equations.

We shall be able to obtain the sequence of asymptotic models (as designing-basic models) in mechanics, corresponding the sequence of shortened s-systems (s=0,1,2,…r-1). The following problem is important both for the theory and applications: in which cases and under what conditions it is possible to reduce the system (1)analysis to shortened s-system? The similar problem for equations with small parameter under higher derivatives was considered by many authors [2-8]. We shall show the solving of some concrete problems of mechanics on examples of systems with big and small papameters, that lead to particular cases of the system (1) of special class, that are not embraced by already known fundamental results. This methodology allows to realize the parallel computing in engineering for original very complex system.

3 MECHANICAL SYSTEMS WITH NONRIGID ELEMENTS

As an example of such technical/mechanical system we shall consider the systems of gyrostabilization, modelling ones as mechanical (or electromechanical) systems with controlling gyroscopic elements. Here there is a critical case of zero roots. We shall solve a stability problem of the steady motion for such system, supposing that the elements of the system are not absolutely rigid (we neglect the mass of elastic elements). Differential equations of perturbed motion we shall accept in a form of Lagrange's equations (as in [5, 15])

$$\frac{d}{dt} a\dot{q}_M + (b+g)\dot{q}_M + cq_M = Q''_M, \quad \frac{dq_M}{dt} = \dot{q}_M \tag{3}$$

Here $q_M = \|q_1, q_2, q_3, q_4\|^T$ is n - dimensional vector of mechanical generalized coordinates, where q_1 is l-dimensional vector of the gyroscopes precessions angles; q_2 is (m-l)-dimensional vector of angles deviations of own rotations of gyroscopes from their values in steady motion; q_3 is (s-m)-dimensional vector of stabilization angles, s=m+l; q_4 is (n-s)-dimensional vector of elastic elements deformations; a, b, g are square $n\times n$ - matrices of forms of the system kinetic energy, dissipative function of friction forces, gyroscopic coefficients accordingly; $c = \|c_{i,j}\|$, $b = \|b_{i,j}\|$ (i, j=1,...,4), c_{ij} and b_{ij} are submatrices of an appropriate sizes; b_{44} is square (n-s)×(n-s) -matrix of dissipative

function of internal friction forces in material of elastic bodies; c_{44} is square $(n\text{-}s)\times(n\text{-}s)$ -matrix, corresponding to potential energy of elasticity forces.

We assume that all functions in (3) are holomorphic (on the totality of their variables) in certain area.

For solving of this problem (and choosing of a reduced model) we shall lead equations (3) to a form (1) with singular perturbations. For this, first, we must introduce in equations (3) a small parameter, using physical considerations. We suppose, that the elements of the considered systems are of a sufficiently high rigidity and according to that $c_{44} = c_{44}^* / m^2$, $b_{44} = b_{44}^* / m$, where $m>0$ is a small parameter. Now, using the constructed transformation of variables

$$z = \|a_1, a_2\|^T q_M + \|b_1^0 + g_1^0,\ b_2^0 + g_2^0\|^T q_M,\ k_1 = \|a_1, a_2, a_3\|^T q_M,\quad k_2 = a_4 q_M,\quad q_j = q_j,\quad (j = 1, 4)$$

where a_i, b_i, g_i (i = 1,…,4) are submatrices of matrices a, b, g correspondingly, we shall lead equations (3) to the singularly perturbed form. This transformation is the non-linear, non-singular under condition that $\left|b_{i,j}^0 + g_{i,j}^0\right|_{i=1,2}^{j=2,3} \neq 0$, evenly regular [6], not changing the statement of the stability problem. System (3) in new variables has a form (1)

$$\frac{dz}{dt} = Z(t, m, z, x), \qquad M(m)\frac{dx}{dt} = P(m) + X(t, m, z, x) \tag{4}$$

where $x = \|x_1, x_2, x_3\|^T$, $x_1 = \|k_1, q_1\|^T$, $x_2 = k_2$, $x_3 = q_4$; $a_1 = 0$, $a_2 = 2$, $a_3 = 0$; $P_{2i}(m) = mP'_{2i}(m)$ (i=1,2).

The characteristic equation has m zero-roots. Other roots can be found from the equation $d(l, m)=0$. We assume the shortened system of 0-level (degenerated system) as an approximate one for a system (4), marking it (4′) without writing. In old variables it is the system

$$\frac{d}{dt}a^* q + (b^* + g^*)q + c^* q = Q^*,\quad \frac{dq}{dt} = q \tag{5}$$

where $q = \|q_1, q_2, q_3\|^T$ is s-dimensional vector of generalized coordinates, describing the state of an absolutely rigid system; a^*, b^*, c^*, g^* are $s\times s$-matrices of absolutely rigid system.

The equation (5) describes a motion of an idealized model of mechanical system. This model corresponds to an approximate system (4′) of 0-level. We shall call it a “limit model”. A problem: in what conditions a transition from the initial model (3) to its idealized model (to absolutely rigid system) is possible in qualitative analysis, designing, computing? Using methods of stability theory [1, 2], combined with the singular perturbations methods [7,8] and introducing the differential equations for deviations that respond to non-critical (basic) variables x, we can find out the acceptability conditions for transition validity from system (4) to the system (4′) in concrete dynamical problems. After returning to old variables, taking into account the properties of the considered mechanical system, we receive the corresponding statements.

3.1 Stability problem

When the stability property for reduced model (5) will be ensuring same property for original (full) model (3)?

Theorem 1. If $\left|b_{i,j}^0 + g_{i,j}^0\right|_{i=1,2}^{j=2,3} \neq 0$, $\left|c_{31}^0\right| \neq 0$ and all roots (except m zero roots) of characteristic equation of reduced system (5) have negative real parts, then with sufficiently small values of μ (sufficiently high rigidity of the system elements) the zero solution stability of the full system will be succeeding from the zero solution stability of reduced system (5). And reduced system (5) has integral

$$\left\|\begin{matrix} a_1^* \\ a_2^* \end{matrix}\right\| \dot{q} + \left\|\begin{matrix} b_1^{*0} + g_1^{*0} \\ b_2^{*0} + g_2^{*0} \end{matrix}\right\| q + j\,(q, \dot{q}) = B$$

and full system (3) has integral of Lyapunov:

$$\left\|\begin{matrix} a_1 \\ a_2 \end{matrix}\right\| \dot{q}_M + \left\|\begin{matrix} b_1^0 + g_1^0 \\ b_2^0 + g_2^0 \end{matrix}\right\| q_M + F(q_M, \dot{q}_M) = A\,.$$

3.2 Estimations of approximate solutions

Let $q_i = q_i(t,m)$, $\dot{q}_i = \dot{q}_i(t,m)$, $(i = 1...4)$ be the solution of system (3) with the initial conditions $q_{i0} = q_i(t_0,m)$, $\dot{q}_{i0} = \dot{q}_i(t_0,m)$;we shall designate $q_i^* = q_i^*(t)$, $q_i^{\cdot *} = q_i^{\cdot *}(t)$, ($i$ =1,…4) as the solution of approximate system (5), defined by the initial conditions $q_{j0}^* = q_j^*(t_0)$, $\dot{q}_{j0}^* = \dot{q}_j^*(t_0)$ (j=1, 2, 3), where $q_4^* \equiv 0$, $\dot{q}_4^* \equiv 0$.

Making use of stability theory methods we can prove the following statement:

Theorem 2. If the characteristic equation for system (5) has all roots in the left half-plane (except m zero roots) for $d(0, 0)\neq 0$, then under sufficiently big stiffness of the system elements (i.e. m is sufficiently small) there exists such a m_*-value for $x>0$, $h>0$, $g>0$ given in advance (no matter how small x and g are), that in a perturbed motion: $\left\|q_i - q_i^*\right\| < x$, $\left\|\dot{q}_i - \dot{q}_i^*\right\| < x$ (i=1,…,4) when $0<m<m_*$ for $t \geq t_0+g$, if $q_{j0} = q_{j0}^*$, $\dot{q}_{j0} = \dot{q}_{j0}^*$, ($j$=1,2,3) $\left\|q_{40}\right\| < h$, $\left\|\dot{q}_{40}\right\| < h$.

It should be pointed out that while demonstrating and using variables z, x we introduce deviations $a=z-z^*$, $b=x-x^*$ and consider a differential equation for b. The analysis of these equations as well as the integral structure enable to derive the statement of Theorem.

These results, complementing already known [9], justify for the systems, considered here, admissibility of approximate limit model (as asymptotic model of 0-level) and determine the conditions, under which the considered transition is correct (in a meaning, adopted here).

Remark. According to this we can introduce other approximate model (as designing-basic model) for (3). This is asymptotic model of 1-level (m-approximation), that has (s+(n-s)/2) of freedom degrees (if in (4) take into consideration members containing μ in power not more than 1). This model is new one (it is very interesting result).

System (4) belongs to the special critical case, when all eigenvalues of matrix P_{22}, corresponding to the fast x_2, are zero.

4 SYSTEMS WITH FAST ROTORS

Using the same asymptotic approach, we can solve a problem of the transition strict substantiation to a reduced (approximate) model for the mechanical systems with the fast rotors (gyroscopes) [13]. No-giving the formulas and computations here, we note only the some results. In this case original mathematical model is accepted in a form of Lagrange's equations [5]; big parameter is introduced through gyroscopic forces [5, 13]; the necessary transformation of state variables is constructed; the initial equations are reduced to standard form (1). The reduced models are got on our scheme. According to elaborated method, by strict mathematical manner we obtained the known (precessional) model and new («limit») model (as shortened model of 1-st level and 0-level, correspondingly). The conditions of acceptability of these models are determined.

5 SYSTEMS WITH SMALL DELAY TIME

Here the electromechanical systems (EMS), modelling the gyrostabilization systems, are investigated. Original model is presented in general form of Lagrange-Maxwell (Gaponov) equations [14]. The problems: the constructing of reduced model; and their acceptability (in corresponding sense) for these systems. For case of fast-acting systems, interpreting ones as singularly perturbed system, according to our method, we solve these problems. The required transformation is constructed; the reduced models (two types) are obtained; the domains of acceptability are determined.

6 CONCLUSION

In the applications to engineering practice the elaborated methods are very effective, those are enabling to construct the acceptable shortened submodels(as *s-approximations*) by strict mathematical way; to substantiate strongly their correctness in dynamics, including Lyapunov's critical cases; to consider specific cases, inherent for mechanical systems; to evaluate the corresponding errors in such transition-simplifying. It is allowing to realize the using of parallel supercomputing in designing processes on modern computing machines .

The elaborated methods are illustrated on examples from engineering practice, from Mechanics. In framework of this approach it is considered actual problems for fast gyros theory, electromechanical systems, robotic systems; mechanical systems with the friction, non-holonomic systems; Newton's model of point mass dynamics,…

New elegant outcomes are obtained, that are interesting both for theory and for applications, both in general theory of singularly perturbed systems and in applied engineering problems. Also this approach is very perspective from gnosiological view point, for general knowledge theory, with revealing interesting new models, with possibility for investigation of the original complex multi-scale system **with using analytical or computer- analytical parallel methods from first steps of engineering designing**.

Finally as some additional remarks we notice that by analogy with these systems, using the same methods, other singularly perturbed problems and systems of mechanics may be considered.

The subject-matter of investigations is general problem of modelling in mechanics. *The development of mathematical modelling questions of mechanics is closely concerned with actual tasks of mechanical systems dynamics, of differential equations theory* ***with big and small parameters,*** *of stability theory.* In one's turn it is generating new trends in mathematics, interesting mathematical and mechanical problems.

The received results are generalizing and supplementing ones, known in theory of perturbations; these results are developing interesting applications in engineering. With reference to Mechanics and engineering applications the rigorous theoretic justification is

obtained for considered approximate models and theories, both traditional (K.Magnus, A.Andronov, D.Merkin,…) and *new ones*; the separation of state variables on different-frequency groups is developed from first stages of designing; the acceptability of approximate theories, models is discussed, including "exotic" Aristotle's model in Dynamics.
Deep philosophical aspect of idealization problem in Mechanics is highlighted.

Keywords: aeroelasticity, wind turbine blades, large displacements, finite rotations, geometrically non-linear effects, Total Lagrangian formulation

Abstract. *Due to the substantial increase of the size of current and future wind turbine designs, the blades tend to be quite flexible, resulting to large displacements and finite rotations under the action of the aerodynamic loading. As a result, the geometry of the blades changes, in some cases the flap deflection exceeds* 10% *of the blade radius, and thus, geometrically non-linear effects of significant importance take place.*
Two geometrically non-linear models are available in the multi-body hydro-servo-aeroelastic tool hGAST [1, 2], the first employs a 2nd order Euler-Bernoulli beam approach and the second is based on a non-linear sub-body modeling of the blades. In the present paper, a degenerate-continuum based Timoshenko beam approach is presented, which has been implemented in the code. The main kinematic assumptions are that the cross-section remains plane and rigid in its own plane, hence, the cross-sectional out-of-plane and in-plane warpings are neglected. The material is assumed homogeneous, isotropic, linear and elastic.
Comparisons between the non-linear models and the linear one are presented. The basic outcome from the analysis of a three-bladed rotor, with aerodynamic and structural properties same to the 5MW NREL reference wind turbine, is that the non-linear models result to a significant difference in torsional response compared to the linear model, due to the bending-torsion non-linear coupling. This could be an important aspect for the design of the blades, since it contributes to passive load reduction strategies.

1 INTRODUCTION

In bibliography, geometrically non-linear beam theories could be separated into two categories: a degenerate-continuum beam theory [3, 4, 5] and a geometrically exact beam theory [6, 7]. The first category, which has been inspired by the work done for shells (first introduced in 1968 by Ahmad et al. [8]), is directly derived from the 3D-continuum. The strain-displacement relations used are written in a strong sense, i.e. at the material particle level. The second category, which has been introduced by Reissner [6] for the plane case and by Simo [7] for the spatial case, deals with the problem formulation at a beam theory level. The strain-displacement relations used are written in a weak sense, i.e. at the reference point of the beam. These *generalized* strain measures do not spoil the geometric exactness, as this is expressed via the resultant form of the differential equilibrium equations at the deformed state. Actually, Reissner [9] had proposed a formulation in 3D before Simo, but, using a rotation matrix simplification to derive the required strain-displacement relations, he spoiled the geometric exactness [10]. Many finite-element developers of the beam theories, e.g. Jelenić & Crisfield [10], Cardona & Geradin [11], Ibrahimbegović [12], based their approach on the geometrically exact beam theory.

The more flexible wind turbine blades of modern design lead to a strong coupling between aerodynamics and structural dynamics, namely the aeroelasticity. Thus, the structural models used in aeroelasticity of the blades need to account for the exact geometry of the deformed shape, so that an accurate input for the aerodynamics load estimation may be provided. A review on the structural models used in aeroelasticity of the blades is given in [13]. As far as the 1D structural models are concerned, linear beam models had been used for long. Important terms which consider certain non-linearities were included, i.e. coupling-type terms associated with the centrifugal forces. Today, two non-linear beam theory models for rotor blades are used: One is the moderate deflection beam model [9, 14] based on ordering schemes, and, the other is the large deflection beam model [15, 16] developed according to the aforementioned geometrically exact beam theory.

As far as the aerodynamics is concerned, the aerodynamic model, used to transform the wind flow field to loads on the blades, is a (BEM) Blade-Element Momentum model, which accounts for dynamic inflow, yaw misalignment, and dynamic stall effects [17].

In this work, a Total Lagrangian beam approach based on the degenerate-continuum concept, for using it in aeroelasticity, is presented. The difference compared to the beam theory model presented in [3, 4, 5] is that before the element interpolation is performed, an analytical integration over the cross-section is carried out to reduce the 3D integration to a 1D integration. The same procedure is followed in [18] for an Updated Lagrangian formulation. The paper outline is as follows: In section 2, the kinematics and kinetics of the degenerate-continuum based beam formulation are presented. An important issue is how to represent the finite rotations of the cross-section. In the present work, the rotational vector representation technique is used to avoid the non-uniqueness problem associated to the Euler angles one [19]. The exponential mapping of the skew-symmetric matrix of the rotational vector is evaluated to update the cross-sectional orientation. Consistent linearization of the configuration state is presented in the following, needed to construct a step-by-step analysis, in the context of a Total Lagrangian formulation. In section 3, the linearized equilibrium equation is presented, from which the beam matrices are derived after the discretization procedure, using the finite element method. In section 4, the numerical results from the three-bladed 5MW NREL [20] rotor motion, under uniform inflow conditions, are presented. Comparisons are given between the three options of the geometrically non-linear modeling (degenerate-continuum based, 2nd order Euler-Bernoulli, sub-body

approach models) and the linear one.

2 DEGENERATE-CONTINUUM BASED TIMOSHENKO BEAM APPROACH

2.1 Assumptions

- The cross-section of the beam remains plane and rigid inside its own plane, hence, warping is not included. However, the warping displacement behavior could be added to the assumed deformations.
- Shear deformation is taken into account, and, it is assumed constant in the cross-section as a consequence of the previous non-warping assumption.
- The initial reference line of the beam is assumed, for the sake of simplicity, straight.
- The material is homogeneous, isotropic and linear elastic.

2.2 Basic kinematics

The reference bases used in kinematics are (fig. 1),

- $\boldsymbol{E_j}, j = 1 - 3$, is the orthonormal body-attached reference basis (which is rotating in the context of the blade dynamics)
- $\boldsymbol{V_i}(\xi), i = r, s, t$, is the orthonormal moving basis, attached to each cross-section

where, ξ is the arc-length variable along the reference line of the beam.

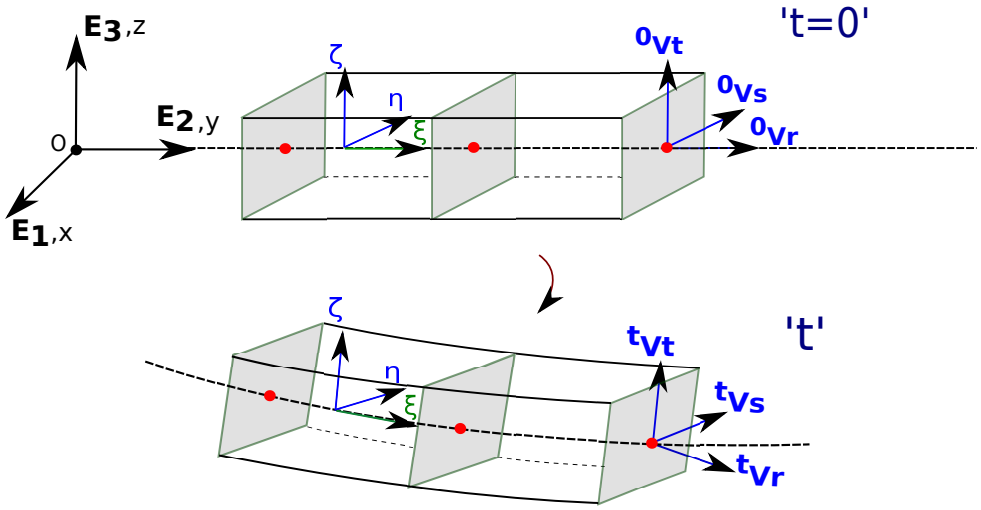

Fig. 1: Initial and deformed configuration of the beam.

2.2.1 Initial configuration state

The initial cross-sectional orientation is expressed via the initial orthogonal transformation $\xi \rightarrow {}^0\mathbf{\Lambda}(\xi) \in SO(3)$, $SO(3)$ is the special orthogonal group, thus, the moving frame basis at the initial (undeformed) state (fig. 1) is given by,

$$ {}^0\boldsymbol{V_i}(\xi) = {}^0\Lambda_{ij}(\xi)\boldsymbol{E_j} \tag{1}$$

The triads ${}^0\boldsymbol{V_i}(\xi), i = r, s, t$ are directed along the axes shown in fig. 1, which are parallel to the reference basis $\boldsymbol{E_j}, j = 1 - 3$, (in blade dynamics the origin of these triads is located on the pitch axis of the blade). The basis vectors ${}^0\boldsymbol{V_i}(\xi)$, in general, depend on ξ due to the presence of initial curvatures and/or twist. In the present, because of the straight beam assumption, these vectors are constant along the beam. The corresponding position vector $\boldsymbol{R}$ of an arbitrary material particle (ξ, η, ζ) of the undeformed beam is given by,

$$ \boldsymbol{R}(\xi, \eta, \zeta) = \boldsymbol{R_0}(\xi) + {}^0\mathbf{\Lambda^T} \cdot \begin{Bmatrix} 0 \\ \eta \\ \zeta \end{Bmatrix} = \boldsymbol{R_0}(\xi) + \eta \cdot {}^0\boldsymbol{V_s} + \zeta \cdot {}^0\boldsymbol{V_t} \tag{2}$$

where, $\boldsymbol{R_0}(\xi)$ is the position vector of the undeformed beam reference point.

2.2.2 Current configuration state

In a similar way, the deformed cross-sectional orientation is expressed via the orthogonal transformation $\xi \rightarrow {}^t\mathbf{\Lambda}(\xi) \in SO(3)$, thus, the moving frame basis at the current (deformed) state (fig. 1) is given by,

$$ {}^t\boldsymbol{V_i}(\xi) = {}^t\Lambda_{ij}(\xi)\boldsymbol{E_j} \tag{3}$$

The Bernoulli hypothesis of the plane cross-sections remaining planar after deformation and retaining their shape and area is assumed to hold, thus, the corresponding position vector ${}^t\boldsymbol{r}$ of an arbitrary material particle (ξ, η, ζ) of the deformed beam is given by,

$$ {}^t\boldsymbol{r}(\xi, \eta, \zeta) = {}^t\boldsymbol{r_0}(\xi) + {}^t\mathbf{\Lambda^T}(\xi) \cdot \begin{Bmatrix} 0 \\ \eta \\ \zeta \end{Bmatrix} = {}^t\boldsymbol{r_0}(\xi) + \eta \cdot {}^t\boldsymbol{V_s}(\xi) + \zeta \cdot {}^t\boldsymbol{V_t}(\xi) \tag{4}$$

where, ${}^t\boldsymbol{r_0}(\xi)$ is the position vector of the deformed beam reference point.

2.3 Updated (trial) configuration state

The update of the configuration state w.r.t. the displacements is conventional, i.e. additive, due to their vectorial nature. To update the configuration state w.r.t. the rotations, the cross-sectional orientation at configurations $t + \Delta t$ and t are related via the rotational (pseudo)-vector $\boldsymbol{\theta}(\xi)$ (fig. 2), which rotates the base vectors ${}^t\boldsymbol{V_i}(\xi)$ into the base vectors ${}^{t+\Delta t}\boldsymbol{V_i}(\xi)$ around the axis $\frac{1}{\theta(\xi)} \cdot \boldsymbol{\theta}(\xi)$ for the angle $\theta(\xi)$, through

$$ {}^{t+\Delta t}\boldsymbol{V_i}(\xi) = \mathbf{\Lambda}(\xi)\ {}^t\boldsymbol{V_i}(\xi) = exp(\hat{\boldsymbol{\theta}}(\xi))\ {}^t\boldsymbol{V_i}(\xi), \quad i = r, s, t \tag{5}$$

where, the rotation matrix $\mathbf{\Lambda}(\xi)$ is given by,

$$ \mathbf{\Lambda}(\xi) = exp(\hat{\boldsymbol{\theta}}(\xi)) = \boldsymbol{I} + \frac{sin\theta}{\theta}\hat{\boldsymbol{\theta}} + \frac{1 - cos\theta}{\theta^2}\hat{\boldsymbol{\theta}}\hat{\boldsymbol{\theta}} \tag{6}$$

where $\hat{\boldsymbol{\theta}}(\xi)$ is the skew-symmetric matrix formed by the components of the rotational vector $\boldsymbol{\theta}(\xi)$ ($\hat{\boldsymbol{\theta}}(\xi) = -e^{ij}_k \theta^k \boldsymbol{E_i} \boldsymbol{E_j^T}$; e^{ij}_k is the permutation symbol). The above formula is the well-known Rodrigues formula. Details about the derivation of the formula one could find at [3, 21].

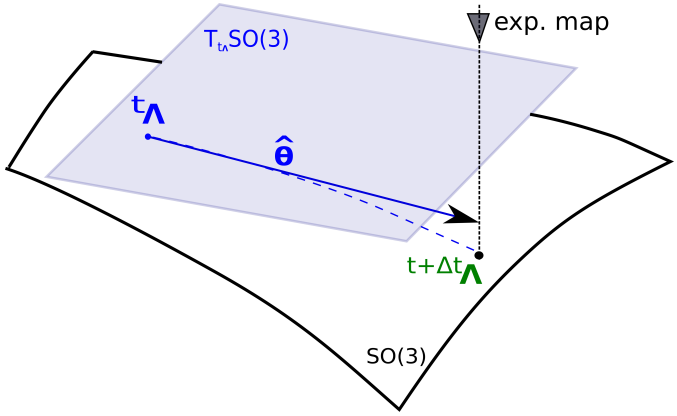

Fig. 2: Geometric interpretation of the exponential map, $T_{{}^t\Lambda}SO(3)$: tangent plane at ${}^t\boldsymbol{\Lambda}$ [22].

2.3.1 Strain and stress measures at the updated (trial) configuration state

By subtracting the position vector at $t = 0$, given in eq. (2), from the position vector at $t + \Delta t$, given in eq. (4) for $t = t + \Delta t$, for an arbitrary material particle (ξ, η, ζ) of the beam, the displacement field at $t + \Delta t$ is written as follows,

$$ {}^{t+\Delta t}\boldsymbol{u}(\xi,\eta,\zeta) = {}^{t+\Delta t}\boldsymbol{u}_0(\xi) + \eta \cdot {}^{t+\Delta t}\boldsymbol{\Delta V_s}(\xi) + \zeta \cdot {}^{t+\Delta t}\boldsymbol{\Delta V_t}(\xi) \tag{7} $$

where, ${}^{t+\Delta t}\boldsymbol{u}_0(\xi)$ is the updated displacement of the beam reference point, and, ${}^{t+\Delta t}\boldsymbol{\Delta V_s}(\xi)$, ${}^{t+\Delta t}\boldsymbol{\Delta V_t}(\xi)$ are the differences between the initial and the updated cross-sectional directors.

To know the stress condition contributing to the geometric stiffness in the context of the Newton-Raphson iterative procedure, the internal forces and moments of the beam at the trial state $t + \Delta t$ need to be evaluated. To do so, the steps below are followed (for convenience, the variables ξ, η, ζ are omitted from the RHS),

1. The material particle (ξ, η, ζ) global displacement gradients are evaluated,

$$ \left\{ {}^{t+\Delta t}u_{,x}\ {}^{t+\Delta t}u_{,y}\ {}^{t+\Delta t}u_{,z}\ {}^{t+\Delta t}v_{,x}\ {}^{t+\Delta t}v_{,y}\ {}^{t+\Delta t}v_{,z}\ {}^{t+\Delta t}w_{,x}\ {}^{t+\Delta t}w_{,y}\ {}^{t+\Delta t}w_{,z} \right\}^T $$

   where, ${}^{t+\Delta t}u$, ${}^{t+\Delta t}v$, ${}^{t+\Delta t}w$ are the components of the updated displacement (eq. 7) w.r.t. the reference basis $\boldsymbol{E}$, while, (,) denotes the spatial derivative relative to the x, y, z coordinates.

2. Using the coordinate transformation of a 2nd order tensor [23], the global displacement gradients are rotated to get the initial local ones, i.e. relative to the initial cross-sectional basis ${}^0\boldsymbol{V}$.

3. The components of the Green strain tensor [3, 4] are evaluated. Because of the assumption that the cross-sectional shape does not change during deformation, the only remaining

components of the Green strain tensor are,

$$
\begin{aligned}
{}^{t+\Delta t}\epsilon_{\xi\xi}(\xi,\eta,\zeta) &= {}^{t+\Delta t}u_{\xi,\xi} + \frac{1}{2}({}^{t+\Delta t}u_{\xi,\xi})^2 + \frac{1}{2}({}^{t+\Delta t}v_{\eta,\xi})^2 + \frac{1}{2}({}^{t+\Delta t}w_{\zeta,\xi})^2 \\
{}^{t+\Delta t}\epsilon_{\xi\eta}(\xi,\eta,\zeta) &= \frac{1}{2}({}^{t+\Delta t}u_{\xi,\eta} + {}^{t+\Delta t}v_{\eta,\xi} + {}^{t+\Delta t}u_{\xi,\xi}{}^{t+\Delta t}u_{\xi,\eta} + {}^{t+\Delta t}v_{\eta,\xi}{}^{t+\Delta t}v_{\eta,\eta} \\
&\qquad + {}^{t+\Delta t}w_{\zeta,\xi}{}^{t+\Delta t}w_{\zeta,\eta}) \\
{}^{t+\Delta t}\epsilon_{\xi\zeta}(\xi,\eta,\zeta) &= \frac{1}{2}({}^{t+\Delta t}u_{\xi,\zeta} + {}^{t+\Delta t}w_{\zeta,\xi} + {}^{t+\Delta t}u_{\xi,\xi}{}^{t+\Delta t}u_{\xi,\zeta} + {}^{t+\Delta t}v_{\eta,\xi}{}^{t+\Delta t}v_{\eta,\zeta} \\
&\qquad + {}^{t+\Delta t}w_{\zeta,\xi}{}^{t+\Delta t}w_{\zeta,\zeta}) \qquad (8)
\end{aligned}
$$

where, ${}^{t+\Delta t}u_{\xi}, {}^{t+\Delta t}v_{\eta}, {}^{t+\Delta t}w_{\zeta}$ are the updated displacements of an arbitrary material particle w.r.t. the cross-sectional basis ${}^{\mathbf{0}}\boldsymbol{V}$, while, (,) denotes the spatial derivative relative to the ξ, η, ζ coordinates.

4. The internal forces/moments that arise in the geometric stiffness due to the 2nd Piola-Kirchhoff normal stress ${}^{t+\Delta t}S_{\xi\xi}(\xi,\eta,\zeta)$ are defined as,

$$
\begin{aligned}
{}^{t+\Delta t}F_{\xi\xi}(\xi) &= \int_{{}^0A} {}^{t+\Delta t}S_{\xi\xi}\, d^0A, & {}^{t+\Delta t}M_{\eta\eta}(\xi) &= \int_{{}^0A} \zeta \cdot {}^{t+\Delta t}S_{\xi\xi}\, d^0A \\
{}^{t+\Delta t}M_{\zeta\zeta}(\xi) &= \int_{{}^0A} \eta \cdot {}^{t+\Delta t}S_{\xi\xi}\, d^0A, & {}^{t+\Delta t}M_{\xi\xi 1}(\xi) &= \int_{{}^0A} \eta^2 \cdot {}^{t+\Delta t}S_{\xi\xi}\, d^0A \\
{}^{t+\Delta t}M_{\xi\xi 2}(\xi) &= \int_{{}^0A} \zeta^2 \cdot {}^{t+\Delta t}S_{\xi\xi}\, d^0A, & {}^{t+\Delta t}M_{\xi\xi 3}(\xi) &= \int_{{}^0A} \eta\zeta \cdot {}^{t+\Delta t}S_{\xi\xi}\, d^0A \qquad (9)
\end{aligned}
$$

where, ${}^0A$ is the initial cross-sectional area, ${}^{t+\Delta t}S_{\xi\xi}(\xi,\eta,\zeta) = E \cdot {}^{t+\Delta t}\epsilon_{\xi\xi}$, E is the Young's modulus, ${}^{t+\Delta t}F_{\xi\xi}(\xi)$ is the normal force, ${}^{t+\Delta t}M_{\eta\eta}(\xi)$, ${}^{t+\Delta t}M_{\zeta\zeta}(\xi)$ are the bending moments, and, ${}^{t+\Delta t}M_{\xi\xi 1-3}(\xi)$ lead to the effective torsional moment components due to the bending, all referred to the initial state. A geometrical interpretation of the last internal moment is given in [24].
The internal forces/moments that arise in the geometric stiffness due to the 2nd Piola-Kirchhoff shear stress ${}^{t+\Delta t}S_{\xi\eta}(\xi,\eta,\zeta), {}^{t+\Delta t}S_{\xi\zeta}(\xi,\eta,\zeta)$ are defined as,

$$
\begin{aligned}
{}^{t+\Delta t}F_{\xi\eta}(\xi) &= \int_{{}^0A} {}^{t+\Delta t}S_{\xi\eta}\, d^0A, & {}^{t+\Delta t}F_{\xi\zeta}(\xi) &= \int_{{}^0A} {}^{t+\Delta t}S_{\xi\zeta}\, d^0A \\
{}^{t+\Delta t}M_{\xi\xi 4}(\xi) &= \int_{{}^0A} \zeta \cdot {}^{t+\Delta t}S_{\xi\eta}\, d^0A, & {}^{t+\Delta t}M_{\xi\xi 5}(\xi) &= \int_{{}^0A} \eta \cdot {}^{t+\Delta t}S_{\xi\zeta}\, d^0A \qquad (10)
\end{aligned}
$$

where, ${}^{t+\Delta t}S_{\xi\eta}(\xi,\eta,\zeta) = G \cdot (2^{t+\Delta t}\epsilon_{\xi\eta})$, ${}^{t+\Delta t}S_{\xi\zeta}(\xi,\eta,\zeta) = G \cdot (2^{t+\Delta t}\epsilon_{\xi\zeta})$, G is the shear modulus, ${}^{t+\Delta t}F_{\xi\eta}(\xi)$, ${}^{t+\Delta t}F_{\xi\zeta}(\xi)$ are the shear forces, and, ${}^{t+\Delta t}M_{\xi\xi 4-5}(\xi)$ lead to the torsional moment components, all referred to the initial state.

By performing the cross-sectional integration analytically, the internal forces and moments are derived in relation with the cross-sectional properties and a resultant form of the strain measures.

Remark: At the updated configuration $t + \Delta t$,

- *'Rotations'* contribute in the internal elastic energy are depicted in the difference

$$
{}^{t+\Delta t}\boldsymbol{\Delta V_i}(\xi) = {}^{t+\Delta t}\boldsymbol{V_i}(\xi) - {}^0\boldsymbol{V_i}, i = s, t \qquad (11)
$$

- *'Curvature' measures* contribute in the internal elastic energy are depicted in the derivative of the above difference along the beam arc-length, $\frac{\vartheta^{t+\Delta t}\boldsymbol{\Delta V_i}(\xi)}{\vartheta\xi}, i = s, t$:

$$\frac{\vartheta({}^{t+\Delta t}\boldsymbol{V_i}(\xi) - {}^{0}\boldsymbol{V_i})}{\vartheta\xi} = \frac{\vartheta(exp(\hat{\boldsymbol{\theta}}(\xi))\,{}^{t}\boldsymbol{V_i}(\xi))}{\vartheta\xi} \tag{12}$$

where the orientation update relation (5) has been used.

For the differentiation of the exponential mapping we refer to [25], where a family of trigonometric functions, that have been used, facilitate the procedure significantly.

2.4 Perturbation of the configuration state at $t + \Delta t$

To construct the perturbed configuration state at $t + \Delta t$,

- The perturbed position of the reference line relative to ${}^{t+\Delta t}\boldsymbol{r_0}(\xi)$ is constructed as,

$${}^{t+\Delta t,\epsilon}\boldsymbol{r_0}(\xi) = {}^{t+\Delta t}\boldsymbol{r_0}(\xi) + \epsilon\,\delta\boldsymbol{u_0}(\xi) \tag{13}$$

where, $\delta\boldsymbol{u_0}(\xi) = \delta u_{0i}(\xi)\boldsymbol{E_i}$ is a vector field, interpreted, for $\epsilon > 0$, as superposed infinitesimal displacement onto the reference line [22].

- The perturbed orthogonal transformation relative to ${}^{t+\Delta t}\boldsymbol{\Lambda}(\xi)$, which consists of the cross-sectional basis ${}^{t+\Delta t}\boldsymbol{V}(\xi)$ as given in eq. (5), is constructed by two ways (fig. 3),

a)

$${}^{t+\Delta t,\epsilon}\boldsymbol{\Lambda}(\xi) = exp(\epsilon\boldsymbol{\delta\Psi}(\xi))^{t+\Delta t}\boldsymbol{\Lambda}(\xi) = exp(\epsilon\boldsymbol{\delta\Psi}(\xi))exp(\hat{\boldsymbol{\theta}}(\xi))\,{}^{t}\boldsymbol{\Lambda}(\xi) \tag{14}$$

where, $\boldsymbol{\delta\Psi}(\xi)$ is a skew-symmetric tensor field, interpreted, for $\epsilon > 0$, as superposed infinitesimal rotation (spin) onto the moving frame [22]. The eq. (5) has been used above, in the form ${}^{t+\Delta t}\boldsymbol{\Lambda}(\xi) = exp(\hat{\boldsymbol{\theta}}(\xi))\,{}^{t}\boldsymbol{\Lambda}(\xi)$.

b)

$${}^{t+\Delta t,\epsilon}\boldsymbol{\Lambda}(\xi) = exp(\hat{\boldsymbol{\theta}}(\xi) + \epsilon\delta\hat{\boldsymbol{\theta}}(\xi))\,{}^{t}\boldsymbol{\Lambda}(\xi) \tag{15}$$

where, $\delta\hat{\boldsymbol{\theta}}(\xi)$ is a skew-symmetric tensor field, interpreted, for $\epsilon > 0$, as infinitesimal rotation that can be added to the previous rotation.

To get a relation between the axial vectors $\boldsymbol{\delta\psi}(\xi)$ and $\delta\boldsymbol{\theta}(\xi)$ of the skew-symmetric matrices $\boldsymbol{\delta\Psi}(\xi)$ and $\delta\hat{\boldsymbol{\theta}}(\xi)$ respectively, the Rodrigues formula is used in eqs. (14, 15) and then, the derivative with respect to the scalar parameter ϵ is taken, for $\epsilon = 0$ [26],

$$\boldsymbol{\delta\psi}(\xi) = \boldsymbol{T(\theta)}\delta\boldsymbol{\theta}(\xi) \tag{16}$$

where,

$$\boldsymbol{T(\theta)} = \frac{sin\theta}{\theta}\boldsymbol{I} + \frac{1 - cos\theta}{\theta^2}\hat{\boldsymbol{\theta}} + \frac{\theta - sin\theta}{\theta^3}\boldsymbol{\theta}\otimes\boldsymbol{\theta} \tag{17}$$

For the derivation of the transformation $\boldsymbol{T(\theta)}$ (named as the tangential transformation because is a linear map between tangent spaces, fig. 3) see [3, 11, 27].

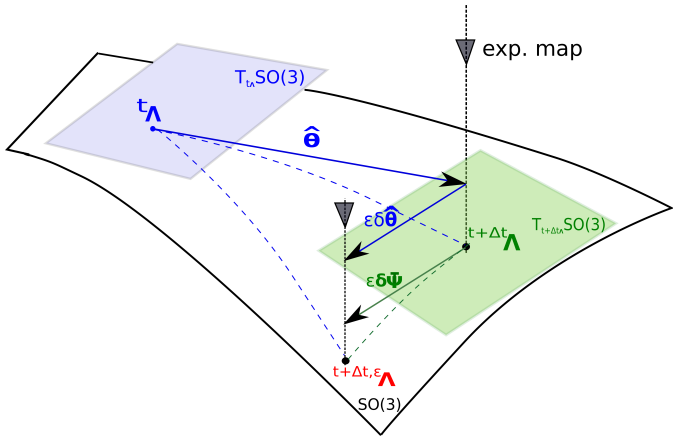

Fig. 3: Rotation increments and their projection onto the manifold SO(3) [11, 26].

2.4.1 Virtual strain measures

By employing the directional derivative onto the perturbed configuration state (eqs. 13, 14), the variation of the configuration state $(\delta \boldsymbol{r_0}(\xi), \delta \boldsymbol{\Lambda}(\xi))$ is derived,

$$\delta \boldsymbol{r_0}(\xi) = \frac{d}{d\epsilon}\bigg|_{\epsilon=0} {}^{t+\Delta t,\epsilon}\boldsymbol{r_0}(\xi) = \delta \boldsymbol{u_0}(\xi) \tag{18}$$

$$\delta \boldsymbol{\Lambda}(\xi) = \frac{d}{d\epsilon}\bigg|_{\epsilon=0} {}^{t+\Delta t,\epsilon}\boldsymbol{\Lambda}(\xi) = \boldsymbol{\delta\Psi}(\xi)\, {}^{t+\Delta t}\boldsymbol{\Lambda}(\xi) \tag{19}$$

Thus, the virtual displacement for an arbitrary material particle (ξ, η, ζ) is written as,

$$\delta \boldsymbol{u}(\xi,\eta,\zeta) = \delta \boldsymbol{u_0}(\xi) + \eta \cdot \delta \boldsymbol{V_s}(\xi) + \zeta \cdot \delta \boldsymbol{V_t}(\xi) \tag{20}$$

where, $\delta \boldsymbol{u_0}(\xi)$ is the virtual displacement of the beam reference point and $\delta \boldsymbol{V_i}(\xi) = \delta \boldsymbol{\Lambda_{ij}}(\xi)\boldsymbol{E_j}$, $i = r, s, t, j = 1-3$. Specifically, by using eqs. (16, 17, 19), the virtual cross-sectional directors are given as follows,

$$\delta \boldsymbol{V_s}(\xi) = \boldsymbol{\delta\Psi}(\xi)^{t+\Delta t}\boldsymbol{V_s}(\xi) = \boldsymbol{\delta\psi}(\xi) \times {}^{t+\Delta t}\boldsymbol{V_s}(\xi) = (\boldsymbol{T(\theta)}\delta\boldsymbol{\theta}(\xi)) \times {}^{t+\Delta t}\boldsymbol{V_s}(\xi) \tag{21}$$

$$\delta \boldsymbol{V_t}(\xi) = \boldsymbol{\delta\Psi}(\xi)^{t+\Delta t}\boldsymbol{V_t}(\xi) = \boldsymbol{\delta\psi}(\xi) \times {}^{t+\Delta t}\boldsymbol{V_t}(\xi) = (\boldsymbol{T(\theta)}\delta\boldsymbol{\theta}(\xi)) \times {}^{t+\Delta t}\boldsymbol{V_t}(\xi) \tag{22}$$

By substituting eq. (21) and eq. (22) in eq. (20), the material particle virtual displacement is written in relation with the unknown variables $\delta \boldsymbol{u_0}(\xi)$ and $\delta\boldsymbol{\theta}(\xi)$. The steps (1) and (2) from the section 2.3.1 are followed to get the initial local infinitesimal displacement gradients. Following [4] for a Total Lagrangian formulation, the corresponding components of Green-Lagrange strain tensor are given by,

- The linear virtual strain components are (for convenience the variables ξ, η, ζ are omitted from the RHS),

$$\begin{aligned}
\delta e_{\xi\xi}(\xi,\eta,\zeta) &= \delta u_{\xi,\xi} + {}^{t+\Delta t}u_{\xi,\xi}\,\delta u_{\xi,\xi} + {}^{t+\Delta t}v_{\eta,\xi}\,\delta v_{\eta,\xi} + {}^{t+\Delta t}w_{\zeta,\xi}\,\delta w_{\zeta,\xi} \\
\delta e_{\xi\eta}(\xi,\eta,\zeta) &= \frac{1}{2}(\delta u_{\xi,\eta} + \delta v_{\eta,\xi} + {}^{t+\Delta t}u_{\xi,\xi}\,\delta u_{\xi,\eta} + {}^{t+\Delta t}v_{\eta,\xi}\,\delta v_{\eta,\eta} + {}^{t+\Delta t}w_{\zeta,\xi}\,\delta w_{\zeta,\eta} \\
&\quad + {}^{t+\Delta t}u_{\xi,\eta}\delta u_{\xi,\xi} + {}^{t+\Delta t}v_{\eta,\eta}\,\delta v_{\eta,\xi} + {}^{t+\Delta t}w_{\zeta,\eta}\,\delta w_{\zeta,\xi}) \\
\delta e_{\xi\zeta}(\xi,\eta,\zeta) &= \frac{1}{2}(\delta u_{\xi,\zeta} + \delta w_{\zeta,\xi} + {}^{t+\Delta t}u_{\xi,\xi}\,\delta u_{\xi,\zeta} + {}^{t+\Delta t}v_{\eta,\xi}\,\delta v_{\eta,\zeta} + {}^{t+\Delta t}w_{\zeta,\xi}\,\delta w_{\zeta,\zeta} \\
&\quad + {}^{t+\Delta t}u_{\xi,\zeta}\,\delta u_{\xi,\xi} + {}^{t+\Delta t}v_{\eta,\zeta}\,\delta v_{\eta,\xi} + {}^{t+\Delta t}w_{\zeta,\zeta}\,\delta w_{\zeta,\xi})
\end{aligned} \tag{23}$$

where, $\delta u_\xi, \delta v_\eta, \delta w_\zeta$ are the components of the virtual displacement for the material particle (ξ, η, ζ), eq. (20), rotated to the cross-sectional basis ${}^{\mathbf{0}}\boldsymbol{V}$, and, (,) denotes the spatial derivative relative to the ξ, η, ζ coordinates.

- The non-linear virtual strain components are (for convenience the variables ξ, η, ζ are omitted from the RHS),

$$\begin{aligned}
\delta\eta_{\xi\xi}(\xi,\eta,\zeta) &= \frac{1}{2}(\delta u_{\xi,\xi}^2 + \delta v_{\eta,\xi}^2 + \delta w_{\zeta,\xi}^2) \\
\delta\eta_{\xi\eta}(\xi,\eta,\zeta) &= \frac{1}{2}(\delta u_{\xi,\xi}\delta u_{\xi,\eta} + \delta v_{\eta,\xi}\delta v_{\eta,\eta} + \delta w_{\zeta,\xi}\delta w_{\zeta,\eta}) \\
\delta\eta_{\xi\zeta}(\xi,\eta,\zeta) &= \frac{1}{2}(\delta u_{\xi,\xi}\delta u_{\xi,\zeta} + \delta v_{\eta,\xi}\delta v_{\eta,\zeta} + \delta w_{\zeta,\xi}\delta w_{\zeta,\zeta})
\end{aligned} \tag{24}$$

3 VIRTUAL WORK EQUATION FOR A TOTAL LAGRANGIAN FORMULATION

The equilibrium equation of the body at $(t + \Delta t, \epsilon)$ is given by [4],

$$\int_{{}^0V} {}^0\rho\, {}^{t+\Delta t,\epsilon}\ddot{r}_{Gk}\, \delta u_k d^0V + \int_{{}^0V} {}^{t+\Delta t,\epsilon}S_{ij}\, \delta^{t+\Delta t,\epsilon}\epsilon_{ij}\, d^0V = \int_{{}^0V} {}^{t+\Delta t}f_k^G\, \delta u_k\, d^0V + \int_{{}^{t+\Delta t}S_f} {}^{t+\Delta t}f_k^S\, \delta u_k^S\, d^{t+\Delta t}S \tag{25}$$

where, ${}^0V$ is the initial volume, ${}^0\rho$ is the mass density referred to the initial state, ${}^{t+\Delta t,\epsilon}\ddot{r}_{Gk}$, $k = \xi, \eta, \zeta$ is the acceleration of the particle due to all the inertia effects [2], i.e. the acceleration of the body origin, the Coriolis acceleration, and, the acceleration due to the body deformation, $\delta u_k = \left\{\delta u_\xi, \delta v_\eta, \delta w_\zeta\right\}^T$ are the virtual displacements, ${}^{t+\Delta t,\epsilon}S_{ij}$, $i, j = \xi, \eta, \zeta$, are the 2nd Piola-Kirchhoff stress components, $\delta^{t+\Delta t,\epsilon}\epsilon_{ij}$ are the virtual strains, ${}^{t+\Delta t}f_k^G$ is the gravitational load and ${}^{t+\Delta t}f_k^S$ is the surface aerodynamic load, where ${}^{t+\Delta t}S_f$ corresponds to the last calculated surface area.

For the linearization of the internal virtual work (2nd term of the LHS of the above relation 25), the iterative decompositions for stresses and strains are used,

$${}^{t+\Delta t,\epsilon}S_{ij} = {}^{t+\Delta t}S_{ij} + dS_{ij} \tag{26}$$

$${}^{t+\Delta t,\epsilon}\epsilon_{ij} = {}^{t+\Delta t}\epsilon_{ij} + d\epsilon_{ij},\ d\epsilon_{ij} = de_{ij} + d\eta_{ij} \tag{27}$$

where, ${}^{t+\Delta t}S_{ij} = C_{ijrs}\,{}^{t+\Delta t}\epsilon_{ij}$, C_{ijrs} expresses the material constitutive behaviour, ${}^{t+\Delta t}\epsilon_{ij}$ are given by eq. (8), $dS_{ij} = C_{ijrs}\, d\epsilon_{ij}$, de_{ij} is the linear strain part, given by the same relations as the corresponding virtual strain components (eqs. 23), and $d\eta_{ij}$ is the non-linear strain part, the variation of which is related to the geometrical stiffness. While variation and linearization can commute, the variation $\delta d\eta_{ij}$ is given by the chain-differentiation of eqs. (24).

Substituting in relation (25) the iterative decompositions (26) and (27), and following the

linearization process as it is presented in [4], the linearized equilibrium equation is derived,

$$\int_{{}^0V} {}^0\rho\, {}^{t+\Delta t,\epsilon}\ddot{r}_{Gk}\, \delta u_k d^0V + \left\{ \underbrace{\int_{{}^0V} C_{ijrs}\, de_{rs}\, \delta e_{ij}\, d^0V}_{\Rightarrow \boldsymbol{K_{mat}}} + \underbrace{\int_{{}^0V} {}^{t+\Delta t}S_{ij}\, \delta d\eta_{ij}\, d^0V}_{\Rightarrow \boldsymbol{K_{geom}}} \right\} =$$

$$\int_{{}^0V} {}^{t+\Delta t}f_k^G\, \delta u_k\, d^0V + \int_{{}^{t+\Delta t}S_f} {}^{t+\Delta t}f_k^S\, \delta u_k^S\, d^{t+\Delta t}S - \left(\underbrace{\int_{{}^0V} {}^{t+\Delta t}S_{ij}\, \delta e_{ij} d^0V}_{\Rightarrow \boldsymbol{F_{int}}} \right) \tag{28}$$

To construct the under-braced integrals, one has to substitute the strain components de_{rs}, δe_{ij} and $\delta d\eta_{ij}$ in eq. (28). By performing analytical integration over the cross-sectional area, the 1D form of the linearized virtual work is derived. After discretization, the matrices $\boldsymbol{K_{mat}}$, $\boldsymbol{K_{geom}}$ and the vector $\boldsymbol{F_{int}}$ are constructed. The first matrix refers to the resistance due to the linear constitutive behaviour of the material, while, the second one refers to the resistance due to the non-linear geometrical stiffness.

As far as the numerical implementation is concerned, one has to note two issues. The first is that the developed finite element is based on a quadratic interpolation, using a 2nd order Lagrange polynomial, of both the displacement and the rotation parameters, while, the second is that the mass matrix is evaluated using the initial configuration of the body, and thus, it is calculated prior to the step-by-step solution. Time integration is performed using the Newmark 2nd order implicit method [4].

4 NUMERICAL RESULTS

Time domain non-linear aeroelastic simulations for the isolated rotor of the 5MW NREL reference wind turbine [20] are performed, using the multi-body hydro-servo-aeroelastic tool hGAST [1, 2]. The present non-linear Degenerate-Continuum based Timoshenko beam model (non-linear DC) is compared to the 2nd order Euler-Bernoulli beam model (non-linear EB), the sub-body beam model (non-linear SB) and the linear one (linear). The transverse shear effect was neglected in view of enabling direct comparison with the 2nd order Euler-Bernoulli model. The 2nd order Euler-Bernoulli beam model accounts for moderate deflections by using an ordering scheme acted on the cross-sectional rotations [14, 28]. The sub-body modeling is an extension of the multi-body formulation to the body level. It consists of dividing the body (blade) into sub-bodies, which are subsequently treated as beam elements. At the sub-body level, local deflections and rotations are assumed small, and thus, the use of a linear Timoshenko beam model is justified, while by imposing kinematic and dynamic continuity between consecutive sub-bodies at their connection points, large deflections and rotations are gradually built [28]. The linear model accounts for the non-linear tension-bending coupling effect, which is added in the analysis of rotating bodies, since the centrifugal force increases their bending stiffness.

Uniform inflow conditions are considered at the rated wind speed of $11.4m/s$, where the deflections are expected to attain their maximum value and, in turn, the non-linear effects will be more pronounced. The rotor is operated at fixed rotational speed of $12rpm$ and at zero pitch angle (open loop operation, i.e. the controller is not active), corresponding to average operating conditions at the rated wind speed. The results are presented in terms of time histories, after the initial transients are damped.

In fig. 4, the blade tip twist angle is presented. The three non-linear models (non-linear DC, non-linear EB, non-linear SB) predict higher amplitudes of the twist angle variation as compared with the linear model. This is linked to the bending-torsion coupling effect [28] which is predicted only by the non-linear models. Although the twist angle amplitude as predicted by the non-linear SB model is $\sim 20\%$ reduced compared to the other two non-linear models, the phase of the signal is in perfect agreement between the three of them. Moreover, the non-linear models result to an increase of the twist angle mean value ($\sim 0.4^o$ for the non-linear SB model and $\sim 0.25^o$ for the other two non-linear models) compared to the linear model ($\sim 0.1^o$).

The increase in the amplitude of the twist angle affects the flapwise deflection (fig. 5) through the corresponding change in the effective angle of attack. So, in fig. 5, the three non-linear models depict a phase shift of the flapwise deflection signal compared to the linear model, following the phase of the torsion angle. Moreover, the non-linear DC and non-linear EB models predict the same amplitude of the flapwise deflection variation, although the non-linear DC model results to a slightly reduced mean value compared to the non-linear EB model. The non-linear SB model shows reduced amplitude of the variation ($\sim 25\%$) compared to the other two non-linear models, and slightly reduced compared to the linear model. The flapwise deflection mean value predicted by the non-linear SB model is identical to this of the linear modeling.

In fig. 6, the blade tip edgewise deflections are presented. As expected, the agreement between the four models is good, since the edgewise direction of the blade is stiff compared to the flapwise one, and, the corresponding loads are driven just by the gravity. In fig. 7, the blade tip extension is presented. The linear model predicts a positive extension due to the centrifugal force, while, the three non-linear models consistently predict the virtual axial shortening of the blade due to the bending.

Regarding the loads, the non-linear models predict considerably higher amplitude of the blade root torsion moment due to the bending-torsion coupling, as seen in fig. 8. The linear model results to an almost constant torsion moment, independent of the azimuth position of the blade. Its mean value is reduced about 40% compared to all the non-linear beam models, which predict almost the same mean values of the torsion moment. The amplitude of the variation is identical for the non-linear DC and non-linear EB models, while, the non-linear SB model predicts reduced amplitude ($\sim 30\%$).

In similar with the flapwise deflections (fig. 5), the amplitude of the flapwise bending moment at the blade root (fig. 9) is clearly affected by the increase in the amplitude of the twist angle (fig. 4). This is depicted in the results of all the non-linear models. Specifically, the non-linear DC model predicts a slightly increased amplitude of the variation ($\sim 5\%$) compared to the non-linear EB model, while, the other models follow with $\sim 20\%$ reduced amplitude for the non-linear SB model and $\sim 70\%$ reduced amplitude for the linear one, compared to the non-linear DC model. The mean value of the flapwise moment is almost the same for the non-linear DC, the non-linear EB and the linear model, while, the non-linear SB model predicts slightly increased mean value. A good agreement between the three non-linear models is obtained in the phase of the signal (which again follows the phase of the twist angle variation).

5 CONCLUDING REMARKS

A Total Lagrangian degenerate-continuum based Timoshenko beam approach was presented. The important features are that there is no constraint in the magnitude of displacements and rotations and that the beam model may be easily extended to a general curved beam. The main kinematic assumption is that the cross-sectional plane remains planar and rigid during deformation, although warping can be included in the formulation.

The present beam approach was implemented in the multi-body hydro-servo-aeroelastic tool hGAST. The stiffness of the beam is derived by retaining all the geometrical non-linear terms from the Green strain tensor, while, the beam inertia is taken into account using the initial configuration. The aeroelastic analysis of the three-bladed rotor of the 5MW NREL reference wind turbine was performed. The numerical results compare four modelings, the present beam approach, the 2nd order Euler-Bernoulli, the sub-body and the linear one, to assure the validity of the present formulation. The comparisons show that the present formulation works well, while the non-linear coupling effects compare well with the 2nd order Euler-Bernoulli beam theory model. The basic outcome from the analyses is that the geometrical non-linearity is significant w.r.t. the torsion-bending coupling terms and this is shown mainly in the torsional response, which is the basic factor for the determination of the aerodynamic loading.

ACKNOWLEDGMENT

The first author wishes to acknowledge the funding received towards the present work from the Fanourakis Foundation fellowship and Leventis Foundation fellowship. She also wishes to thank MSc. Structural Engineer Evangelos Katsavrias for his support in programming and for helpful discussions.

Keywords: Wind Turbine, Blade, Beam, Finite Element Method.

Abstract. *On wind energy context, the blades of horizontal axes wind turbines have, in their majority, a closed multicellular thin-walled cross section, which varies along the blade length due to aerodynamic requirements. If one wants to analyze the structural behavior of such blades, a dynamic model is necessary. Such models are desirable, since it is important the development of lighter and more flexible wind turbine designs. The desirable results of the models include evaluating the possible large deflections along time, the internal loads along the blade length and natural frequencies experimented by the structure. Moreover, one can address the magnitude and frequency of the reactions lying at the top of the turbine tower structure, due to the action of the blades. In order to model the blades with a small number of degrees of freedom, geometrically-exact beam elements are employed. The equivalent properties to be input in the model, however, are not straightforward to be obtained. This is one of the goals of the present work. A pre-processor was developed to evaluate the cross sections properties of a wind turbine blade. It calculates all the necessary input data to represent the blade as an equivalent beam and, generates an input file with data of the model to be solved in the geometrically-exact GIRAFFE dynamic simulator. Since dealing with multicellular thin-walled cross section, it is important to evaluate the centroid, the barycenter, the shear center, the inertia properties, and the equivalent specific mass. All these properties may vary along the blade length. It is possible to manipulate the blade profile, changing the number of cells, thickness, materials involved, shape of the external shell and webs positioning. The developed pre-processor, together with the dynamic simulator, can be used to predict large displacements in a dynamic simulation of wind turbines.*

1 INTRODUCTION

The idea of using the kinetic energy provided from wind is not new. There are registers of windmills dated even from medieval times. However, the current increase for energy demand, has made of the wind energy one of the most important renewable energy resources. One of the issues raised during the last years is the structural design that best fits on the role of extracting the kinetic energy from wind. Although many innovative designs are being proposed, the most common still used is the horizontal axis wind turbine (HAWT).

HAWT are structures which usually are made by some slender bodies, composed mainly by a foundation, a tower, a nacelle a rotorhub and blades. It comes that HAWT have been presenting good results on energy production. Although many issues, such as the local wind flow may affect an HAWT, it has been seen that the energy production is directly associated with the diameter of the rotor and the design of the blades. As expected, a large rotor diameter produces more energy. For example, a HAWT 41 m rotor diameter may produce 600 kW, while a 66 m rotor may produce up to 1500 kW (Hau, 2013). Unlikely the rotor diameter, there is no straightforward relation between the blades airfoil design and the energy production. In fact, the relation between the shape of the blade and the energy production is much more complex and plays a major role, since it is the structure responsible for extracting the wind energy. The blade shape is influenced by aspects such as:

- Rotor diameter;
- Aerodynamic loads;
- Gravitational loads;
- Fluid structure interaction;
- Others.

An accurate modeling of those aspects should result in a structure able not just to resist to internal and external forces, but also that has the best use of the materials and gives the minimum maintenance. It follows that modern blade of HAWT's are becoming more slender, more flexible and composite made. All of those questions lead to a huge complexity when modeling and simulating HAWT. These models should be able to handle dynamics, nonlinearities and instability.

Deal with all the variables that compose the problem on a high-hierarchy context (e.g.: finite elements solids) may result on non-practical solution time and on hard to evaluate inputs and outputs. On the other hand, beam-like modeling presents, generally, fast solution time and easier to handle inputs and outputs. Although beam-like models present some simplifications, a huge amount of works proves that they are very representative and still useful.

Despite of the inherent simplifications, there are different beams theories that may apply, accordingly to the problem to be solved. Depending on the slenderness and on the cross section characteristics, one may choose to represent the structure using the Bernoulli-Euler beam, the Timoshenko beam, the Vlasov's beam (when warping plays a role), among other theories - refer to (Gere and Timoshenko, 1997), (Timoshenko and Goodier, 1951) and (Vlasov, 1961) for the classical theories here referenced.

1.1 The geometrically-exact beam model

When presenting the distinct beam theories, always one has a kinematic assumption regarding the behavior of the beam cross-sections. The Bernoulli-Euler beam theory is known as the classic beam theory. Their main assumption is that the beam cross-section moves as a rigid body and that it keeps orthogonal to the beam axis. On the Timoshenko beam theory the beam cross-section has rotation degrees of freedom around the beam axis, leading to distortion due to shear. The Timoshenko-Vlasov theory has the non-uniform Vlasov torsion in addition to the Timoshenko beam theory hypothesis. Therefore, it is necessary to introduce the concept of bimoment and bishear as a consequence of the non-uniform torsion of the beam.

The geometrically-exact beam theory may consider Bernoulli-Euler, Timoshenko or more elaborated kinematic assumptions of the cross-section. The main feature of such model is that the cross-section movement may present finite rotations and large translations in space. We here mention some works, basis of current developments: the first developments on this theory were presented on Simo (1985), Simo and Vu Quoc (1991) and Pimenta and Yojo (1993). Although the rotation tensors were expressed by Yojo (1993) using the Euler parameters, the development using Rodrigues parameters were after presented on Pimenta and Campello (2001).

The geometrically-exact beam theory plays a very important role on high-nonlinear engineering structures, such as offshore risers and slender wind turbines. A geometrically-exact model for static offshore risers for oil exploitation was presented by Gay Neto et al. (2014a), which was used to study the riser stability under torsion by Gay Neto and Martins (2013), Gay Neto et al. (2014b) and Wriggers et al. (2015). On these models, the contact between the riser and the seabed is considered, and in some cases a rolling beam to flat surface contact model is used, as presented by Gay Neto et al. (2014a).

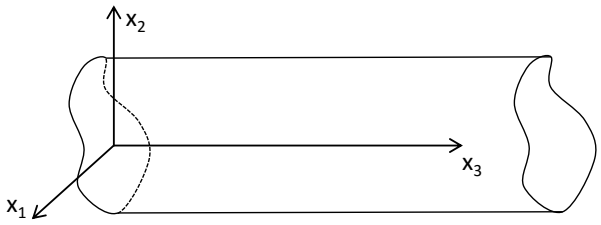

Figure 1: Beam axis notation.

Although all the complexity involved on the development of the geometrically-exact beam formulation, a linear constitutive equation regarding the cross section of a warping-free beam element is given by:

$$\boldsymbol{\sigma} = \boldsymbol{D}\boldsymbol{\varepsilon}, \tag{1}$$

where $\boldsymbol{\sigma}$ is a vector that collects the generalized stresses (internal loads) of the beam and is defined as:

$$\boldsymbol{\sigma} = \begin{bmatrix} N_1 \\ N_2 \\ N_3 \\ M_1 \\ M_2 \\ M_3 \end{bmatrix}, \tag{2}$$

where N_1, N_2 and N_3 are the components of the internal force and M_1, M_2 and M_3 are the components of the internal moment. The variable $\boldsymbol{\varepsilon}$ is a vector that collects the generalized strains of the beam and is defined as

$$\boldsymbol{\varepsilon} = \begin{bmatrix} \eta_1 \\ \eta_2 \\ \eta_3 \\ \kappa_1 \\ \kappa_2 \\ \kappa_3 \end{bmatrix}, \tag{3}$$

and $\boldsymbol{D}$ is the constitutive matrix of the beam as follows

$$\boldsymbol{D} = \begin{bmatrix} GA & 0 & 0 & 0 & 0 & G(S_1^s - S_1) \\ 0 & GA & 0 & 0 & 0 & G(-S_2^s + S_2) \\ 0 & 0 & EA & ES_1 & -ES_2 & 0 \\ 0 & 0 & ES_1 & EI_{11} & -EI_{12} & 0 \\ 0 & 0 & -ES_2 & -EI_{12} & EI_{22} & 0 \\ G(S_1^s - S_1) & G(-S_2^s + S_2) & 0 & 0 & 0 & GI_t \end{bmatrix}, \tag{4}$$

where E is the material Young Modulus, G is the material Shear Modulus, A is the beam cross-section area, S is the first order moment of inertia, I is the second order moment of inertia, I_t is the torsion stiffness and S_1^s and S_2^s are given by:

$$S_1^s = A(g_2 - s_2) \tag{5}$$

$$S_2^s = A(g_1 - s_1), \tag{6}$$

where the (g_1, g_2) are cross-section centroid coordinates and (s_1, s_2) are the shear center coordinates. The subscript numbers indicate from which axis the property is calculated and the 12 subscript is used to refer to the product of inertia. Figure 2 presents a generic beam section located at an arbitrary point $\boldsymbol{O}$, the centroid $\boldsymbol{g}$ in green and the shear center $\boldsymbol{s}$ in red.

1.2 Wind Turbine Blade Cross-Section Profiles

As commented in Section 1, HAWT blades design may be very complex due to all the requirements that it should satisfy such as the dynamic loads, the materials involved, the manufacturing process and others. Due to all of these needs it is very common to have blades with varying cross sections along their length. This solution permits each blade section to be designed according to their specific requirements. It is also very common the usage of two webs,

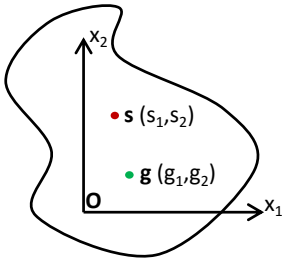

Figure 2: Beam cross-section.

in order to improve the mechanical properties of the cross section. A typical HAWT blade profile is presented in Figure 3, where one may observe an outer shell in black color and two webs in red color.

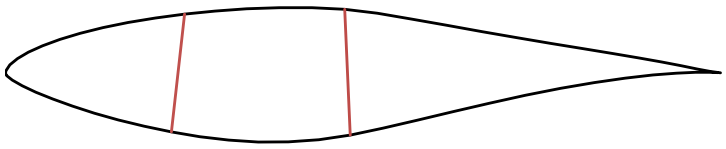

Figure 3: Typical HAWT blade profile.

The first profiles used on HAWT blades were designed by the Nation Advisory Committee for Aeronautics (NACA). The results, however, were not as expected. It was proved then that an aeronautical profile is not necessarily the best profile for an HAWT (Burton et al., 2011).

The early developments of profiles for specific use on HAWT began with a partner work with the National Renewable Energy Laboratory (NREL) and Tangler and Somers (1995). This work produced some families of profiles for specific stall-regulated, variable pitch and variable-rpm wind turbines. Some of the NREL profiles information is available on their website (`https://wind.nrel.gov/airfoils/`). Other families of airfoils designed for HAWT are the Risø airfoils family (Fugslang and Bak, 2004) and the Delft airfoils family (Timmer and van Rooij, 2003).

1.3 Shear Center and Shear Stresses on Thin-Walled Beams

As presented on subsection 1.1, a necessary property to evaluate the constitutive matrix $\boldsymbol{D}$ is the shear center of the beam cross-section. The shear center is a specific point in the cross section where shear forces may be applied, producing no twist. Although this simple definition, the distribution of the shear stresses may be very complex regarding the material of the cross section, thickness considerations and the number of cells. More definitions about the shear center are found in works such as Pilkey (2002) and Fung (1993). The shear center referred to an arbitrary origin $\boldsymbol{O}$ may be defined, assuming the known shear stresses distribution $\boldsymbol{q} = \hat{\boldsymbol{q}}(A)$ from an applied shear force magnitude V, with components V_1 and V_2, in the cross-section plane. It is also possible to calculate each coordinate of the shear center separately. To calculate

the s_1 it is necessary to apply a shear force parallel to the axis 2 such as V_2. An analogue process also applies for the other beam section axis. Therefore, the shear center coordinates are:

$$s_1 = \frac{1}{V_2} \int_A |\boldsymbol{r} \times \boldsymbol{q}| dA \tag{7}$$

$$s_2 = \frac{1}{V_1} \int_A |\boldsymbol{r} \times \boldsymbol{q}| dA, \tag{8}$$

where $\boldsymbol{r}$ measures the distance between the origin $\boldsymbol{O}$ to the s element. Figure 4 presents a beam section, an arbitrary origin $\boldsymbol{O}$ and a thin-walled element s of the beam.

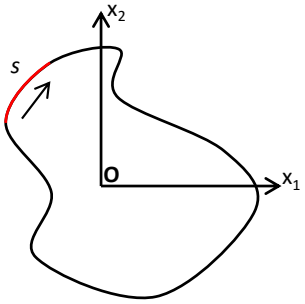

Figure 4: Beam thin-walled section and element s.

Thus, the major difficult arises from finding the shear stress distribution on the cross section of the beam. On this work, in order to reduce the complexity on finding the shear stress distribution, the thin-walled hypothesis is adopted. Furthermore, on this work the shear center follows the definition presented on Megson (2014) and expands it to a multicellular profile. The hypothesis adopted is that since the force is applied at the shear center each cell should have zero twist.

The thin-walled approach allows the consideration of constant stresses across the thickness of the beam. Other simplifications of this hypothesis is that squares and higher order terms of t are neglected on the section properties calculations and that the section is represented by its mid-line. Regarding the thin-walled assumption, according to Megson (2005) there is no exactly definition for a thin-walled structure, however it is pointed that the approximations are reasonably accurate for section which the ratio

$$\frac{t_{max}}{b} < 0.1 \tag{9}$$

where t_{max} is the maximum thickness of the section and b is a typical cross section dimension.

1.4 Torsion on Thin-Walled Beams

The last missing parameter for the constitutive matrix $\boldsymbol{D}$ presented on Subsection 1.1 is the torsion stiffness I_t. The torsion stiffness may be interpreted as the axial rotation stiffness of a given beam cross-section to an applied pure torque. It is defined as

$$GI_t = \frac{T}{\theta} \tag{10}$$

where T is the applied torque, G is the Shear Modulus and θ is the rate of twist of the section. Moreover, in order to calculate the torsion stiffness it is necessary to evaluate the rate of twist response to an applied torque. It is possible to prove, by equilibrium conditions, that a closed section thin-walled beam subject to a pure torque T, without axial constraints, has solution only for a constant shear flow q. On the case of a constant shear flow the rate of twist per unit length may be expressed as

$$\theta = \frac{q}{2GA} \oint \frac{ds}{t}, \tag{11}$$

where A is the enclosed area of the cell, ds is the differential thin-walled element and t is the thickness of the s element. Therefore, the torsion stiffness calculation of a single thin-walled profile may be summarized as:

1. Define a convenient rate of twist θ.
2. Calculate the equivalent shear flow q.
3. Calculate the torsion equivalent T.
4. Use equation 10 to calculate the torsion stiffness GI_t.

Although this simple process for the calculation of a single cell torsion stiffness, the multi-cellular torsion stiffness calculations are quite more complex. This work follows the the multi-cellular torsion stiffness definition presented by Shama (2010). The main hypothesis presented on this work is that each cell has the same twist per unit length. This condition generates one additional equation for each cell and makes the problem determined.

2 WIND TURBINE FEM MODEL

2.1 GIRAFFE

The GIRRAFE platform represents an advance on a previous finite element code named "FemCable", which main motivation was a finite element simulation of offshore structures, more specifically, the simulation of oil explotation risers. More information about the FemCable and their use is available at Gay Neto (2012).

The Generic Interface Readily Accessible for Finite Elements (GIRAFFE) is a generic platform for finite element analysis specially suitable for structural problems which may include translational and rotational DOFs and possible multiphysics applications (Gay Neto, 2015). Although GIRAFFE is not a fully generic platform, it was developed using the C++ object oriented language in a such way that new formulations, including translational and rotational DOFs, may be easily incorporated.

Furthermore, one of the finite element formulations available in GIRAFFE is the geometrically-exact beam presented on the subsection 1.1 which makes it a properly tool for the analysis of a highly nonlinear problem such as an HAWT dynamic simulation.

2.2 Wind Turbine Program

Although the simplicity of an beam-like model, some difficulties may arise to the assembly of an HAWT blade model. Some of the possible difficulties are:

- Varying airfoil shape along the blade.
- Calculation of geometric properties such as torsion stiffness and shear center of each cross-section.

The varying airfoil shape nature of an HAWT blade maybe an important issue since it has a huge variation along the length due to all structural requirements. Furthermore, the common use of webs on the cross section of HAWT blades may turn the calculation of the geometric properties such as the torsion stiffness and the shear center into a very laborious task.

In order to help on these issues it was developed a C# program with a GUI that helps on the geometric description of the blades for an HAWT. The program uses the thin-walled approximation and defines the profile by a set of points and the webs by the index of these points. The program interface is presented on Figure 5.

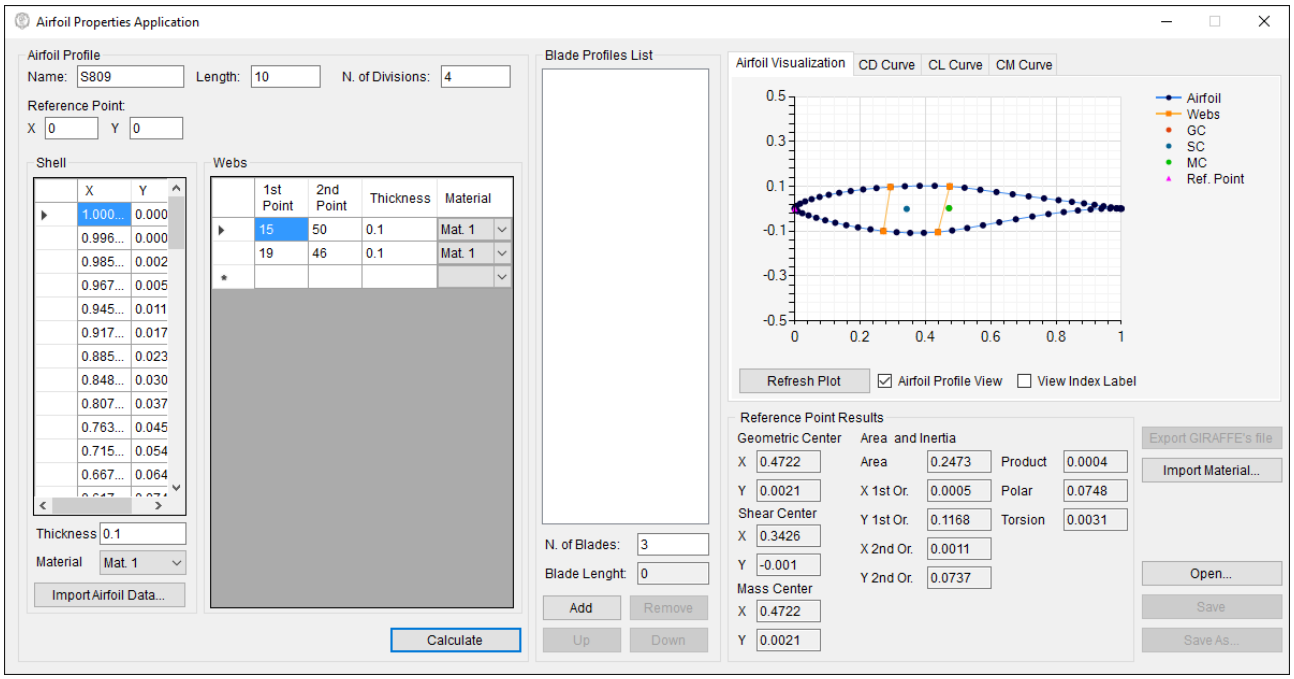

Figure 5: Wind Turbine GUI.

Some of the main features of the program are:

- Instant calculation of airfoil profile geometric properties.
- Permits the creation of a group of airfoil profiles.
- Permits the definition of any point as the beam axis.
- Exports all the necessary information to build the constitutive matrix for the GIRAFFE geometrically-exact beam formulation.

2.3 FEM Model Description

The aim of this subsection is to describe, in detail, all the characteristics that defines the wind turbine finite element model in analysis. This work presents dynamic simulation of the blades of an HAWT based on gravitational loads and a prescribed rotation on the central node of the wind turbine.

Some characteristics of the finite element model are:

- 3 equally-spaced wind turbine blades;
- 9 m length blade;
- 30 equally-spaced nodes per blade, total of 91 nodes;
- 3-node beam elements, total of 45 beam elements;
- 100 s simulation with integration time step of 0.01 s;
- 9.81 m/s^2 gravity acceleration to the negative z direction;
- Newmark integration method as presented on Ibrahimbegovic and Mikdad (1998) and Ibrahimbegovic and Mamouri (2000) with $\beta = 0.28$ and $\gamma = 0.54$.

In order to have a more realistic model, the local axis of each blade section is rotated on its containing plane. Table 1 summarizes the local vectors $\boldsymbol{e_1}$ and $\boldsymbol{e_3}$ that defines the local orientation of the cross-sections.

Blade	$\boldsymbol{e_1}$	$\boldsymbol{e_3}$
1	$(0, 0.9701, 0.2425)$	$(1, 0, 0)$
2	$(-0.2100, 0.9701, -0.1212)$	$(-0.5, 0, 0.8660)$
3	$(0.2100, 0.9701, -0.1212)$	$(-0.5, 0, -0.8660)$

Table 1: Local axis orientation of the blades.

The material properties of the blades has the following characteristics

- Young Modulus $E = 200$ GPa;
- Poisson coefficient $\nu = 0.3$;
- Density $\rho = 7500$ kg/m^3;

Although there is a known airfoil profile variation along the length of an HAWT blade, this work describes the blade using 4 profiles. The selection of these profiles is based on the NREL typical blades profiles described on Burton et al. (2011) for an stall regulated HAWT with diameter from 10 to 20 m. All the airfoil information used is available at the NREL website (`http://wind.nrel.gov/airfoils/`). The adopted thickness of the outer shell and the webs is 0.05 m. Table 2 summarize the profiles used on each beam section from 1 to 15 of the blade starting from the central node to the tip of the blade.

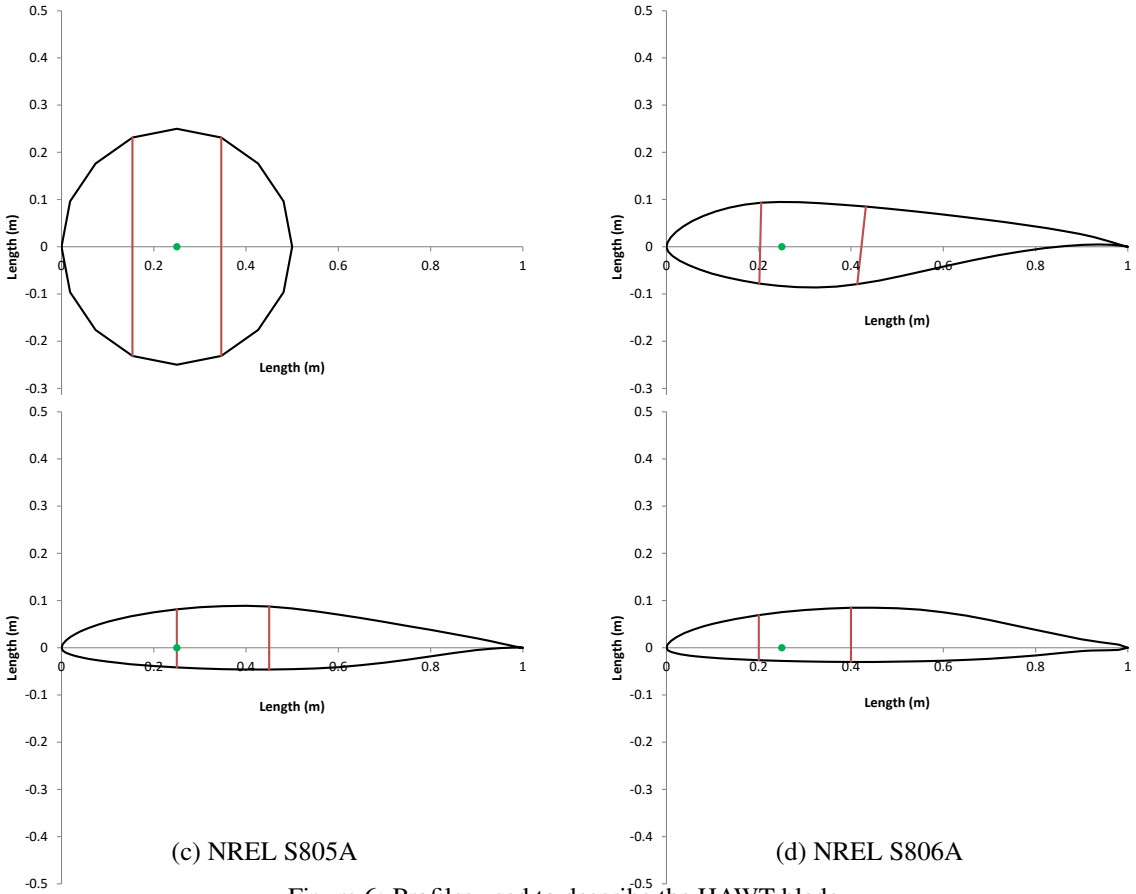
Beam	Airfoil Profile
1-2	16 point discrete circle (0.5 diameter)
3-7	NREL S807
8-12	NREL S805A
13-15	NREL S806A

Table 2: HAWT blade profiles.

Figure 6 presents the profiles used along the blade's length, their webs in red and the beam axis in green. The horizontal axis of of the profiles on Figure 6 represent the beam axis 1 and the vertical axis represent the beam axis 2 (see notation in Figure 1).

In order to evaluate the dynamics of the wind turbine structure some elements of the model will be monitored. In other words, these elements will have their displacements and reactions monitored on every time step of the simulation. On this work the monitored elements will be:

- Central wind turbine node (node 1);
- Tip node of each blade (nodes 31, 61 and 91);
- Beam element number 12;



(c) NREL S805A (d) NREL S806A

Figure 6: Profiles used to describe the HAWT blade.

Figure 7 presents the wind turbine model and the monitors highlighted in red. The horizontal axis represents the x global orientation while the vertical axis represents the z global orientation and node 1 is at $(0, 0, 0)$.

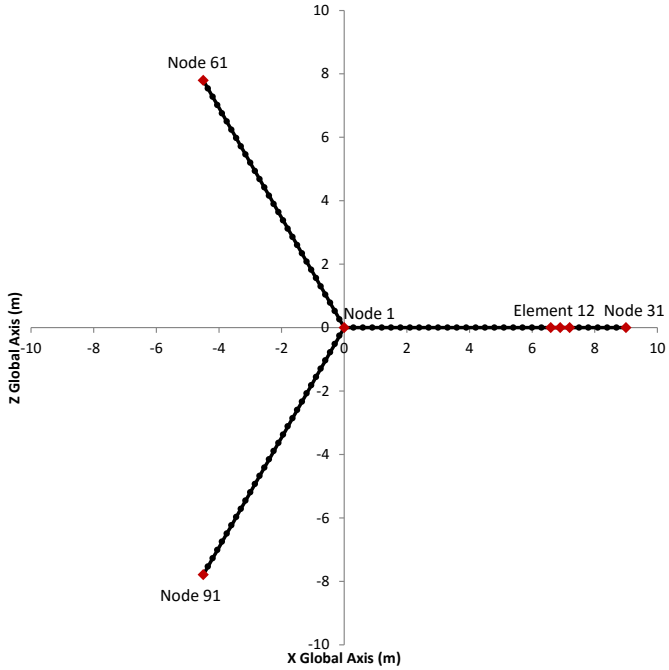


Figure 7: Wind turbine finite element model with monitors in red.

3 RESULTS

As previously described this dynamic simulation is induced by a prescribed rotation on the central node of the wind turbine. Although this simplification, the node 1 prescribed rotation expressed in radians is divided in 4 steps, described as follows:

- Step 1 - The rotation velocity increases from $t = 0s$ to $t = 20s$ according to the function $\phi_1(t) = 15\sin(0.025\pi t - \pi/2) + 15$;
- Step 2 - The rotation is velocity is maintained constant from $t = 20s$ to $t = 60s$, $\phi_2 = 15 + 1.2(t - 20)$;
- Step 3 - The rotation decreases from $t = 60s$ to $t = 80s$ according to the function $\phi_3(t) = 15\sin(0.025\pi t - \pi/2) + 63$;
- Step 4 - The rotation ceases from $t = 80s$ to $t = 100s$, $\phi_4 = 78$

Figure 8 presents a graphic that describes the node 1 rotation versus time. It is possible to note on this graph all the steps described previously.

On wind turbines the rotation of the blades yields on very important dynamic loads for the tower. These loads have huge influence on the structural behavior of an HAWT since they are crucial to evaluate aspects such as peak loads and fatigue. On this simulation the interface between the tower and the blades is monitored on node 1. Although the gravitational and inertial loads acting on the xz plane that contains the wind turbine blades, the axial peak forces occurred on the y direction. Figure 9 presents the y forces along time for node 1.

These peak loads may come from the way that the geometry of the blades was described. It follows that the centroid of each blade may not lie on the xz plane and that the axis of each blade is twisted on the plane of its cross section.

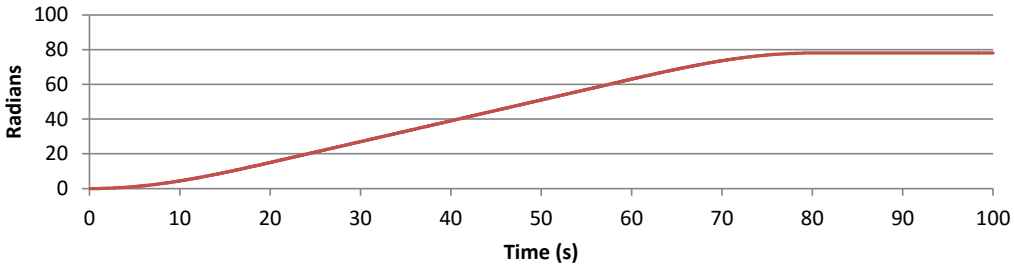

Figure 8: Node 1 rotation versus time.

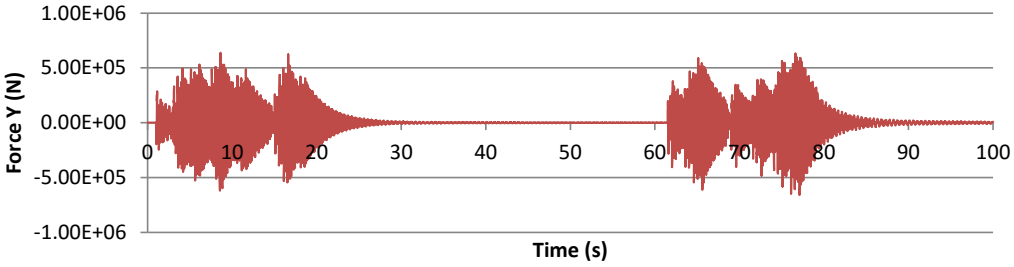

Figure 9: Force y along time.

It is also important to note that the peak loads occurs on step 1 and 3 that are the ones where there is change on the rotation velocity. This result is very interesting since the energy of a wind turbine comes from the motion resistance of the turbine inside the nacelle. Moreover, large force peaks may come from a severe acceleration/breaking operation applied to the rotor.

Figure 10 presents the z forces along time. It is seen on this graphic that the loads on the z direction are very relevant and include a non-null average, due to the structure self-weight. On steps 3 and 4 when the turbine is at a constant rotation speed and the turbine is stopped, the z direction force is the main force acting on node 1.

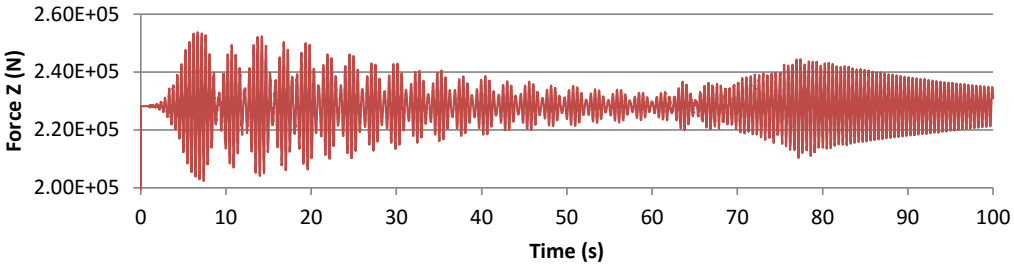

Figure 10: Force z along time.

Figure 11 presents the node 1 x forces along time. This graphic shows that although there are peak loads on steps 1 and 3, the highest peak loads are on step 4. The peak loads experienced

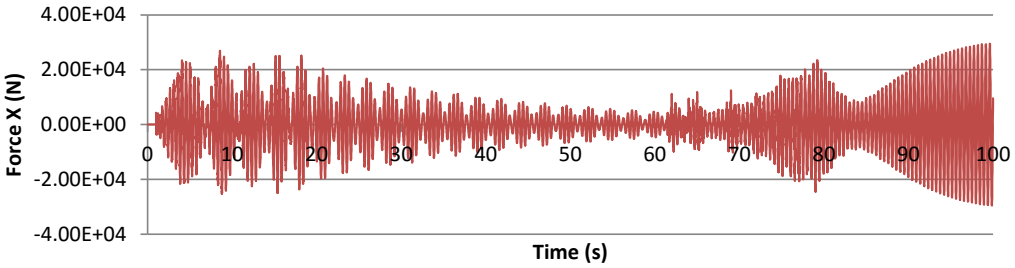

Figure 11: Force x along time.

on step 4 occurs due to the excitation of the blade tip and is considerably relevant.

One way to confirm the cyclic behavior of the dynamic model is by the analysis of the nodal displacement of each blade's tip. Figure 12 presents the x direction displacement of the nodes 31, 61 and 91.

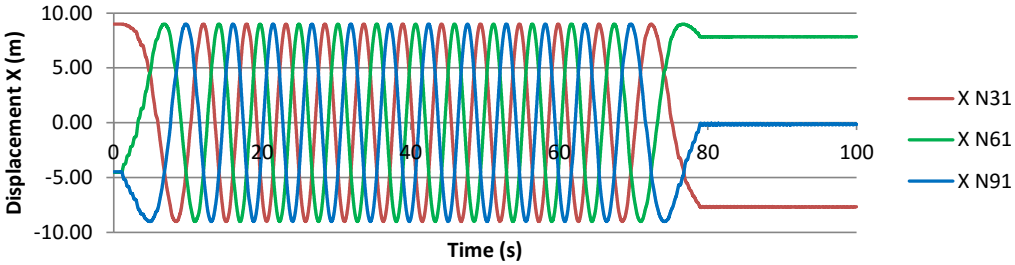

Figure 12: Displacement x along time of nodes 31, 61 and 91.

It is possible to note from this graphic that the turbine behaves as expected regarding the cyclic position of the coordinates. It is also interesting to note the node displacements when the turbine stops. Figure 13 presents a graphic of the x displacement of node 91 from $t = 80s$ to $t = 100s$. On this graphic is seen that the node position still oscillating, however tending to stop. This behavior was expected since there is an inherent numerical dumping on the simulation process due to the choice of Newmark integration parameters.

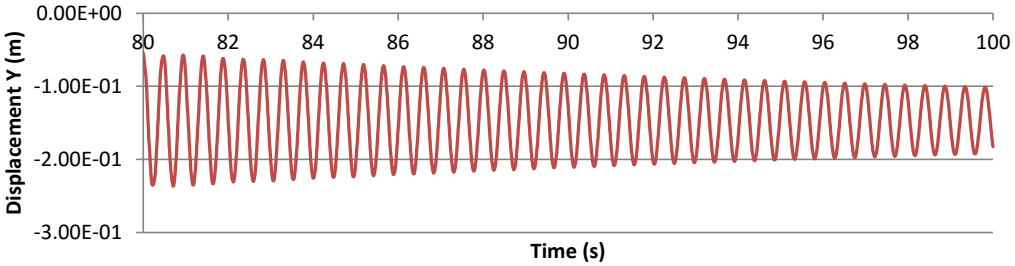

Figure 13: X displacement of node 91 from $t = 80$ to $t = 100$.

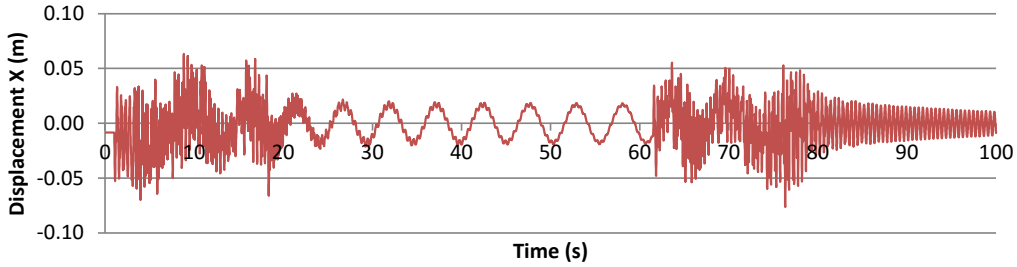

Figure 14: Y displacement of node 91 .

It is also interesting to see that the tip of the blade has out of plane displacements that appears from the geometry issues already discussed. Figure 14 presents the graphic that shows the out of plane displacement y of node 91. It seen that even when the wind turbine is at constant speed (step 2), there is an out of plane oscillating behavior of the node.

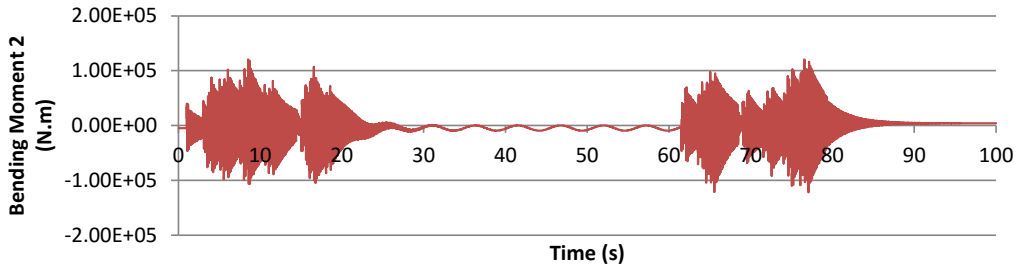

Figure 15: Bending moment around element axis 2 along time.

Despite of all the possible analysis of an HAWT dynamic simulation, the main usual goal is to evaluate the generalized stresses (tension, bending moment and torsion moment) acting on a specific part of the blade. On this simulation the part of interest on the blade structure is represented by the beam element 12. The bending moments around element axis 2 along time is shown on Figure 15. On this graphic is possible to note that the peak loads occurs when there is change on the rotation velocity of the wind turbine. It is also interesting to note that this bending moment still oscillating even when the rotation speed is constant (step 2).

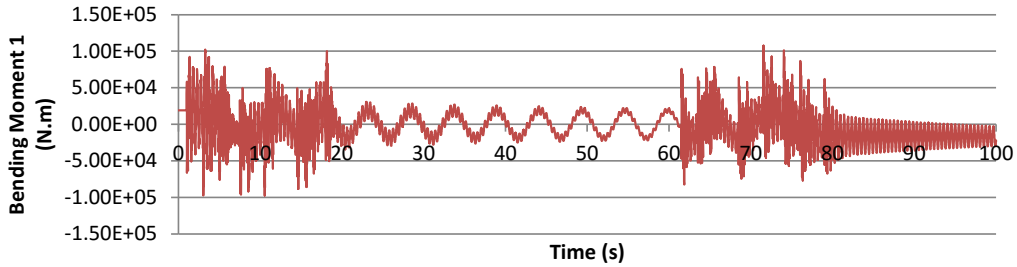

Figure 16: Bending moment around element axis 1 along time.

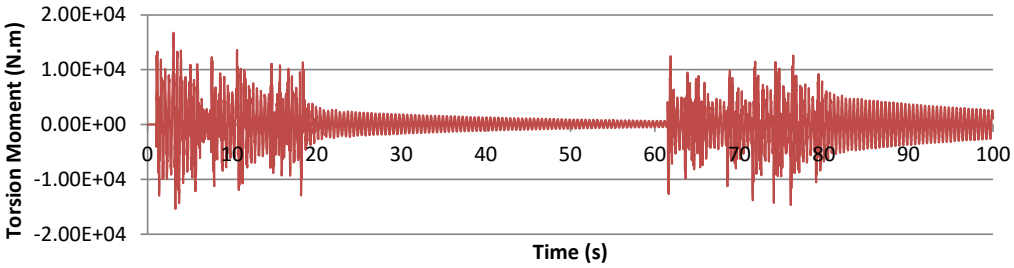

Figure 17: Torsion moment along time.

The bending moment around element axis 1 along time is presented on Figure 16. As other results, the peak loads are on steps 1 and 3. However the oscillating moment on step 4 indicates that the beam is still in movement.

Finally, the torsion moments along time is presented on Figure 17. Despite of the peak loads on steps 1 and 3, the torsion moments on step 4 are very relevant. Therefore, it is possible to assume that the stopping process of an wind turbine should be soft enough to avoid the possible high torsion moments on the blade.

4 CONCLUSION

The main conclusion of this work is that the GIRAFFE platform and the Wind Turbine program are very promising tools to evaluate the dynamics of an HAWT. The GIRAFFE geometrically-exact beam regarding the possibility of any cross section and beam axis position turns it into a very suitable tool for this kind of simulation. Furthermore, the user-friendliness of the Wind Turbine Program on handling defined cross sections and geometric properties calculations on a GUI is a very helpful tool for HAWT simulations.

Although on this simulation the aerodynamic loads were not included, it was seen that the variation of speed of an HAWT induces very relevant internal loads on the structure.

4.1 Future Works

Some of the possible advances regarding this work are:

- Verification of the thin-walled hypothesis;
- Verification of the shear center precision using shell elements;
- Verification of the torsion stiffness precision using shell elements;
- Inclusion of the aerodynamic loads.

EXTENDED FORMULA FOR THE CRITICAL VELOCITY OF A LOAD MOVING ON A BEAM SUPPORTED BY A FINITE DEPTH FOUNDATION

Zuzana Dimitrovová

Departamento de Engenharia Civil, Faculdade de Ciências e Tecnologia, Universidade Nova de Lisboa and IDMEC, Instituto Superior Técnico, Universidade de Lisboa, Lisboa, Portugal
e-mail: zdim@fct.unl.pt

Keywords: Critical velocity, Finite soil depth, Moving load, Integral transforms, Analytical solution, Moving window method.

Abstract. *In this paper, an extended formula for the critical velocity of a uniformly moving load is derived. It is assumed that the load is traversing an infinite beam supported by finite depth foundation under plane strain condition. The critical velocity is extracted by parametric analysis applied on the analytical solution of the steady state deflection beam shape. Results obtained are compared with the previously published results of this author, where simplified assumptions were implemented on the shear contribution. It is confirmed that there is an interaction between the beam and the foundation and thus the critical velocity is dependent on the mass ratio defined as the square root of the fraction of the foundation mass to the beam mass. Several options for damping are also analysed and results of displacement fields are compared with finite element simulations. In order to obtain steady-state form of the finite element results, the enhanced moving widow method is implemented in software ANSYS.*

1 INTRODUCTION

The response of rails to moving loads is important research topic of high-speed railway transportation. If simple geometries of the track and subsoil are considered, it can be assumed that the track structure acts as a continuously supported beam resting on a uniform layer of springs. Two distinct interpretations are used, either the beam is modelled by the rail and the layer of springs represents the underlying remainder of the track structure, or an equivalent beam encompassing the whole track is used and the spring layer stands for the subgrade or foundation. The stiffness of the spring layer along the length of the beam is named as the track modulus and defines Winkler's model, which is often referred to as a "one-parameter model". Such a simplified model was traditionally used to estimate the critical velocity of moving trains.

The first solution of steady-state dynamic response of an infinite beam on elastic foundation traversed by moving load was presented by Timoshenko [1]. In [2], the moving coordinate system is introduced to convert the governing equation to ordinary differential equation that can be solved by the Fourier integral transform. In [3], the concept of the dynamic stiffness matrix is implemented. Two semi-infinite beams are solved for and connected by continuity equations. Then the critical velocity can be determined as the velocity that ensures the nullity of the determinant of the dynamic stiffness matrix. This concept was extended to finite and infinite beams with sudden change in foundation stiffness [4].

If the beam is modelled as the rail, the classical formula, predicts very high critical velocity, giving impression that is unreachable by high-speed trains and consequently no attention was paid to this fact during expansions of high-speed railway network. Unfortunately, practical experience showed that the realistic critical velocity can be much lower [5] and should be related to the wave-velocity of propagation in the foundation. Therefore, in further investigations the spring layer was replaced by elastic half-space and the critical velocity was determined as the Rayleigh-wave velocity of propagation [6].

Nevertheless, it is important to release, that only finite active depth of the foundation soils should be included in the analysis. Under such assumption, it was shown in [7] that there is an interaction between the beam and the foundation. In [7] only simplified plane models of the foundation were used for analyses of finite and infinite beams, but it was confirmed that the critical velocity is not given either by the classical formula from [2] or by the lowest wave-velocity of propagation in the foundation, but there is a smooth transition between these two extreme values governed by the mass ratio. For a low mass ratio, the critical velocity approaches the classical formula and for a higher mass ratio, it approaches the lowest wave-velocity of propagation in the foundation. In this paper generalizations, in conformity with [8] are derived. It is proven that in such extension, the final results depend on the interface condition between the beam and the foundation.

2 CRITICAL VELOCITY

The critical velocity of the load traversing an infinite Euler-Bernoulli beam on an elastic foundation is given by the classical formula [2]

$$v_{cr} = \sqrt[4]{\frac{4kEI}{m^2}} \tag{1}$$

where m and EI stand for the mass per unit length and the bending stiffness of the beam, respectively, and k for the Winkler constant of the foundation. If the beam is modelled by the rail, then Eq. (1) predicts a critical velocity that is generally much higher than the one ob-

served in reality. The main reason is related to the fact that there is no mass in the foundation and thus no wave propagation is possible. Several works have been published on this subject replacing the spring layer by an elastic half-space and concluding that the critical velocity corresponds to the Rayleigh-wave velocity of propagation, which is the slowest wave-velocity [6].

Nevertheless, better estimation should account for the active finite depth of the foundation, which can either be the actual depth at which a stiff substratum is located or a depth after which no appreciable soil deformations occur. Under simplified assumptions on a plane model under plane strain conditions, it was derived in [7] that the critical velocity is governed by the mass ratio according to approximately

$$V_{cr} = v_{cr}\left[\left(1-\vartheta_s\right)\sqrt{\frac{2}{2+M^{2+\sqrt{\vartheta_s}}}}+\vartheta_s\right] \tag{2}$$

where V_{cr} is the new value of the critical velocity, ϑ_s is the shear ratio defined as $\vartheta_s = v_s / v_{cr}$ with v_s being the shear-wave velocity, and M is the mass ratio defined as the square root of the foundation mass to the beam mass. Thus, for a low mass ratio, the critical velocity approaches the classical value v_{cr} and for a higher mass ratio, it approaches the velocity of propagation of shear waves in the foundation. In this simplified model horizontal displacements were neglected and therefore the Rayleigh velocity could not be detected. Due to the proximity of these two velocities defined by the approximate formula

$$\frac{v_R}{v_s} = \frac{0.87+1.12\upsilon}{1+\upsilon} \tag{3}$$

where υ is the soil Poisson ratio and v_R is the Rayleigh-wave velocity, this does not have to be considered a disadvantage.

In this paper new results are derived in conformity with [8]. Deductions from [8] are simplified by considering only a constant moving force, thus the analytical solution can be restricted only to its steady-state part. Final results of the critical velocity, which can then be extracted by parametric analyses, are dependent on the interface condition between the beam and the foundation. However, there is only a small difference between the three possibilities: the previously published approximate formula (2) and results according to two options for the interface condition. Namely, results with the interface condition in form of zero horizontal displacement give values very similar to Eq. (2) and results obeying the zero shear stress condition have the asymptotic tendency to slightly lower velocity, the velocity of propagation of Rayleigh waves.

Deflection shapes and adequacy of the interface condition are analysed by finite element results. In order to obtain steady-state form of the finite element results, the enhanced moving widow method is implemented in software ANSYS as described in [9].

3 THE MODEL AND ITS SOLUTION

It is assumed that the load is traversing an infinite beam supported by a foundation of finite depth *H*, as depicted on Figure 1. It is further assumed that: (i) the beam obeys linear elastic Euler-Bernoulli theory; (ii) the beam vertical displacement is measured from the equilibrium deflection caused by the beam weight; (iii) the foundation is represented by a finite strip of width *b* under plane strain condition; (iv) the foundation soil is linear elastic homogeneous material.

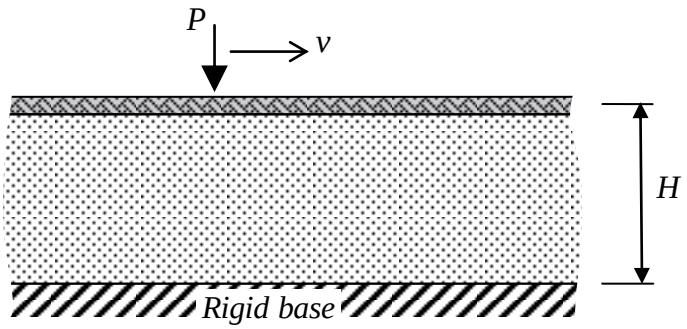

Figure 1: Infinite beam on an elastic foundation of finite depth subjected to a moving load.

The governing equations for determination of the beam deflection shape and displacement fields in the foundation soil are given by

$$\mu\Delta\mathbf{u}+\left(\lambda+\mu\right)\nabla\left(\nabla\cdot\mathbf{u}\right)=\rho\mathbf{u}_{,tt} \tag{4}$$

$$EIw_{,xxxx}\left(x,t\right)+c_b w_{,t}\left(x,t\right)+mw_{,tt}\left(x,t\right)+p\left(x,t\right)=P\delta\left(x-vt\right) \tag{5}$$

where $\mathbf{u}=\left(u_x,u_z\right)$ is the displacement field in the foundation, λ, μ are Lame's constants of the soil, ρ is the soil density and t is the time. Overall this paper, derivatives will be designated by the corresponding variable symbol in the subscript position, preceded by a comma. Moreover, ∇ is the gradient and Δ is the Laplace operators applied on spatial variables x, z. Further, P is the moving load, v is its velocity, p is the foundation pressure and c_b is the viscous damping coefficient of the beam. The unknown beam deflection $w\left(x,t\right)$, spatial coordinate z and P are assumed positive when acting downward. Spatial coordinate x is positive to the right, the load travels from the left to the right and finally, δ is the Dirac delta function.

Damping in the soil can be assumed as hysteretic

$$\lambda=\lambda_0\left(1+\mathrm{i}\eta_h\right),\ \mu=\mu_0\left(1+\mathrm{i}\eta_h\right) \tag{6}$$

or viscous

$$\lambda=\lambda_0\left(1+c_s\bullet_{,t}\right),\ \mu=\mu_0\left(1+c_s\bullet_{,t}\right) \tag{7}$$

where η_h is the loss factor of the soil and c_s is the coefficient of the viscous damping in the soil.

The solution method follows these steps: firstly, the governing equations for the soil layer are expressed in terms of displacement potentials. Then all equations are simplified by introduction of moving coordinates and leaving only the terms that contribute to the steady-state part of the solution. After that several dimensionless variables are introduced to facilitate the equations manipulation and posterior results analyses. The main solution method is the single Fourier transform, which allows analytical solution of all displacement and stress components in the frequency domain. The inverse transform is accomplished numerically. Dimensionless variables allow identifying results for all possible input data combinations. Except for the damping values, which define viscous damping in the beam, viscous and hysteretic damping in the foundation, results depend only on the mass ratio M, the velocity ratio $\alpha=v/v_{cr}$, the shear ratio ϑ_s and soil Poisson's ratio υ.

4 THE ENHANCED MOVING WINDOW METHOD

Finite element confirmation of steady-state analytical predictions in infinite media is generally a complicated issue because it is difficult to choose the correct (i) size of the model, (ii) size of the finite elements; (iii) type of the boundary conditions and (iv) a method that would allow deflection fields stabilization. The model itself must be large enough in order to eliminate satisfactorily transient effects due to a sudden placement of the load on the structure and, on the other hand, small enough to be computationally accessible. The edges of the finite elements must be sufficiently small in order to represent adequately propagating waves. The boundary conditions are even more delicate issue. The dynamic analysis of solids of infinite dimensions with discrete methods such as finite elements calls for the use of special boundary that are normally referred to as absorbing, non-reflecting or transmitting boundaries. The purpose of these special boundaries is to prevent wave reflections at the edges of the mathematical models used, which, by necessity, must remain finite in size. A number of these boundaries have been proposed in the past with recourse to various mathematical or physical principles. Unfortunately, none of the transmitting boundaries can fully prevent all possible reflections under the full range of possible incident angles.

Some of the difficulties named above could be overcome by implementation of the moving window method. In the moving window method the load is kept still, and the finite element model of the railway track moves in the direction opposing the originally assumed load movement. This can be achieved by several ways. Either the finite elements are altered in order to implement the effect of the load velocity [10], or results are shifted against the load.

A shift of results is impossible in commercial finite element software, because such an operation is usually protected against inappropriate usage. Implementation of the enhanced moving window method in commercial finite element software ANSYS is described in [9]. The method is tested on one-, two- and three-dimensional models. It is shown that the steady-state response of an infinite structure can be obtained with sufficient accuracy, which significantly reduces the calculation time by reduction of both, the model size and the analysis time.

When the model is large enough, periodic boundary conditions can be used on the front and rear faces of the model. Regarding the bottom face, other considerations must be taken. A reduction of the model depth by representative springs and viscous boundary is used here according to [11]. These distributed elastic springs are defined as:

$$k_n = \frac{\lambda_0 + 2\mu_0}{H - h},\ k_t = \frac{\mu_0}{H - h} \tag{8}$$

where k_n and k_t are spring stiffnesses in the normal and tangential directions, respectively and h is the depth that is modelled by finite elements. These elastic boundaries allows introduction of absorbing boundaries, which help to stabilization of the results.

5 NUMERICAL RESULTS

Final results are shown in Figure 2 for shear ratio 0.5 and soil Poisson ratio 0.2. It is seen that results from [7] and new results with zero displacement interface condition are quite proximate, especially regarding the asymptotic value for higher mass ratio. When zero shear is admitted at the interface, than the asymptotic tendency directs to lower velocity. In such a case the ratio given by Eq. (2) indicates that this velocity is the Rayleigh-wave velocity of propagation.

Deflection shapes were confirmed by the finite element results exploiting the enhanced moving window method. One case is shown in Figure 3. The case presented considers two

rails supported by soft foundation with input data summarized in Table 1. In the first part of Figure 3 finite element solution is compared to the analytical solution with zero horizontal displacement interface condition. It is seen that the coincidence is very good. The other part compares the analytical solutions for the two interface conditions. It can be observed that the zero shear condition allows for higher displacements.

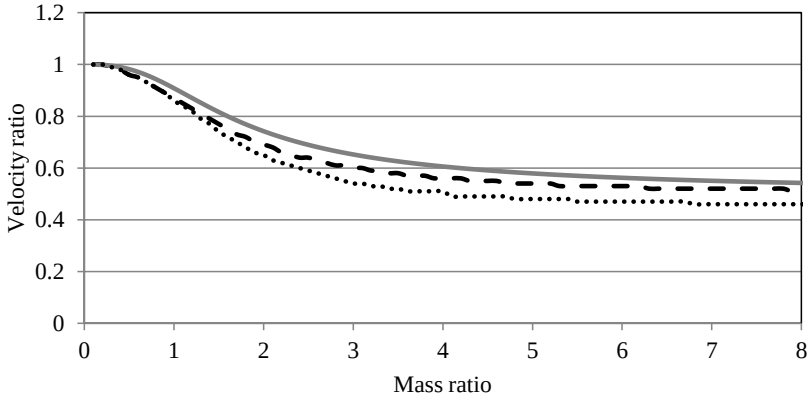

Figure 2: Critical velocity as a function of the mass ratio for shear ratio 0.5: previous estimate according to Eq. (2) (grey), solution with zero displacement interface condition (black dashed), solution with zero shear interface condition (black dotted).

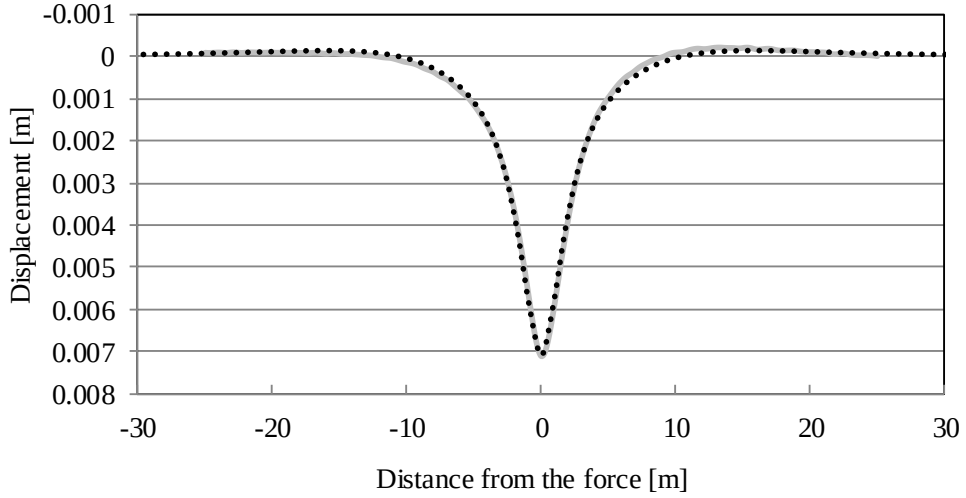
Property	Value
Beam bending stiffness EI (MN·m^2)	12.8
Beam mass per unit length m (kg·m^{-1})	120
Soil Young's modulus E_s (MN·m^{-2})	10
Soil Poisson's ratio υ	0.3
Soil density ρ (kg·m^{-3})	1850
Active depth H (m)	12
Moving force P (kN)	200
Velocity v (m·s^{-1})	50

Table 1: Numerical data used with a unit strip width of the soil.



a)

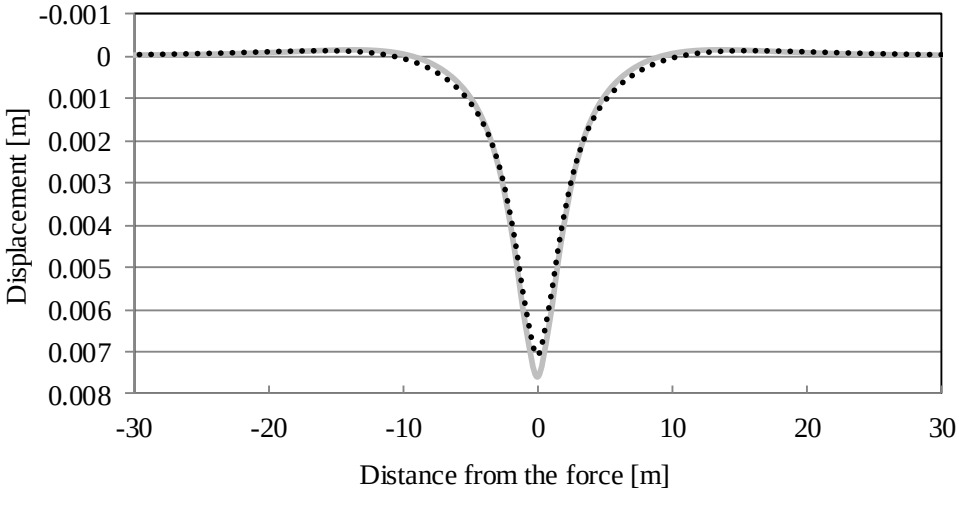


Figure 3: Deflection shapes comparison: a) finite element solution (grey) and solution with zero displacement interface condition (black dotted); b) solution with zero shear interface condition (grey) and solution with zero displacement interface condition (black dotted).

In addition, shear stress and horizontal displacement were extracted in the vertical cut below the load from the finite element solution. It is seen that it is more adequate to assume zero horizontal displacement at the interface between the beam and the foundation.

6 CONCLUSIONS

In this contribution, the critical velocity of a uniformly moving load on a beam supported by a finite depth foundation was analysed. Generalizations of the method published in [7] were derived. The new approach follows developments in [8] but simplifies the analysis by admitting only a constant moving force. Analytical results for the deflection beam shape and displacement fields in the foundation are obtained by the Fourier transform. The inverse transform is accomplished numerically.

Final results of the critical velocity are then extracted by parametric analyses. It is confirmed that there is an interaction between the beam and the foundation, and thus there is a smooth transition between the classical value of the critical velocity and the lowest velocity of wave propagation in the foundation, depending on the assumptions adopted. However, the new results are dependent on the interface condition between the beam and the foundation. Only small differences occur between the three possibilities: the previously published results in [7] and results according to two options for the interface condition. Results with the interface condition in form of zero horizontal displacement give values very similar to the ones published in [7] and results obeying the zero shear stress condition have the asymptotic tendency to slightly lower velocity, the velocity of propagation of Rayleigh waves.

Deflection shapes and adequacy of the interface condition were analysed by finite element results exploiting the enhanced moving widow method implemented in software ANSYS. It was confirmed that, if the model considers the beam axis coincident with the soil upper surface, which is the common finite element approach, then it is more adequate to assume that the horizontal displacements are zero at the interface.

Keywords: Zigzag theory, multilayer plates, sandwich plates.

Abstract. *The paper gives a critical review and new accomplishments of the displacement-based zigzag theories for laminated composite and sandwich structures, with special emphasis to the underlying ideas, relative strengths and weaknesses. Some numerical results substantiate the conclusions.*

1. INTRODUCTION

Composite laminates and sandwich structures are characterized by high stiffness-to-weight and strength-to-weight ratios and by the possibility to be tailored according to the particular application. Sandwich structures exhibit further promising properties such as high-energy absorption, impact resistance, noise and vibration reduction, excellent damping behavior, [1, 2]**.** Due to these appealing properties, in the last thirty years an increasing number of high-performance and lightweight primary load-bearing structures in the aerospace, automotive, nuclear, naval and civil constructions, are comprised of relatively thick composite laminates and sandwich structures with one hundred or more layers. Such structures are inherently heterogeneous and anisotropic and may suffer unwanted failure due to transverse shearing and out-of-plane stretching.

As failure predictions call for an accurate evaluation of the stress field within each layer of laminated composite and sandwich structures, affordable computational costs for these structures are the main concern. In order for the computational costs to be affordable, accurate computational models for multilayered composite and sandwich structures need to be independent of number of layers and of their micro-structure.

Different approaches have been adopted to face these modeling challenges [3]. A first broad classification could be the following one: three-dimensional (3D) models and two-dimensional (2D) models. Example of 3D models can be found in [4,5,6,7,8,9]. The reduction of the 3D model to the 2D model rely generally on the use of the *axiomatic approach*, that is, on the a-priori assumed trough-the-thickness distribution of the primary variables. In the *displacement-based approach* [10,11], the primary variables are generalized displacements (displacement, rotation, etc.); in the *mixed approach* [12], both generalized displacements and stresses (generally, out-of-plane stresses) are adopted as primary variables.

Following [3], the 2D plate/shell models can be divided into Equivalent Single Layer (ESL) models (also known as Smeared Laminate models) and Layer-wise (LW) models according to the type of kinematics assumed.

Equivalent Single Layer (ESL) (also known as Smeared Laminate) models are generally based on a smooth expansion (generally, a power series expansion) over the whole laminate thickness of the displacement field in terms of the thickness-wise co-ordinate. This means that the kinematics along the thickness is assumed to be at least C^1-continuous and independent of the laminate lay-up. As a consequence, the multilayer structure is substituted with a plate/shell made by an equivalent single layer. While computationally not expensive, ESL models are generally not accurate, especially when through-the-thickness distribution of strains and stresses are the main concern and the laminate is highly heterogeneous.

Among the displacement-based ESL models, the most popular are the Classical Lamination Plate Theory (CLPT), based on the Kirchhoff's plate theory [13] and the First-order Shear Deformation Theory (FSDT), based on the Mindlin's and Reissner's plate theories [14,15] . Both CLPT and FSDT make use of a linear expansion of the in-plane displacement. In addition to the weaknesses of the ESL models, it is well-know that FSDT needs ad hoc shear correction factors to yield accurate results [14,15,16,17,18]. As well-known, CLPT and FSDT perform relatively well in predicting global quantities, such as, transverse displacement, fundamental natural frequency and buckling load for thin and moderately thick laminates that have a relatively low degree of transverse heterogeneity; however, their accuracy diminishes rapidly when they are used to predict the displacement and stress fields in highly heterogeneous and/or thick composite and sandwich laminates [11,19,16,20,21]. Improved predictions can be obtained using higher order through-the-thickness expansions of the displacements and/or stresses [22]. Computationally efficient analytical models for beams,

plates and shells that account for transverse shear and thickness-stretch deformations have recently been advanced in [23,24,25]. Reviews on the ESL theories are given in [26,27,28].

Contrary to the ESL models, Layer-wise (LW) models [3,29,30,31,32,33,34,35,36] make a-priori assumptions on the distribution of the displacement and stress fields within each layer. Limiting the discussion to the displacement-based approach, LW models postulates a C^0-continuous kinematics, that is a distribution of displacements (first of all, in-plane displacements) continuous along the thickness with first derivative showing a jump at layer interfaces (the reason of this discontinuity will be explained hereinafter). According to [26], the LW models are further divided into (i) *layer dependent models*, wherein the number of kinematic variables increases with the number of layers; and (ii) *layer independent models*, wherein the number of variables remains constant and independent on the number of layers. Hereafter in this paper, the terminology Layer-wise (LW) models will be adopted only to indicate the layer dependent LW models, while the terminology Zigzag (ZZ) models will be adopted for the layer independent LW models.

Layer dependent LW models [29,30,31,34] are generally very accurate but computationally costly; in these models the number of unknowns increases with the number of layers, as in 3D models. As we said, in order for the computational costs to be affordable (this is especially relevant for nonlinear and/or progressive failure analysis of thick laminates made up of hundreds of layers), computational models for multilayered composite and sandwich structures need to be independent of number of layers and of their micro-structure, while preserving the ability to take into account the distortion of cross-section typical in composite laminate and sandwich structures.

From the above, we easily understand the strong interest for computational models allowing to take into account the layered nature of the composite laminates and sandwich structures, while preserving the affordable computational cost of the ESL models.

To date, ZZ models seem to be the best candidates to meet these requirements, [37,38,39,40,41,42,43,44,45,46,47,48,49,50,51,52,53,54,55,56,57,58,59,60,61,62,63,64,65,66,67]. In fact, they attempt to combine the advantages of ESL and LW models. In the ZZ models (as in ESL models), the number of kinematic unknowns does not depend on the number of layers. The in-plane displacements combine the smooth (generally, polynomial) functions defined across the entire laminate thickness (linear [37,38,39,40,41,52,55,56,57] or higher-order polynomial, [42,43,44,45,46,51,53,58,59] with the piecewise linear (i.e., zigzag) distributions. The zigzag contributions enable a more realistic modeling of the in-plane cross-sectional distortion in multilayered composites, giving rise to a computationally efficient theory for the modeling of relatively thick laminated composite and sandwich structures. The zigzag model predictions are often as accurate as those obtained by the computationally expensive LW and higher-order models. LW-based zigzag models have also been explored in [30,31].

Extensions of the kinematics of the Di Sciuva's First-order zigzag theory (linear zigzag model) include, among other: (i) extension to the linear [41] and nonlinear [48] multilayered shell theory; (ii) general lamination lay-up [42,47,49]; (iii) satisfaction of the shear stress-free boundary conditions on the top and bottom surfaces [44,46,50]; (iv) polynomial expansion of the global part to any degree [47,49]; (v) extension to the dynamics, buckling [16,47,49,48]; (vi) thermal effects [68],[69]; (vii) sublaminates approach [68,69,70,71,72,73,74]; (viii) inclusion of von Kármán geometrically nonlinear effects [16,48,49]; (ix) extension to the nonlinear theory of laminated composites with damaged interfaces [49,68,69,74,75,76]; (x) inclusion of the transverse normal strain and stress [74,77,78]; (xi) visco-elastic effects [79]; (xii) active control of beams, plates and shells [80].

Averill [55] pointed out two drawbacks of the classical zigzag models, (1) the transverse shear stresses derived from the constitutive equations vanish erroneously along clamped boundaries, and that (2) C^1-continuous finite element approximations are required for the transverse deflection variable leading to a type of approximation that is particularly undesirable for plate and shell finite elements.

In an attempt to resolve the aforementioned drawbacks of the classical zigzag models, Tessler, Di Sciuva and Gherlone developed the Refined Zigzag Theory (RZT), [61,62,63,64,65,66,67] that makes use of a set of novel zigzag functions and uses FSDT as a baseline. The transverse shear stresses are allowed to be discontinuous along the ply interfaces; this relaxation of stress continuity permits more accurate predictions of all response quantities including the transverse shear stresses that provide accurate average values of the ply-level stresses. RZT overcomes the key drawbacks of the original zigzag theories, i.e., (1) transverse shear stresses and forces do not vanish erroneously along clamped edges, and (2) since the strains are defined in term of first derivatives of the kinematic variables, computationally efficient C^0-continuous finite elements are readily formulated. The RZT has shown to be very accurate over a wide range of aspect ratios and material systems, including thick laminates with a high degree of transverse shear flexibility and heterogeneity [61,62,63,64,65,66,67].

Another first-order zigzag theory largely used in the literature [53,58,81,82,83,84,85] is the Murakami's zigzag theory [52], which shares with RZT the same kinematics, but different zigzag functions. As will be seen later, Murakami's zigzag functions are basically of geometrical nature, in the sense that the jump in their thickness-wise derivative depends only on the thickness of each layer, when the same jump in the derivative of the RZT zigzag functions depends on the lay-up and on the transverse shear elastic compliance of the layers.

In closing this introductory overview of the zigzag approaches for the analysis of laminated composite laminates and sandwich structures, it should be noted that they belong to the more general modern approaches, known either as Multi-scale or Global-local approaches [86,87,88,89,90,91,92], where the displacement field within each layeris represented as a superposition of a layer-wise field, defined over each layer, and a global field spanning the entire laminate. Thus, the governing equations exhibit explicit coupling between effects associated with different (global and local) length scales. This multi-scale representation allows the accuracy of layer-wise theories to be achieved at a reduced computational cost [88]. It also facilitates the use of highly refined kinematic descriptions in regions of critical interest with reduced-order descriptions elsewhere in the structure, and affords a straight-forward means of transitioning between such descriptions. The distribution of available computational resources in this manner can improve both accuracy and efficiency, and can be carried out adaptively to maximize its potential benefits.

Aim of this paper is to give a review of the first-order displacement-based zigzag theories for composite laminates and sandwich structures, with special emphasis to the underlying ideas, relative strengths and weaknesses. First, the basic ideas on which rests the first-order Di Sciuva's zigzag theory are presented. This will serve as a starting point for introducing the main concern of the paper: a rewiev and comparison of the first-order Refined Zigzag Theory (RZT) and the first-order Murakami's Zigzag theory. The paper ends with the presentation of some Numerical results and the Conclusions.

2. GEOMETRICAL PRELIMINARIES

We consider a multi-layered plate of constant thickness $2h$, built-up of a finite number N of linearly elastic anisotropic layers, each of them exhibiting different mechanical properties, see Figure 1. The layers are joined by N-1 interfaces and may be either perfectly bonded or have displacement jumps across the interface due to interfacial damage. The points of the plate are referred to a global orthogonal Cartesian co-ordinate system (**x**,,z), with $\mathbf{x} \equiv (x_\alpha, \alpha = 1,2)$ the reference plane of the plate and z the thickness-wise co-ordinate. In the body of paper, Italic indices range from 1 to 3, Greek indices range from 1 to 2 and the summation convention on the repeated indices on a monomial expression is adopted. In general, superscript (k) placed in brackets on the right of any quantity identifies its affiliation to the layer *k*. The layer *k* has a constant thickness, $2h^{(k)}$. The coordinates of the bottom and top faces and of the mid-surface of the k*th* layer are denoted by $z_B^{(k)}$, $z_T^{(k)}$ and $z_M^{(k)}$, respectively. The interfacial coordinate between the k*th* and (k+1)*th* layers is denoted by $z^{(k)}$. $z_{(k)}$, so that $z_{(k)} = z_T^{(k)} = z_B^{(k+1)}$.

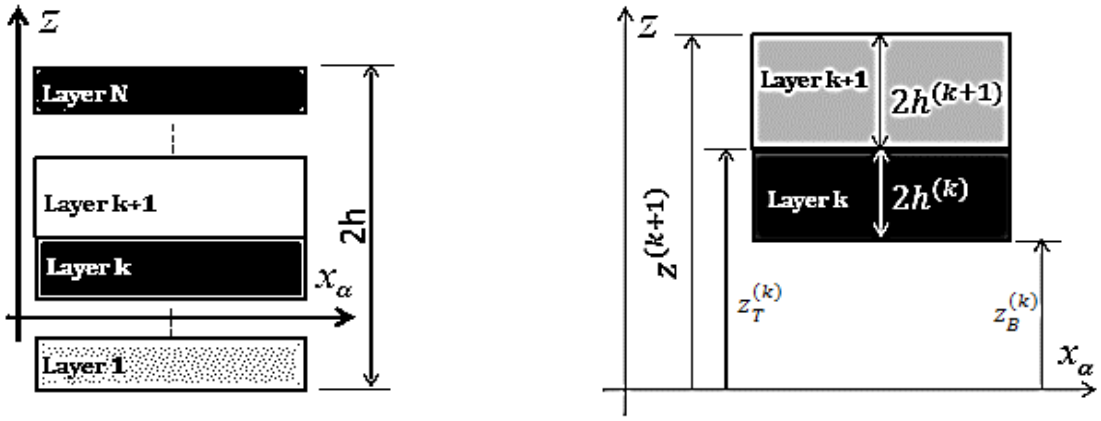

Fig. 1-Geometry and layer numbering of the multilayered plate.

For further convenience, we introduce non-dimensional local layer coordinates, $\zeta^{(k)}$, such that $\zeta^{(k)} \in [-1, +1]$, and k=1,...,N,

$$\zeta^{(k)} = \frac{z^{(k)} - z_M^{(k)}}{h^{(k)}} = \frac{z^{(k)} - z_B^{(k)}}{h^{(k)}} - 1 \text{ with } z^{(k)} \equiv z \in [z_B^{(k)}, z_T^{(k)}].$$

The origin of this local layer coordinate is located $z_M^{(k)}$abroad the coordinate system.

3. CONTACT AND BOUNDARY CONDITIONS

In order to understand the assumed kinematics of zigzag models for multilayered plates, we recall some important issues from 3D theory of elasticity. From 3D theory of elasticity it is well known that displacements and stresses must satisfy interlayer continuity conditions at the interface between two perfectly bonded layers and boundary conditions on the top and bottom surfaces.

3.1 Interlayer continuity or contact conditions

(i) continuity of the displacement field (geometric)

$$U_i^{(k)}\left(\boldsymbol{x}, z_T^{(k)}\right) = U_i^{(k+1)}\left(\boldsymbol{x}, z_B^{(k+1)}\right) \tag{1}$$

(ii) continuity of the transverse shear and normal stresses and of the gradient of the transverse normal stress (static)

$$\sigma_{iz}^{(k)}\left(\boldsymbol{x}, z_T^{(k)}\right) = \sigma_{iz}^{(k+1)}\left(\boldsymbol{x}, z_B^{(k)}\right) \tag{2}$$

$$\partial_z\sigma_{zz}^{(k)}\left(\boldsymbol{x}, z_T^{(k)}\right) = \partial_z\sigma_{zz}^{(k+1)}\left(\boldsymbol{x}, z_B^{(k)}\right) \tag{3}$$

where $U_i^{(k)}(\boldsymbol{x}, z)$ is the displacement component along the x_i $(i = 1,2,z)$ co-ordinate axis, and σ_{iz} are the components of the stress tensor.

3.2 Boundary conditions on the top (T) and bottom (B) surfaces

If the bottom and top surfaces of the laminate are loaded only by the pressure $\bar{p}_z^{(B)}(\boldsymbol{x}, -h)$ and $\bar{p}_z^{(T)}(\boldsymbol{x}, +h)$, then on the bottom (B) and top (T) surfaces of the laminate the following boundary conditions apply:

(i) On the transverse shear stresses (free-transverse shear stresses boundary conditions)

$$\sigma_{\alpha z}^{(1)}\left(\boldsymbol{x}, z_B^{(1)}\right) = \sigma_{\alpha z}^{(N)}\left(\boldsymbol{x}, z_T^{(N)}\right) = 0 \tag{4}$$

(ii) On the transverse normal stress and its gradient

$$\sigma_{zz}^{(1)}\left(\boldsymbol{x}, z_B^{(1)}\right) = \bar{p}_z^{(B)}(\boldsymbol{x}, -h); \qquad \sigma_{zz}^{(N)}\left(\boldsymbol{x}, z_T^{(N)}\right) = \bar{p}_z^{(T)}(\boldsymbol{x}, +h) \tag{5}$$

$$\partial_z\sigma_{zz}^{(1)}\left(\boldsymbol{x}, z_B^{(1)}\right) = \partial_z\sigma_{zz}^{(N)}\left(\boldsymbol{x}, z_T^{(N)}\right) = 0 \tag{6}$$

i.e., the transverse normal stresses must be equals to the applied pressure and the transverse shear stresses and the gradient of the transverse normal stress must vanishe.

4. EQUIVALENT SINGLE LAYER (ESL) THEORIES

As we said, Equivalent Single Layer (ESL) theories are generally based on a smooth expansion (generally, a power series expansion) over the whole laminate thickness of the displacement field in terms of the thickness-wise co-ordinate.

As a general expression for the expansion, we can assume the following one [41],

$$U_i\ (\mathbf{x},z) = \mathcal{Z}_{r(i)}(z)\widehat{U}_i^{(r(i))}(\mathbf{x}) = (\mathbf{x},z)\ \ (i = 1,2,3),\ \ r(i) = 0,1,2,\dots,R_i \tag{7}$$

where $\mathcal{Z}_{r(i)}(z)$ stands for any set of a-priori chosen linearly independent functions. Generally, they are assumed to be a power series of z,

$$\mathcal{Z}_{r(i)}(z) = z^r\ ,\quad r = 0,1,2,..,R_i \tag{8}$$

or their orthogonal corresponding Legendre's polynomial of first kind. They are known as polynomial theories.

This means that the kinematics along the thickness is assumed to be at least C^1-continuous and independent of the laminate lay-up. As a consequence, the multilayer structure is substituted with a plate/shell made by an equivalent single layer.

Almost all the polynomials theories assume

$$R_1 = R_2 > R_3 \tag{9}$$

In addition, many theories make the further assumption, $R_1 = R_2 > R_3 = 0$. In order to emphasize the order of expansion adopted for the in-plane displacement (i=1,2) and the transverse displacement (i=3), the following notation is adopted, $\{R, R_3\} -$ order polynomial theory.

4.1 ESL First-order Shear Deformation Theory-FSDT

This theory assumes the following kinematics [3,14,15],

$$\begin{aligned} U_\alpha\ (\mathbf{x},z) &= \widehat{U}_\alpha^{(0)}(\mathbf{x}) + z\widehat{U}_\alpha^{(1)}(\mathbf{x}) \qquad (\alpha = 1,2),\ \ R_\alpha = 1 \\ U_3\ (\mathbf{x},z) &= \widehat{U}_3^{(0)}(\mathbf{x}) = w^{(0)}(\mathbf{x}) \qquad\qquad\qquad\quad R_3 = 0 \end{aligned} \tag{10}$$

Following the previous terminology, this ESL First-order shear deformation theory is a $\{1,0\} -$ order polynomial theory.

4.2 ESL Third-order Shear Deformation Theory-TSDT

Most of the third-order shear deformation theories start by assuming the following kinematics [10]

$$\begin{aligned} U_\alpha\ (\mathbf{x},z) &= \widehat{U}_\alpha^{(0)}(\mathbf{x}) + z\widehat{U}_\alpha^{(1)}(\mathbf{x}) + z^2\widehat{U}_\alpha^{(2)}(\mathbf{x}) + z^3\widehat{U}_\alpha^{(3)}(\mathbf{x}) \qquad (\alpha = 1,2),\ \ R_\alpha = 3 \\ U_3\ (\mathbf{x},z) &= \widehat{U}_3^{(0)}(\mathbf{x}) = w^{(0)} \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad R_3 = 0 \end{aligned} \tag{11}$$

Following the previous terminology, this ESL Third-order shear deformation theory is a $\{3,0\} -$ order polynomial theory.

Requiring the transverse shear stresses to vanish on the top and bottom surfaces of the plate ($z = \pm h$), the number of generalized in-plane displacements reduces from 4 to 2. For example, one well-known TSDT is Reddy's TSDT [3,22]. In this theory, for the in-plane displacements the following expression is assumed

$$U_\alpha(\mathbf{x},z) = \widehat{U}_\alpha^{(0)}(\mathbf{x}) + z\widehat{U}_\alpha^{(1)}(\mathbf{x}) + z^3\widehat{U}_\alpha^{(3)}(\mathbf{x}) \tag{12}$$

where

$$\widehat{U}_\alpha^{(3)}(\mathbf{x}) = -\frac{1}{3h^2}\left(\partial_\alpha w^{(0)}(\mathbf{x}) + \widehat{U}_\alpha^{(1)}(\mathbf{x})\right) \tag{13}$$

In Eq.(13) and in the following, $\partial_i\ (.) = \frac{\partial(.)}{\partial x_i}$.

While computationally not expensive, ESL models are generally not accurate, especially when through-the-thickness distribution of strains and stresses are the main concern and the laminate is highly heterogeneous.

5. FIRST-ORDER DI SCIUVA's ZIGZAG THEORY-DSCZZT

Guided by these constraints, the majority of zigzag theories attempt to model accurately the transverse shear deformability and cross-section warping by satisfying the continuity constraints on the displacement field (Fig.2a) and on the inter-laminar shear stresses (Fig.2b). In other words, the displacement field is C^0 -continuous across the plate thickness, as well as the transverse shear stresses.

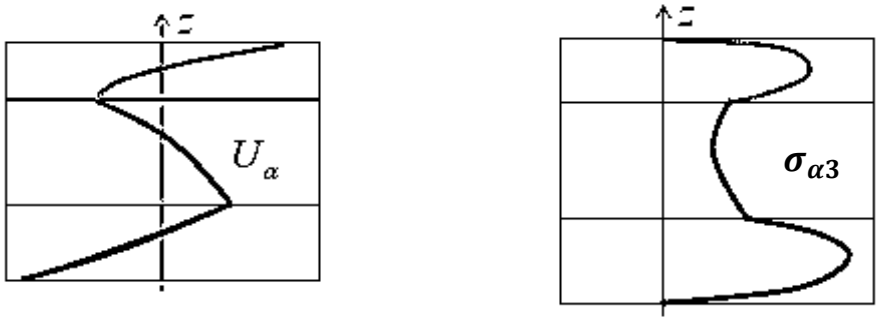

Fig. 2 - Thickness-wise distribution of the (a) in-plane displacements and (b) transverse shear stresses. Both the distributions are of the zigzag type, that is, their derivative along z is discontinuous at the interface (zigzag behavior).

As most of the plate theories assume constant transverse displacement in the z-direction and zero transverse normal stress, the contact conditions on the transverse normal stress and its gradient (Eqs. 5-6) are a-priori satisfied, thus reducing the interface static contact conditions to the transverse shear stresses (Eq. 4). For material possessing a plane of elastic symmetry parallel to the reference plane of the plate, Hooke's law allows to write these contact conditions in terms of transverse shear elastic coefficients and transverse shear strains.

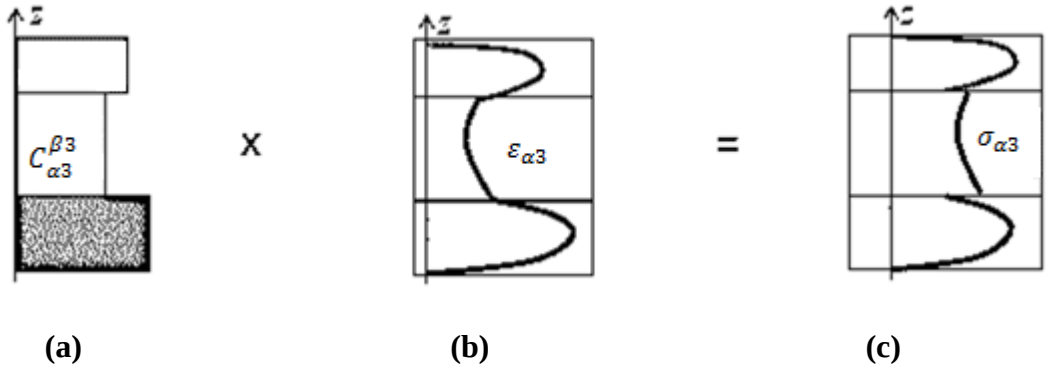
$$C_{\alpha 3}^{\beta 3(k)}\epsilon_{\beta 3}^{(k)}\left(\mathbf{x}, z_T^{(k)}\right) = C_{\alpha 3}^{\beta 3(k+1)}\epsilon_{\beta 3}^{(k+1)}\left(\mathbf{x}, z_B^{(k+1)}\right) \tag{14}$$

where $2\epsilon_{\beta 3} = \partial_z\ U_\alpha\ + \partial_\alpha\ U_z$ are the transverse shear components of the strain tensor and and $C_{\alpha 3}^{\beta 3(k)}$ the transverse shear components of the elasticity tensor.

From Eq. (14) we easily deduce that in general the contact conditions on the transverse shear stresses cannot be met when the transverse shear elastic coefficients vary between two adjacent layers. Usually, the thickness-wise distribution of the elastic coefficients in

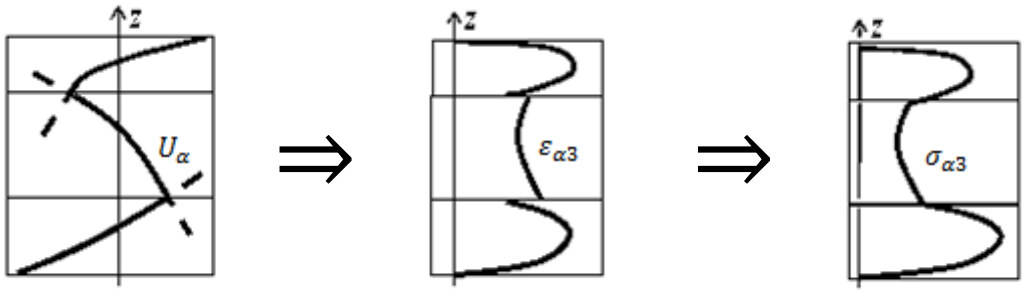
laminated plates are piecewise constant functions of the thickness coordinate. Then, if the through-the-thickness distribution of the in-plane displacements are assumed to be smooth functions, i.e., at least C^1 -continuous functions of the z-coordinate, the transverse shear stress will have jumps across the interfaces proportional to the jumps in the transverse shear elastic coefficients. We conclude that in order to be the **transverse shear stresses continuous at the interfaces, the transverse shear strains must have a jump at the interfaces.**

By taking into account the expression of the transverse shear strain, we conclude that the **gradient of the in-plane displacements must be discontinuous at the interfaces,** that is the **in-plane displacements need to be $\boldsymbol{C^{(0)}}$ −continuous,** that is, $\partial_z\, U_\alpha^{(k)}(\mathbf{x}, z_T^{(k)}) \neq \partial_z\, U_\alpha^{(k+1)}\left(\mathbf{x}, z_B^{(k+1)}\right)$. Figure 4 shows graphically this.



(a) **(b)** **(c)**

Fig. 3 - Typical thickness-wise distributions of (a) transverse shear elastic stiffness coefficients, (b) transverse shear strains, and (c) transverse shear stresses, in a laminated structures if the in-plane displacements are assumed to be at least C^1 -continuous functions of the z-coordinate.



(a) **(b)** **(c)**

Fig. 4 - (a) C^0 -continuous in-plane displacements (zig-zag pattern); (b) Jumps in the transverse shear strains; (c) C^0 -continuous transverse shear stresses (zig-zag pattern).

Zigzag theories seek to meet this requirements by adopting a kinematics having a number of generalized displacements as the corresponding ESL theory [16,37,38,40]. To do this, the in-plane displacement field within each layer is taken to be composed of the superposition of

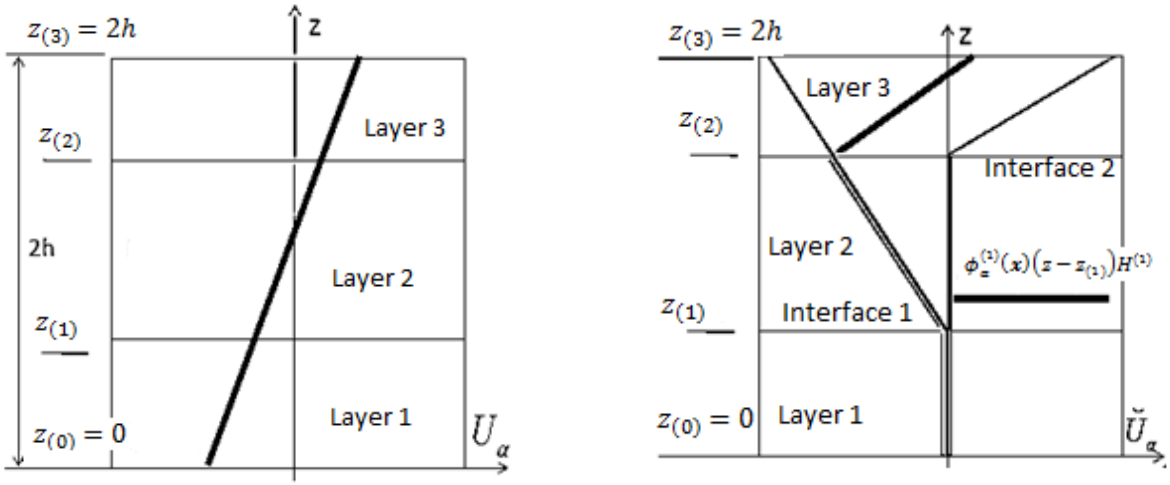
global and local contributions, while the transverse displacement is assumed to be constant over the thickness.

$$U_\alpha^{(k)}(\mathbf{x},z) = \widehat{U}_\alpha^{(k)}(\mathbf{x},z) + \breve{U}_\alpha^{(k)}(\mathbf{x},z) \;\; (\alpha = 1,2)$$
$$U_z \;(\mathbf{x},z) = w(\mathbf{x}) \tag{15}$$

In Eq.(15) $\widehat{U}_\alpha^{(k)}(\mathbf{x},z)$ gives the global kinematics (see, Eq. 7) and $\breve{U}_\alpha^{(k)}(\mathbf{x},z)$ the local enrichment.

In order to introduce the underlying ideas of the zigzag theories without excessive mathematical formalism, I will refer to the First-order zigzag plate theory.

In this zigzag theory, the Global kinematics is the same as that of the ESL First-Order Shear Deformation Theory (Eq. 10), that is, a linear expansion of the in-plane displacements (Figure 5(a)) [16,37,38,40].



(a) **(b)**

Fig. 5 - (a) Global ESL FSDT and (b) local enrichment in the Di Sciuva's FSDZZT.

The local enrichment, known as ***zigzag function***, is given by the expression

$$\breve{U}_\alpha^{(k)}(\mathbf{x},z) = \sum_{q=1}^{k-1} \emptyset_\alpha^{(q)}(\mathbf{x})(z - z_{(q)})H^{(q)} \tag{16}$$

where $\emptyset_\alpha^{(q)}$ are unknown generalized displacements and

$$H^{(q)} = H\left(z - z_{(q)}\right) = \begin{cases} 0 & z \le z_{(q)} \\ 1 & z > z_{(q)} \end{cases}$$

is the Heaviside unit function.

Eq. (16) is the expansion for the local enrichment used to model multilayered plates by enforcing the continuity of the transverse shear stresses at the interfaces (C^0 – contribution),

as is evident from the analytical expression and from the graphs shown in figure 5(b) for the case of a three-layer laminate.

It is easy to convince that the zigzag local enrichment,

(a) is a continuous piece-wise linear function of the z coordinate (it satisfy a-priori the interface continuity conditions on the displacements);

(b) has piece-wise constant first derivative;

(c) adds N-1 unknown generalized displacements $\emptyset_\alpha$ for each coordinate directions;

(d) is zero on the first layer.

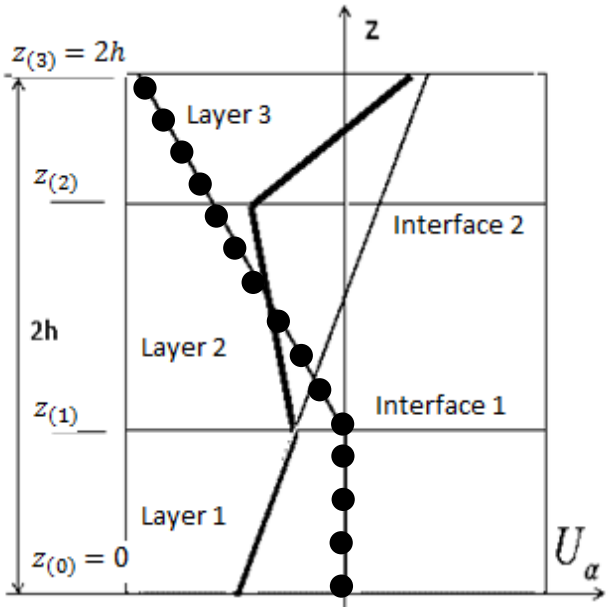


Fig. 6 - Global ESL FSDT (———), local zigzag enrichment (●—●—●) and resulting kinematics (⟶) of Di Sciuva's FSDZZT.

Figure 6 shows the global contribution (ESL FSDT), the zigzag function relative to the contrivìbution of the first interface (see, Fig. 5(b)) and the resulting kinematics adopted in First-order Di Sciuva's zigzag theory-FSDZZT, [16,37,38,40].

Since this zigzag function satisfy a-priori the interface continuity conditions on the displacements, it adds N-1 unknown generalized displacements for each co-ordinate directions. By taking into account that there are N-1 interface continuity conditions on the transverse shear stresses to be satisfied, it follows that, by satisfying these contact conditions, we can compute the N-1 unknowns generalized displacements $\emptyset_\alpha$ in terms of the global generalized displacements.

For example, for laminates with layers of orthotropic materials, the result is the following one,[16,37,38,40]

$$\widehat{U}_\alpha^{(k)}(\mathbf{x},z) = \widehat{U}_\alpha^{(0)}(\mathbf{x}) + z\widehat{U}_\alpha^{(1)}(\mathbf{x}); \qquad \breve{U}_\alpha^{(k)}(\mathbf{x},z) = f_{DSC\alpha}^{(k)}(z)\gamma_\alpha(\mathbf{x}) \tag{17}$$

where

$$\gamma_\alpha = \widehat{U}_\alpha^{(1)}(\mathbf{x}) + \partial_\alpha w(\mathbf{x}) \tag{18}$$

is the shear strain at reference plane and the zigzag function has the following very simple expression

$$f_{DSC\alpha}^{(k)}(z) = \sum_{q=1}^{k-1} a_{\alpha}^{(q)}(z - z_{(q)})H^{(q)} \tag{19}$$

where

$$a_{\alpha}^{(q)} = \left(\frac{C_{\alpha 3}^{\alpha 3(q)}}{C_{\alpha 3}^{\alpha 3(q-1)}} - 1\right)\left(1 + \sum_{j=1}^{q-1} a_{\alpha}^{(j)}\right) \tag{20}$$

are the ***interface continuity constants***. They are functions only of the transverse shear elastic coefficients.

Note that this first-order zigzag plate theory as five unknowns, as in ESL FSDT! This is the strength of the Di Sciuva's zigzag theory. On the other hand, because of the fulfilment of the continuity conditions the model estimates constant transverse shear stresses across the plate thickness. Thus, it is not able to fulfill the conditions of zero transverse shear stresses on the top and bottom plate surfaces. This is the weakness of this zigzag theory.

6. FIRST-ORDER REFINED ZIGZAG THEORY-RZT

As anticipated in the Introduction, in addition to the advantages highlighted above, and to the following ones (i) no shear correction factors are required, (ii) very accurate distribution of the transverse shear stresses are obtained from the integration of the local equilibrium equations, (iii) finite elements based on the First-order Shear Deformation Zigzag Theory are free from shear locking effects, the Di Sciuva's First-order Shear Deformation Zigzag Theory also suffers some deficiencies due to the fulfillment of the contact conditions of the transverse shear stresses. These weaknesses can be summarized as follows, (i) constant transverse shear stresses distribution along the plate thickness, (ii) classical clamped boundary conditions give zero transverse shear strains and, thus, zero transverse shear stresses at the clamped edges, when these last are obtained from the constitutive equations, (iii) due to the presence of $\partial_{\alpha} w$ (see, Eqs. (17) and (18)) in the in-plane displacement field, C^1 shape functions are required, in formulating beam, plate and shell finite elements. FSDT requires C^0 shape functions.

The first and third deficiency are specific of the First-order Shear Deformation Zigzag theory, i.e., higher-order zigzag theories does not suffer of these drawbacks. The second apply in the general case. The third deficiency, concerning the need for C^1 finite elements, has been addressed and solved in [93] in the framework of the Third-order Shear Deformation Zigzag theory.

To overcome the first two drawbacks, Tessler, Di Sciuva and Gherlone in a series of recent papers [61,62,63,64,65] advanced a new version of the first-order zigzag theory, named Refined Zigzag Theory-RZT.

Concerning the kinematics, the starting point is the same as in the Di Sciuva's first-order shear deformation zigzag plate theory, that is, Eq.(15), as the same is the global contribution, Eq. (17a) (that of the first-order shear deformation theory) and the local enrichment, that is, a piecewise linear zigzag function, whose starting mathematical expression is

$$\breve{U}_{\alpha}\left(\mathbf{x}, \zeta^{(k)}\right) = L_B\left(\zeta^{(k)}\right)\breve{U}_{\alpha B}^{(k)}(\mathbf{x}) + L_T\left(\zeta^{(k)}\right)\breve{U}_{\alpha T}^{(k)}(\mathbf{x}) \tag{20}$$

where $\breve{U}_{\alpha B}^{(k)}(\mathbf{x})$ and $\breve{U}_{\alpha T}^{(k)}(\mathbf{x})$ stand for the displacements on the bottom and top surfaces of the layer *k*, and

$$L_B(\zeta^{(k)}) = \frac{1}{2}\left(1-\zeta^{(k)}\right); \quad L_T(\zeta^{(k)}) = \frac{1}{2}\left(1+\zeta^{(k)}\right) \qquad -1 \le \zeta^{(k)} \le +1 \tag{21}$$

are linear Lagrange's interpolation polynomials.
So, the zigzag enrichment adds 2N unknowns generalized displacements for each co-ordinate directions, $\breve{U}_{\alpha}^{(B,k)}(\mathbf{x})$ and $\breve{U}_{\alpha}^{(T,k)}(\mathbf{x})$.

Let us summarize what has been achieved. For each co-ordinate directions, we have 2N unknown generalized displacements and 2(N-1) constraints (interface continuity conditions). This result in 2 free generalized displacements. In RZT this freedom has been exploited by adding the condition that the local contribution is zero on the top and bottom surfaces of the whole plate, as depicted in figure 7 for a three-layer laminate.

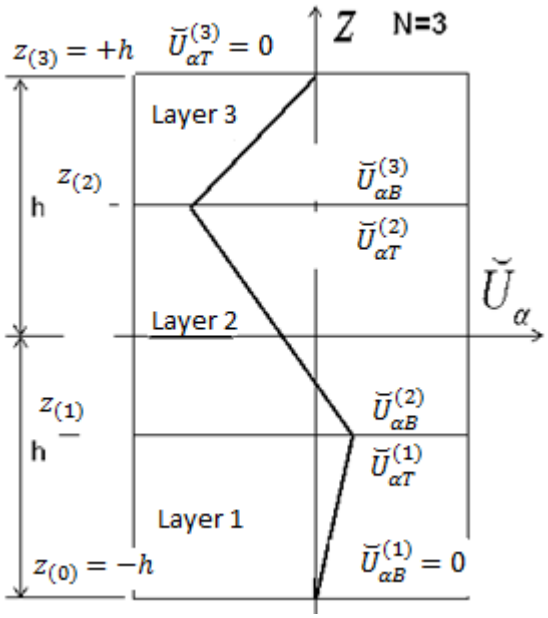

Fig. 7 – Refined Zigzag function for a three-layer laminate.

Where is the difference? The difference is in the expression of the refined zigzag function, $f_{RZT}(z)$.

In an attempt to overcome the drawbacks of Di Sciuva's first-order zigzag theory, i.e., transverse shear stresses are constant over the whole thickness of the plate, transverse shear stresses vanish at clamped end and C^1 shape functions are required in the finite element formulation, in the Refined zigzag theory the continuity conditions on the transverse shear stresses are partially relaxed.

Generalizing the previous results of the Di Sciuva's first-order zigzag theory, FSDZZT, Eq. (17b), RZT starts by writing the local kinematics in the following way

$$\breve{U}_{\alpha}^{(k)}(\mathbf{x}, z) = f_{RZT\alpha}^{(k)}(z)\psi_{\alpha}(\mathbf{x}) \tag{22}$$

where $\psi_\alpha(\mathbf{x})$ is the amplitude of the zigzag function. Note that it is independent of the other kinematic variables, then in RZT the number of independent generalized kinematic variables is greater than that of the ESL FSDT; specifically, they are 4 for the beam and 7 for the plate and shell.
As a consequence, transverse shear stress reads (orthotropic material)

$$\sigma_{\alpha 3}^{(k)} = C_{\alpha 3}^{\alpha 3(k)} \epsilon_{\alpha 3}^{(k)} \left(\mathbf{x}, z^{(k)}\right) = \frac{1}{2} C_{\alpha 3}^{\alpha 3(k)} \left(\gamma_\alpha(\mathbf{x}) + \psi_\alpha(\mathbf{x}) \partial_z f_{RZT\alpha}^{(k)}(z)\right) \tag{23}$$

with γ_α given by Eq. (18). Now we introduce the auxiliary transverse shear strain measure [61],

$$\eta_\alpha(\mathbf{x}) = \gamma_\alpha(\mathbf{x}) - \psi_\alpha(\mathbf{x}) \tag{24}$$

Note that when

$$\eta_\alpha(\mathbf{x}) = 0 \quad \Rightarrow \quad \psi_\alpha(\mathbf{x}) = \gamma_\alpha(\mathbf{x}) \tag{25}$$

and RZT reduces to Di Sciuva's FSDZZT.

Substituting Eq. (24) into Eq. (23), yields

$$\sigma_{\alpha 3}^{(k)} = \frac{1}{2} C_{\alpha 3}^{\alpha 3(k)} \eta_\alpha(\mathbf{x}) + \underline{\frac{1}{2} C_{\alpha 3}^{\alpha 3(k)} \left(1 + \partial_z f_{RZT\alpha}^{(k)}(z)\right) \psi_\alpha(\mathbf{x})} \tag{26}$$

As anticipated, instead to require the transverse shear stress to be continuous at the interfaces, in the Refined Zigzag Theory we require to be continuous only the underlined term in Eq. (26), that is

$$C_{\alpha 3}^{\alpha 3(k)} \left(1 + \partial_z f_{RZT\alpha}^{(k)}(z)\right) \tag{27}$$

Satisfying the interface static continuity condition, Eq. (2), yields

$$\partial_z f_{RZT\alpha}^{(k)}(z) = \frac{G_{\alpha 3}}{C_{\alpha 3}^{\alpha 3(k)}} - 1 \tag{28}$$

As before, there are two free additional conditions to uniquely determine the zigzag function. As we said, in the RZT the following two additional conditions

$$\breve{U}_\alpha^{(1)}(\mathbf{x}, z_B) = \breve{U}_\alpha^{(N)}(\mathbf{x}, z_T) = 0 \tag{29}$$

are imposed (see, Fig. 7). As a consequence, we obtain

$$\frac{2h}{G_{\alpha 3}} = \int_{-h}^{h} \frac{1}{C_{\alpha 3}^{\alpha 3(k)}} dz = \sum_{k=1}^{N} \frac{2h^{(k)}}{C_{\alpha 3}^{\alpha 3(k)}} \tag{30}$$

Note that the slope of zigzag function depends on the lay-up and on the transverse shear elastic compliance of the layers.

7. FIRST-ORDER MURAKAMI'S ZIGZAG THEORY-MZT

A first-order zigag theory formally identical to the first-order ZZT has been advanced by Murakami [52].

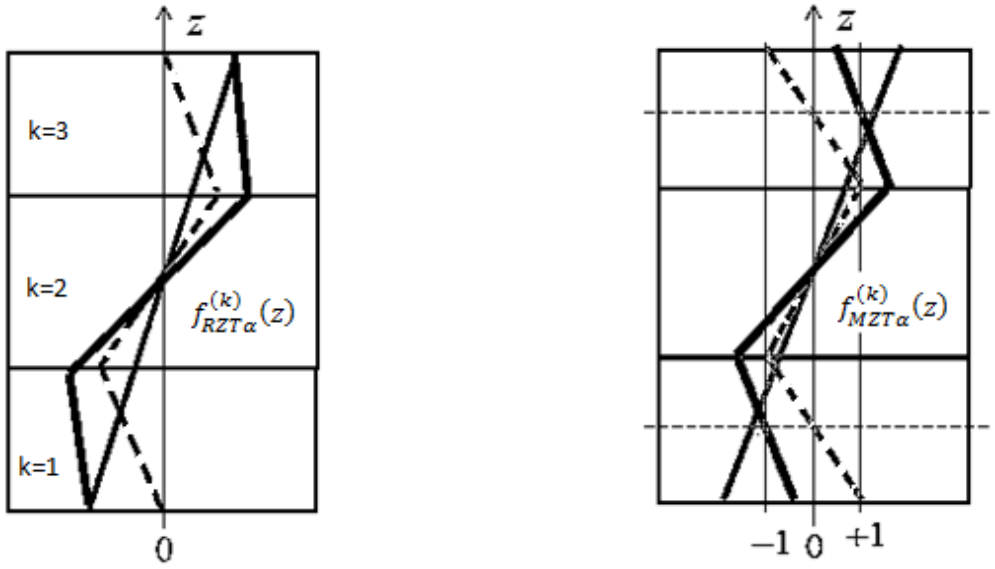
Murakami's zigzag theory (MZT) shares with the RZT the same global displacement field, Eq. (18a) and a formally identical local enrichment, Eq. (22), the difference being in the expression of the zigzag functions. Following Eq. (22), we write the local contribution as

$$\breve{U}_{\alpha}^{(k)}(\mathbf{x},z) = f_{MZT\alpha}^{(k)}(z)\psi_{\alpha}(\mathbf{x}) \tag{31}$$

where

$$\partial_z f_{MZT\alpha}^{(k)}(z) = \frac{(-1)^{(k)}}{h^{(k)}} \quad \Rightarrow \quad f_{MZT\alpha}^{(k)}(z) = (-1)^{(k)}\frac{z-z_M^{(k)}}{h^{(k)}} \tag{32}$$

So, RZT and MZT have the same number of independent kinematic variables. From the above, it is evident that Murakami's zigzag function depends only on the thickness of each layer; it is independent on the mechanical properties of layers. Figure 8 gives plots of the global contribution (ESL FSDT), the zigzag function and the resulting kinematics, for RZT and MZT, for a three-layer symmetric laminate.



(a) **(b)**

Fig. 8 – Kinematics of (a) RZT and (b) MZT. (⟶ global contribution (ESL FSDT), (– – –) local contribution (zigzag function), (▬▬) resulting kinematics, for a three-layer symmetric laminate.

8. NUMERICAL RESULTS

In order to substantiate the accuracy of the first-order zigzag theory and show the relative performances of RZT and MZT, in this Section some numerical results are quoted. Further comparisons can be found in [84,85,94,[95].

All the numerical results presented in this Section refer to the bending, under transverse bi-sinusoidal loading, and natural frequencies of symmetric (0/90/core/90/0) square sandwich plates of side a. The faces are comprised of two-layer regular cross-ply laminate (0/90) having thickness equal to 0.1 times the total thickness of the sandwich plate.

Table 1 gives the mechanical properties of unidirectional lamina with respect to the corresponding mechanical properties of core, the geometry and the boundary conditions of the sandwich plates under investigation.

	$E_1^{(f)}/E_1^{(c)}$	$E_2^{(f)}/E_2^{(c)}$	$a/2h$	$t^{(c)}/t^{(f)}$	Boundary conditions
Sandwich (1)	$5x10^5$	$1x10^5$	6	8	Simply supported
Sandwich (2)	$4.8x10^2$	$1.2x10$	10	8	Fully clamped

Table 1- Geometry, material data and boundary conditions of the sandwich plates.

8.1 Bending of sandwich plate

Figures 8 and 9 refer to sandwich plate (1) under transverse sinusoidal loading

$$\bar{p}_z^{(T)}(\mathbf{x}) = \bar{p}_0 \sin\frac{\pi x_1}{a}\sin\frac{\pi x_2}{a} \tag{33}$$

Numerical results as estimated by the 3D theory of elasticity [4], [5], the ESL FSDT, the RZT, and the MZT are compared.

Figure 9 shows estimates for the normalized transverse deflection at the center of the plate as a function of the span-to-thickness ratio a/2h and figure 10 shows the normalized in-plane displacements and transverse shear stresses. With the exception of 3D, the transverse shear stresses are evaluated by integration of the 3D local equilibrium equations. Concerning shear correction factors, as noted in the Introduction, no shear correction factors have been used in RZT and MZT, i.e., $k_x^2 = k_y^2 = 1$. In the ESL FSDT, in addition to the case, $k_x^2 = k_y^2 = 1$, ad hoc shear correction factors are used, $k_x^2 = 0.0242, k_y^2 = 0.0225$. They have been evaluated following the approach proposed by Ferreira [98]. It is of interest to note that these values are very different from those usually adopted in ESL FSDT, $k = \frac{5}{6};\ 1;\ \frac{\pi^2}{12}$. Moreover, in order to enhance some weakness of the MZT, the unidirectional orthotropic lamina is assumed to have equal transverse shear stiffness in the principal orthotropic directions 1 and 2, that is, $G_{13} = G_{23}$.

It is concluded that, (i) RZT is very accurate in predicting global (transverse displacement) and local (thickness-wise distribution) of displacement and normal in-plane stresses (not shown in figure). Even when considering the integrated shear stresses, clearly emerges the greater accuracy of the predictions made by RZT than MZT and ESL FSDT. Moreover, these results show that (i) ESL FSDT improves its accuracy if a suitable shear correction factor is

adopted (fig. 9); (ii) MZT predicts the same deflections of the FSDT model with unitary shear correction factors (fig. 9).

A point of interest is the behavior of MZT for this specific sandiwch construction. As we said, the orthotropic unidirectional lamina constituting the faces has $G_{13} = G_{23}$. This means that the faces are free of zigzag effect (that is, the actual in-plane displacement doesn't change slope in the faces), while the zigzag effect will be present at the interface between core and face. This behavior is very well caught by RZT theory, while MZT completely fails (fig. 10, top). What happens is this. Having to vanish the zigzag effect in the case of two adjacent layers having the same transverse shear stiffness (this is the case for the faces in our sandwich), since the MZZ functions are independent of the transverse shear stiffness of the layers (see, Eq. (32)), in order to vanish the zigzag effect in the faces, the amplitude of the zigzag function, i.e., $\psi_\alpha(\mathbf{x})$ in Eq. (31), should be zero. This implies zero contribution of the zigzag effect on the whole thickness and, as a consequence, the same trend of the in-plane displacements provided by ESL FSDT (Fig. 10, top). This deficiency also affects the distribution prediction of transverse shear stresses (Fig. 10, bottom).

8.2 Natural frequencies of square sandwich plate

Aim of this investigation is to assess the reliability of the RZT changing the problem under investigation. Here we investigate the natural frequencies of sandwich plate (2), which is different from sandwich plate (1) for material characteristics of the faces and core, aspect ratio and boundary conditions (table 1). Note that in this sandwich the core is stiffer than sandwich (1) and the plate is fully clamped. As a consequence, the ad hoc shear correction factors are changed. They are $k_x^2 = 0.0825, k_y^2 = 0.1446$.

Figure 11 show the estimated free undamped frequencies for the lowest six modes (m is the number of half waves in the x_1 direction and n that in the x_2 direction). As for the bending problem of sandwich (1), RZT provides estimates very close to the 3D elasticity for all modes. FSDT with ad-hoc shear correction factors is also accurate, even if its accuracy decreases for higher modes (fifth and sixth), indicating the need to introduce other values of the correction factors as the modal number increases.

9. CONCLUDING REMARKS

Aim of this paper is to give a review of the first-order displacement-based zigzag theories for composite laminates and sandwich structures, with special emphasis to the underlying ideas, relative strengths and weaknesses. To do this, the Di Sciuva's first-order zigzag theory, the first-order Refined Zigzag Theory, and the Murakami's first-order zigzag theory have been reviewed and numerically compared. It is shown that RZT and Murakami's Zigzag theory share the same kinematics, but different zigzag functions. Specifically, unlike RZT zigzag functions, Murakami's zigzag functions are basically of geometrical type, in the sense that the jump in their thickness-wise derivative depends only on the thickness of each layer (see, Eq. (32)), when the same jump in the derivative of the RZT zigzag functions depends on the lay-up and on the transverse shear elastic compliance of the layers (see, Eq. (28)). This makes Murakami's zigzag functions approach generally unreliable, especially when the laminate does not present a repetitive or periodic lay-up, as pointed out by the same Murakami [52] and recently also by Gherlone [84], Iurlaro et al [85], [94] and Iurlaro [95]. In extreme cases, like that of sandwich taken used for the numerical assessment presented in this paper, the Murakami's zigzag approach completely fails, in the sense that Murakami's zigzag

functions do not give any contribution and Murakami's approach provides the same incorrect results of FSDT with unitary shear correction factors. On the contrary, also for this sandwich plates, RZT provides a very accurate estimates.

From the present numerical investigation and others available in the open literature [61, 62,63,64,65,66,67], it seems reasonable to draw the conclusion that RZT is very accurate in predicting global (transverse displacement) and local (thickness-wise distribution) of displacement and normal in-plane stresses.

By taking into account the additional strength of RZT, mainly, the possibility to develop C^0 beam [97,98,99,100,101,102,103], plate and shell finite elements, [104,105,106,107,108], like ESL FSDT, in my opinion RZT represents, among the first-order zigzag theories, the best compromise between computational efficiency and numerical accuracy.

Keywords: Object-Oriented Modeling, Modeling of Mechanical Constraint, Omni Wheel, Contact Tracking, Unilateral Constraint, Roller Inclination, Model of Friction.

Abstract. *General approach for constructing the computer models of the multibody system dynamics with unilateral constraints and friction is under consideration. Base dynamical abstractions, classes, are described which provide a model building using object-oriented paradigm for the design of dynamic objects virtual prototypes.*

Contact tracking block is the most important one of any algorithm for simulation the mechanical contact. This block provides permanent computations of the contact point/patch where the process of bodies mechanical interaction takes place. A general formulation of contact in algebraic and/or differential forms is under analysis.

The omni directional wheel dynamical testbench is under construction then. This model is built in a way such that the wheel disc equipped by rollers along its rim keeps its vertical orientation permanently. Such an arrangement of the virtual testbench provides indeed the simulation of the wheel motion like it is a part of any virtual omni vehicle.

Using the omni wheel permanent vertical orientation we are able to build up an efficient algorithm for contact tracking between the roller and the floor. The case of so-called angled (being preliminarily rotated) rollers is also included. The angle of roller inclination to the wheel plane is possible to be varied, as a parameter of the dynamical problem, in frame of wide range of its values. This approach is a natural generalization of its previous version which was implemented for the case of zero angle of the roller prerotation.

1 INTRODUCTION

A construct of the omni vehicle dynamical model has been presented in [1], see also papers [2, 3]. Concept of an omni wheel was proposed in [4]. Simplified model for mounting of roller on the wheel disk has been considered there: the roller axis of symmetry assumed to belong to the disk, or equivalently an angle of inclination, denote it by ψ, for the roller axis to the wheel plane is equal to zero.

In engineering applications nevertheless one may encounter frequently a situation with $\psi > 0$. We proposed in [1] fast algorithm for tracking a contact provided the omni wheel keeps vertical orientation of its plane (in frame of the whole vehicle construct). Thus actual is a task for building up the contact tracking algorithm also for the case of $\psi > 0$. This task has been completed in this paper. To reach this goal we accept the working model of a virtual testbench consisting of one wheel equipped by rollers along its rim. One can see easily this simplification has mostly methodical nature and does not prevent us to integrate all the construct back into the whole vehicle having generally several omni wheels already analyzed previously [1].

2 GENERAL DESCRIPTION OF THE MULTIBODY DYNAMICS MODEL ARCHITECTURE

2.1 Object-oriented concept

First of all, in frame of the general approach let us build up the multibody system (MBS) dynamical model using object-oriented paradigm with Modelica language [5]. Consider the MBS consisting of $m+1$ bodies $B_0, \ldots, B_m$. Represent it as a set $\mathcal{B} = \{B_0, \ldots, B_m\}$. Here B_0 assumed to be a base body. We suppose B_0 to be connected with an inertial frame of reference, or to have a known motion with respect to the inertial frame of reference. For example one can imagine the base body as a rotating platform, or as a vehicle performing its motion according to a given law. For definiteness and simplicity we suppose in the following text that all state variables describing the rigid bodies motion always refer to one fixed inertial coordinate system connected to the base body by default.

Some bodies of the MBS assumed connected by mechanical constraints. Suppose all constraints compose the set $\mathcal{C} = \{C_1, \ldots, C_n\}$. We include in our considerations constraints of the following types: holonomic/nonholonomic, scleronomic/rheonomic, bilateral/unilateral.

Thus one can uniquely represent a structure of the MBS via a undirected graph $G = (\mathcal{B}, \mathcal{C}, \mathcal{I})$. Here $\mathcal{I} \subset \mathcal{C} \times \mathcal{B}$ is an incidence relation setting in a correspondence the vertex incident to every edge $C_i \in \mathcal{C}$ of the graph. According to physical reasons it is easy to see that for any mechanical constraint C_i there exist exactly two bodies $B_k, B_l \in \mathcal{B}$ connected by this constraint.

It is clear that consideration of the graph G does not provide a structural information sufficient for the MBS dynamics description. Indeed, in addition to the force interaction represented usually by wrenches between bodies B_k, B_l through the constraint C_i there exist kinematic conditions specific for different kinds of constraints. Wrenches themselves can be represented in turn by constraint forces and constraint torques couples. These forces and couples are connected by virtue of Newton's third law of dynamics.

Thus if the system of ODEs for translatory-rotary motion can be associated with the object of a model corresponding to rigid body, then the system of the algebraic equations can be naturally associated with the object of a model corresponding to constraint. Note that according to above consideration the set of algebraic equations comprises relations for constraint wrenches, and kinematic relations depending on the certain type of constraints.

Thus all the "population" of any MBS model is reduced to objects of two classes: *RigidBody*

(objects $B_0, \ldots, B_m$), *Constraint* (objects $C_1, \ldots, C_n$). According to this approach simulation of the whole system behavior reduces to permanent information interaction between the objects of two considered types. Within the frame of Newton's laws of dynamics one can construct the MBS as a communicative network for this interaction. In this case the objects of bodies "feel" the action of other ones through corresponding objects of constraints.

Physical interactions are conducted in models due to objects splitted also in two classes of ports: *WrenchPort, KinematicPort*. The first one is to be used to transfer wrench. In addition, *WrenchPort* has to be used for transferring the information about current location of the point constraint force acts upon.

In our idealized model the force interaction between bodies supposed exactly at a geometric point. Its coordinates are fed outside constraint object through *WrenchPort* permanently in time.

Now it is possible to describe an architecture of information interactions within the particular constraint C_i corresponding to an individual edge of graph G, see Figure 1.

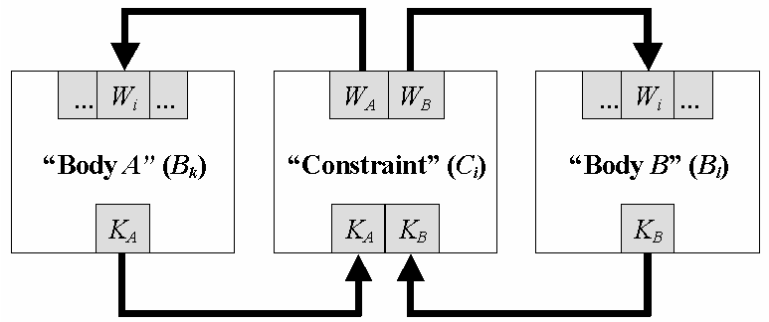

Figure 1: Architecture of constraint

KinematicPort is to be used to transfer the data of rigid body kinematics: configuration (position of center of mass, orientation), velocity (velocity of the center of mass, angular rate), and acceleration (acceleration of the center of mass, angular acceleration) containing in particular information about twist. When getting force information through ports $W_1, \ldots, W_s$ from the incident objects of class *Constraint* the object of class *RigidBody* simultaneously generates, due to an integrator, kinematic information being fed outside through the port K. On the other hand every object of class *Constraint* gets kinematic data from the objects corresponding to bodies connected by the constraint under consideration through its two "input" ports K_A, K_B. Simultaneously using the system of algebraic equations this object generates information concerning wrenches, and transmits the data to "output" ports W_A, W_B for the further transfer to objects of bodies under constraint.

In base class *RigidBody* dynamics of rigid body is described here by means of Newton's differential equations for the body mass center, and by Euler's differential equations for the rotary motion. Note that to be able to have an invariant description of the rotary motion one can use an excellent tool: quaternion algebra $\mathbf{H}$. In this case we "lift" the configuration manifold from $SO(3)$ to $S_3 \subset \mathbf{H}$ and then implement dynamics of rotation in flat space $\mathbf{H} \cong \mathbf{R}^4$ taking into account that S_3 is an invariant manifold of the rotary dynamics redefined on $\mathbf{H}$. In this way we have only one flat chart $\mathbf{H}$ for the underlying due to double covering configuration manifold $SO(3)$, and need not in any special choices of the configuration angles or anything like that.

The double covering $S_3 \to SO(3)$, $\mathbf{q} \mapsto T$ mentioned implemented inside the *RigidBody*

class by the known formula

$$T = \frac{1}{|\mathbf{q}|^2} \cdot \begin{bmatrix} q_0^2 + q_1^2 - q_2^2 - q_3^2 & 2\,(q_1 q_2 - q_0 q_3) & 2\,(q_1 q_3 + q_0 q_2) \\ 2\,(q_0 q_3 + q_1 q_2) & q_0^2 - q_1^2 + q_2^2 - q_3^2 & 2\,(q_2 q_3 - q_0 q_1) \\ 2\,(q_1 q_3 - q_0 q_2) & 2\,(q_0 q_1 + q_2 q_3) & q_0^2 - q_1^2 - q_2^2 + q_3^2 \end{bmatrix},$$

where q_0, q_1, q_2, q_3 are the Euclidean coordinates of the quaternion $\mathbf{q}$ and $|\mathbf{q}|$ is its Euclidean norm. The rotation matrix T is fed outside the object through the *KinematicPort* permanently in time. The Euler equations are constructed using quaternion algebra in a way described in [6].

Note that according to our technology of the constraint construction two connected bodies are identified by convention with the letters A and B fixed for each body. All kinematic and dynamic variables and parameters concerned one of the bodies are equipped with the corresponding letter as a subscript.

All objects of the class *Constraint* must have classes-inheritors as subtypes of a corresponding base class. According to Newton's third law this superclass must contain the equations of the form

$$\mathbf{F}_A + \mathbf{F}_B = \mathbf{0}, \quad \mathbf{M}_A + \mathbf{M}_B = \mathbf{0}. \tag{1}$$

in its behavioral section. Here arrays $\mathbf{F}_A$, $\mathbf{M}_A$ and $\mathbf{F}_B$, $\mathbf{M}_B$ represent constraint forces and torques "acting in directions" of bodies A and B correspondingly. Kinematic equations for different types of constraints are to be added to Eqs. (1) in different classes-inheritors corresponding to these particular types of constraints.

2.2 Example of a joint constraint

Class *Joint* plays an important auxiliary role in the future model of an omni wheel we will build. *Joint* is a model derived from the base class *Constraint*. Remind [7] that in order to make a complete definition of the constraint object behavior for the case of rigid bodies one has to compose a system of twelve algebraic equations with respect to (w. r. t.) twelve coordinates of vectors $\mathbf{F}_A$, $\mathbf{M}_A$, $\mathbf{F}_B$, $\mathbf{M}_B$ constituting the wrenches acting upon the connected bodies.

First six equations (1) always present in the base model *Constraint* due to Newton's third law. For definiteness suppose these six equations are used to express six components of $\mathbf{F}_B$, $\mathbf{M}_B$ depending on $\mathbf{F}_A$, $\mathbf{M}_A$. Thus six components of $\mathbf{F}_A$, $\mathbf{M}_A$ remain unknown. To determine them each constraint of rigid bodies need in six additional independent algebraic equations. These equations can include components of force and torque directly, or be derived from the kinematic relations corresponding to specific type of the constraint.

In the case of the joint constraint being investigated here let us represent the motion of the body B as a compound one consisting of the body A convective motion w. r. t. an inertial frame of reference, and a relative motion w. r. t. the body A. An absolute motion is one of the body B w. r. t. the inertial system.

Define the joint constraint with help of the following parameters: (a) a unit vector $\mathbf{n}_A$ defining in the body A an axis of the joint; (b) a vector $\mathbf{r}_A$ fixed in the body A and defining a point which constantly stays on the axis of the joint; (c) a vector $\mathbf{r}_B$ fixed in the body B and defining a point which also constantly stays on the axis of the joint. The main task of the base joint class is to keep always in coincidence the geometric axes fixed in each of the bodies.

First of all one has to compute the radii vectors of the points fixed in the bodies w. r. t. inertial system

$$\mathbf{R}_\alpha = \mathbf{r}_{O_\alpha} + T_\alpha \mathbf{r}_\alpha \quad (\alpha = A, B),$$

where [7] $\mathbf{r}_{O_\alpha}$ is the position of the α-th body center of mass, T_α is its current matrix of rotation. The joint axis has the following components

$$\mathbf{n}_{Ai} = T_A \mathbf{n}_A$$

in the inertial frame of reference. According to the equation for relative velocity for the marked point of the body B defined by the position $\mathbf{R}_B$ we have

$$\mathbf{v}_{Ba} = \mathbf{v}_{Be} + \mathbf{v}_{Br}, \quad \mathbf{v}_{Ba} = \mathbf{v}_{O_B} + [\boldsymbol{\omega}_B, T_B \mathbf{r}_B], \quad \mathbf{v}_{Be} = \mathbf{v}_{O_A} + [\boldsymbol{\omega}_A, \mathbf{R}_B - \mathbf{r}_{O_A}], \tag{2}$$

where $\mathbf{v}_{Ba}$, $\mathbf{v}_{Be}$, $\mathbf{v}_{Br}$ are an absolute, convective, and relative velocities of the body B marked point, $\boldsymbol{\omega}_A$, $\boldsymbol{\omega}_B$ are the bodies angular velocities.

Furthermore, according to the computational experience of the dynamical problems simulation the precompiler work is more regular if the kinematic equations are expressed directly through accelerations. Indeed, otherwise the compiler tries to perform the formal differentiation of equations for the velocities when reducing an index of the total DAE system. Frequently this leads to the problems either in time of translation or when running the model.

Thus using the known Euler formulae for the rigid body kinematics and the Coriolis theorem we obtain an equations for the relative linear acceleration in the form

$$\begin{aligned} &\mathbf{a}_{Ba} = \mathbf{a}_{O_B} + [\boldsymbol{\varepsilon}_B, T_B \mathbf{r}_B] + [\boldsymbol{\omega}_B, [\boldsymbol{\omega}_B, T_B \mathbf{r}_B]], && \mathbf{a}_{Ba} = \mathbf{a}_{Be} + 2[\boldsymbol{\omega}_A, \mathbf{v}_{Br}] + \mathbf{a}_{Br}, \\ &\mathbf{a}_{Be} = \mathbf{a}_{O_A} + [\boldsymbol{\varepsilon}_A, \mathbf{R}_B - \mathbf{r}_{O_A}] + [\boldsymbol{\omega}_A, [\boldsymbol{\omega}_A, \mathbf{R}_B - \mathbf{r}_{O_A}]], && \mathbf{a}_{Br} = \mu \mathbf{n}_{Ai}, \end{aligned} \tag{3}$$

where $\mathbf{a}_{Ba}$, $\mathbf{a}_{Be}$, $\mathbf{a}_{Br}$ are an absolute, convective, and relative accelerations of the body B marked point, $\boldsymbol{\varepsilon}_A$, $\boldsymbol{\varepsilon}_B$ are the bodies angular accelerations, $\mathbf{v}_{Br}$ is a relative velocity of the body B marked point, $\boldsymbol{\omega}_A$, $\boldsymbol{\omega}_B$ are the bodies angular velocities.

We also need in an analytic representation of the conditions that the only projections of the bodies angular velocities and accelerations having a differences are ones onto the joint axis. Corresponding equations have the form

$$\boldsymbol{\omega}_B = \boldsymbol{\omega}_A + \boldsymbol{\omega}_r, \quad \boldsymbol{\varepsilon}_B = \boldsymbol{\varepsilon}_A + [\boldsymbol{\omega}_A, \boldsymbol{\omega}_r] + \boldsymbol{\varepsilon}_r, \quad \boldsymbol{\varepsilon}_r = \lambda \mathbf{n}_{Ai}, \tag{4}$$

where $\boldsymbol{\omega}_r$, $\boldsymbol{\varepsilon}_r$ are the relative angular velocities and accelerations.

Besides the kinematic scalars μ, λ we will need in their reciprocal values $F = (\mathbf{F}_A, \mathbf{n}_{Ai})$, $M = (\mathbf{M}_A, \mathbf{n}_{Ai})$ correspondingly. Note that the class described above is a partial one (doesn't yet complete the constraint definition) and can be used to produce any imaginable model of the joint type constraint. To obtain a complete description of the joint model one has to add to the behavioral section exactly two equations. One of them is to define one of the values μ, F (translatory case). Other equation is intended to compute one of the values λ, M (rotary case).

Consider one example of joint classes among others being derived from the *Joint* model for the particular, revolute, type of joint being applied in the omni wheel construct. This model *FixedIdealJoint* is defined by the equations

$$\mu = 0, \quad M = 0$$

and prevents the relative motion along the joint axis but allows free rotation about it. It is exactly a revolute joint without any control for the rotary motion.

It is clear one can create a lot of other different combinations of equations to construct the joint constraints of any desirable type needed in engineering applications. The only issue one

has to take into account when constructing the kinematic pair that if there exists an obstacle for the relative motion eliminating one DOF then it causes an additional scalar kinematic equation "lifted" to the level of accelerations. Reciprocally if the corresponding motion is possible then the developer has to include the scalar equation instead imposing the condition on the matching generalized effort, force or torque what applicable.

2.3 Bond graph concept

Referring for the details to the papers [8, 9] let us give here a brief outline of the multibond graph scheme concerning the general constraint architecture under consideration, see Figure 2. Remind that each multibond is a pair comprising twist as its flow component, while the wrench plays a role of the effort component.

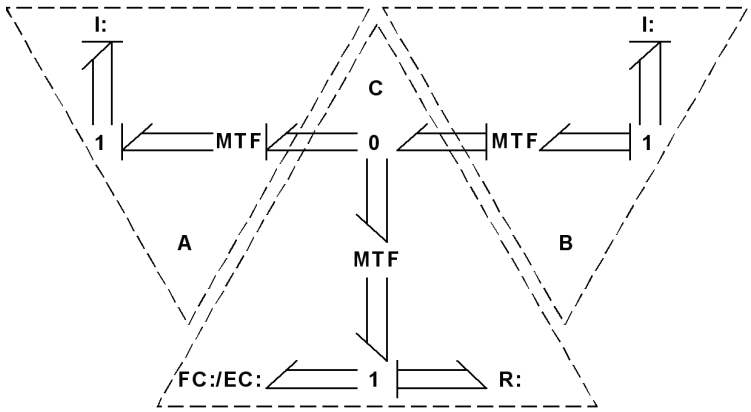

Figure 2: Architecture of constraint: bond graph representation

Describing Figure 2 first of all one has to highlight the multibond true nature. Considering the rigid body as a mechanical system with six degrees of freedom (DOFs) we note that the flow part, twist, of any multibond represents an object tangent to configuration manifold $\mathcal{D} = \mathbf{R}^3 \times SO(3)$ which is in turn the rigid body displacement group [10]. In such a way the multibond effort component representing the wrench of reaction forces is indeed the cotangent object, 1–form, at the same point of $\mathcal{D}$. Thus the multibond power is a natural pairing, the value of 1–form, wrench, evaluated on the configuration manifold tangent vector, twist.

In the way under description we follow the ideas of the paper [10] leaving the rigid body kinematics unsplitted to its translatory and rotary parts. To this end we go farther than the usual approach for the bond graph applications when frequently the developer first keeps in his mind the equations and then builds up the corresponding bond graph. Unlike to this we first construct the bond graph connecting it to the physical nature of the problem, and then the system of DAEs is to be assembled mostly by compiler without any participation of the developer. In this latter case physical invariance of the model independent on the choice of (generalized) coordinates is maintained.

Regarding the general scheme depicted in Figure 2 with its connection to the family of the joint constraint classes we can conclude that the equations (3), (4) together implement implicitly the constraint transformer, central modulated transformer in triangle C of Figure 2, to the joint local coordinate system and four scalar flow constraints forbidding relative translatory and rotary motions in the direction orthogonal to the joint axis. For derived classes only two free scalar bonds remain.

Here we encounter the known complementarity rules [11] in a way similar to one described in [8, 7]. In our context the variables in the pairs (μ, F), (λ, M) are mutually complement, where one of μ, λ is to be utilized for the flow constraint and one of F, M is used to compose the effort constraint. All the variables mentioned complete the set of constraints for the remaining yet unused joint axis creating thus two final scalar constraint elements in the bond graph of Figure 2.

Namely, equations (3) implementing the Coriolis theorem for accelerations simultaneously implement, in an implicit manner, two scalar flow constraints, FC-elements, from the bottom left corner of the multibond graph model in Figure 2. These flow constraints are constructed, due to compiler restrictions, using accelerations instead of velocities being used in a classic bond graph approach. The constraints have an obvious kinematic sense: they prevent the relative motion of the body B marked point in two directions normal to the joint axis fixed in the body A.

In addition, the equations (4) implement two other scalar flow constraints, this time for the rotary motion. These constraints forbid the relative rotation of the body B w. r. t. body A about two axes each normal to the joint axis mentioned above which is rigidly connected with the body A.

Note, that the construct of equations (3) and (4) is such that they allow the body B relative motion along and about the joint axis of the body A thus implementing the kinematic pair with two DOFs. Returning to Figure 2 of the general constraint multi-bondgraph we can conclude that the vertical multibond attached to 0-junction implements flow variables corresponding to the relative body B motion w. r. t. body A in inertial coordinates. Such a description supposes an existence of the special coordinates reference frame connected with the body A at its joint constraint marked point. The transformation to these coordinates is implemented exactly via corresponding transformer, central in the triangle block C. The transformer itself nests in formulae of equations (3) and (4).

The derived joint class example described above is to close the system of kinematic equations (3) and (4) completing them by two scalar additional equations, each playing a role of an either FC-element, like $\mu = 0$, or EC-element, like $M = 0$. Any time to be able to construct a consistent system of equations for the total model we have to follow the guidelines similar to ones of the complementarity rules.

These latter correspond to the notions of the bond graph theory in a natural way. Indeed, the theory of bond graphs is based on the energy interactions. Every our multibond being an energy/power conductor reflects complementarity by its twist/wrench duality. To close the total DAE system for the model under development we have to "close" or rather to "seal" each free scalar bond in EC/FC-element of the block C in Figure 2 by the corresponding one scalar equation for flow or effort variable. Thus here we outline the main rule to compose equations for the models of constraints for MBS of any type in a consistent way when applying the object-oriented approach.

3 GENERAL DESCRIPTION OF THE CONTACT TRACKING ALGORITHM

We outline here general approach for implementing contact tracking algorithm in case of the unilateral constraint. As it was already mentioned we use the so called complementarity rules [11] as a base for the unified description of the unilateral constraint. Taking into account complementarity rules one can see easily that any constraint always is defined by the three scalar equations. To derive these equations consider first local geometry of the problem, see Figure 3.

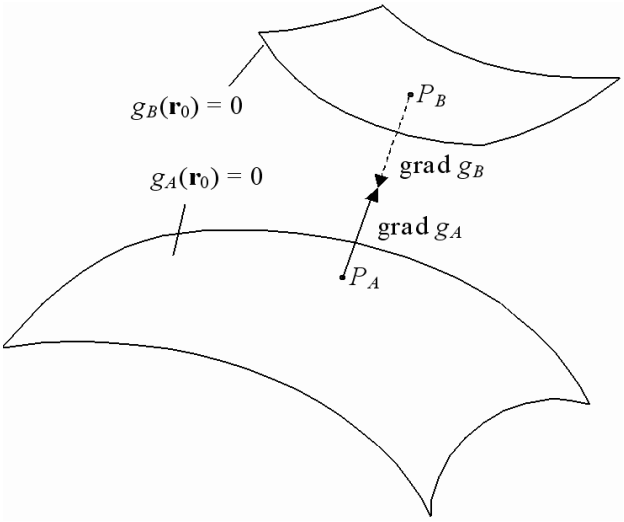

Figure 3: Area of Constraint

Outer surfaces supposed to be defined with respect to principal central axes of corresponding bodies by the equations

$$f_\alpha\left(\mathbf{r}_\alpha\right) = 0 \quad (\alpha = A, B).$$

Then in inertial frame of reference for the whole MBS these equations will take the form

$$g_\alpha(\mathbf{r}_0) = 0 \quad (\alpha = A, B),$$

where

$$g_\alpha\left(\mathbf{r}_0\right) = f_\alpha\left[T_\alpha^*\left(\mathbf{r}_0 - \mathbf{r}_{O_\alpha}\right)\right] \quad (\alpha = A, B),$$

with $\mathbf{r}_{O_A}$, $\mathbf{r}_{O_B}$ being a vectors of masscenters positions O_A, O_B for the bodies A and B, and T_A, T_B mean an orthogonal matrices for current bodies orientations. An asterisk denotes conjugating what equivalent to inverting of matrix for the case of orthogonality. Thus the functions $g_A(\mathbf{r}_0)$, $g_B(\mathbf{r}_0)$ depend upon the time indirectly through the variables $\mathbf{r}_A$, $\mathbf{r}_B$, T_A, T_B.

Constraint object of our model is to compute at each current instant positions of the points P_A and P_B which are the nearest ones for interacting bodies A and B. By virtue of above assumptions such points are to be evaluated in a unique way. Denote the radii vectors of these points with respect to inertial frame of reference by $\mathbf{r}_{P_A}$, $\mathbf{r}_{P_B}$. Then using simple geometric considerations for the coordinates of the mentioned vectors one can derive the following system of algebraic equations

$$\begin{aligned} \operatorname{grad} g_A\left(\mathbf{r}_{P_A}\right) &= \lambda \cdot \operatorname{grad} g_B\left(\mathbf{r}_{P_B}\right), \\ \mathbf{r}_{P_A} - \mathbf{r}_{P_B} &= \mu \cdot \operatorname{grad} g_B\left(\mathbf{r}_{P_B}\right), \\ g_A\left(\mathbf{r}_{P_A}\right) &= 0, \\ g_B\left(\mathbf{r}_{P_B}\right) &= 0. \end{aligned} \tag{5}$$

Here the first equation is a condition of the collinearity for the normals to outer surfaces at the points being computed. The second condition requies the points P_A, P_B to be relocated on the straight line collinear to the normals above.

One can verify easily that one can compute the gradients using the formulae

$$\operatorname{grad} g_\alpha\left(\mathbf{r}_{P_\alpha}\right) = T_\alpha \operatorname{grad} f_\alpha\left[T_\alpha^*\left(\mathbf{r}_{P_\alpha} - \mathbf{r}_{O_\alpha}\right)\right], \tag{6}$$

where $\alpha = A, B$. It easy to see the system (5) consists of eight scalar equations and has eight scalar unknown variables: x_{P_A}, y_{P_A}, z_{P_A}, x_{P_B}, y_{P_B}, z_{P_B}, λ, μ. Variables λ, μ are an auxiliary ones. And the variable μ plays a role of contact detector at that: if $\mu > 0$ then bodies are disconnected, otherwise if $\mu \leq 0$ then bodies are in contact. Equations (5) one uses either without or with a presence of the contact of bodies A, B. In a latter case one uses the equation $\mu = 0$ instead of one of the surfaces equations.

According to computational experience it is more reliable and convenient if one use equations of constraint in a differential form than in an algebraic one (5) instead. Such an approach is used frequently also when analyzing the properties of mechanical systems.

Analytical computations show that one can substitute the equations (5) by the differential ones of the form

$$\frac{d\mathbf{r}_{P_A}}{dt} = \mathbf{v}_A, \quad \frac{d\mathbf{r}_{P_B}}{dt} = \mathbf{v}_B, \quad \frac{d\lambda}{dt} = v_\lambda, \quad \frac{d\mu}{dt} = v_\mu, \tag{7}$$

where the variables of right hand sides are calculated implicitly by help of system of linear algebraic equations of the form

$$\begin{aligned}
[\boldsymbol{\omega}_A, \operatorname{grad} g_A] + T_A \operatorname{Hess} f_A T_A^* (\mathbf{v}_A - \mathbf{v}_{P_A}) - \\
\lambda \{[\boldsymbol{\omega}_B, \operatorname{grad} g_B] + T_B \operatorname{Hess} f_B T_B^* (\mathbf{v}_B - \mathbf{v}_{P_B})\} - \\
v_\lambda \operatorname{grad} g_B &= \mathbf{0}, \\
\mathbf{v}_A - \mathbf{v}_B - \\
\mu \{[\boldsymbol{\omega}_B, \operatorname{grad} g_B] + T_B \operatorname{Hess} f_B T_B^* (\mathbf{v}_B - \mathbf{v}_{P_B})\} - \\
v_\mu \operatorname{grad} g_B &= \mathbf{0}, \\
\operatorname{grad} g_A \cdot \mathbf{v}_A - \operatorname{grad} f_A T_A^* \mathbf{v}_{P_A} &= 0, \\
\operatorname{grad} g_B \cdot \mathbf{v}_B - \operatorname{grad} f_B T_B^* \mathbf{v}_{P_B} &= 0.
\end{aligned} \tag{8}$$

When using this latter, i. e. differential form of a constraint one needs to set a consistent initial values for the variables $\mathbf{r}_{P_A}$, $\mathbf{r}_{P_B}$, λ, μ at the start time instant of simulation. Vectors $\mathbf{v}_{P_A}$ and $\mathbf{v}_{P_B}$ in the system (8) of algebraic linear equations are the velocities of a nearest points of the bodies and are computed according to Euler's formula

$$\mathbf{v}_{P_\alpha} = \mathbf{v}_{O_\alpha} + [\boldsymbol{\omega}_\alpha, \mathbf{r}_{P_\alpha} - \mathbf{r}_{O_\alpha}] \quad (\alpha = A, B). \tag{9}$$

Matrices $\operatorname{Hess} f_A$, $\operatorname{Hess} f_B$ are ones of Hesse for corresponding functions and have the form

$$\operatorname{Hess} f_\alpha = \begin{pmatrix} \dfrac{\partial^2 f_\alpha}{\partial x_\alpha^2} & \dfrac{\partial^2 f_\alpha}{\partial x_\alpha \partial y_\alpha} & \dfrac{\partial^2 f_\alpha}{\partial x_\alpha \partial x_\alpha} \\ \dfrac{\partial^2 f_\alpha}{\partial y_\alpha \partial y_\alpha} & \dfrac{\partial^2 f_\alpha}{\partial y_\alpha^2} & \dfrac{\partial^2 f_\alpha}{\partial y_\alpha \partial z_\alpha} \\ \dfrac{\partial^2 f_\alpha}{\partial z_\alpha \partial x_\alpha} & \dfrac{\partial^2 f_\alpha}{\partial z_\alpha \partial y_\alpha} & \dfrac{\partial^2 f_\alpha}{\partial z_\alpha^2} \end{pmatrix},$$

with $\alpha = A, B$. Normal vector

$$\mathbf{n}_A = \frac{\operatorname{grad} g_A}{|\operatorname{grad} g_A|} \tag{10}$$

will play an important role in the further course. Normal for an outer surface of the body A is chosen here for definiteness. One can use the vector $\mathbf{n}_B$ as well.

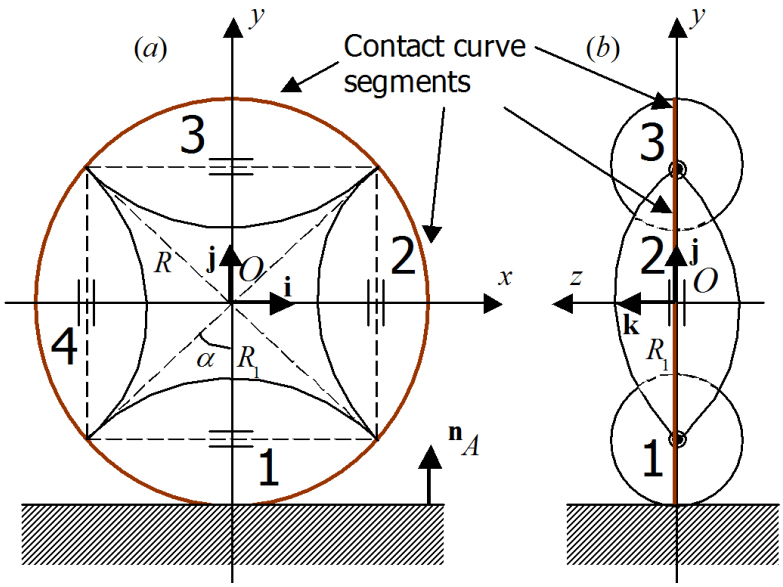

Figure 4: The omni wheel vertically aligned: (a) lateral view; (b) front view.

4 VIRTUAL OMNI WHEEL TESTBENCH ARRANGEMENT

4.1 Preliminaries

Let us consider an omni wheel now. Omni wheel for the case of $\psi = 0$ is shown in Figure 4. There one can see the lateral view, fragment (a), of the wheel being equipped by four axisymmetrical rollers, each having a shape of the circular spindle. These rollers have been enumerated by their numbers. Each roller is connected to the wheel by a joint which axis coincides with the roller axis of rotation. These latter axes both are orthogonal to the wheel radius exiting from the central point O and passing through the the roller central point. So it is possible for the wheel to have a free rolling in direction perpendicular to its plane. Corresponding contacting curve with respect to the wheel coordinate system, being a circle in the case shown, has a coloured highlighting. This curve has a circular shape provided the wheel plane keeps its vertical orientation. Front view of the omni wheel is shown in fragment (b).

For the case of $\psi = 0$ being shown in Figure 4 a roller outer profile, generatrix, along its axis of rotation has evidently a circular shape, see Figure 4, fragment (a), again. This shape provides smooth transfer from one roller to another while the motion occurs. Evidently if $\psi \neq 0$ then it is not the case. Thus, the contact tracking algorithm for the case of $\psi = 0$ implemented in [1] turned out to be simple enough. In the case of $\psi > 0$ it becomes visibly complicated. And its implementation on Modelica language is the main goal of this paper.

Other details of Figure 4 are the following: R is the omni wheel radius, R_1 is the distance between the wheel central point O and the roller central point, α is the half roller angular length from the viewpoint O. Unit vectors $\{\mathbf{i}, \mathbf{j}, \mathbf{k}\}$ of the base being connected with the wheel are shown in their initial positions.

In engineering applications one may encounter frequently a situation with $\psi > 0$. We proposed in [1] fast algorithm for tracking a contact provided the omni wheel keeps vertical orientation of its plane (in frame of the whole vehicle construct). Thus the task for building up the contact tracking algorithm also for the case of $\psi > 0$ is of interest. This task has been completed

in this paper. To reach this goal we accept the working model of a virtual testbench consisting of one wheel equipped by rollers along its rim. One can see easily that this simplification has mostly methodical nature and does not prevent us from integrating all the construct back into the whole vehicle having generally several omni wheels previously analyzed [1].

So let us consider an omni wheel, see Figure 4 its lateral and front views with four rollers, which is able to keep vertical orientation of its plane. We will see later how to arrange an implementation of such a servo-constraint. Note in addition, that in the case of $\psi > 0$ a generatrix of the roller outer surface will not be a segment of the circle anymore. It is represented by a more complicated curve. Moreover, point break of contact on the roller surface does not correspond to the surface tip for the case of $\psi > 0$ as it took place for the simple case of $\psi = 0$. To arrange correct simulation on event of the contact exchange between rollers one has to truncate the roller surface properly.

4.2 Model of the omni wheel dynamics

Vehicle equipped by omni wheels might be replaced by a wrench consisting of force and torque in the multibody, rigid, representation. The force supposed to act at the wheel center. Thus approximately we can analyze the omni wheel dynamics with the wrench applied instead of a remainder of the vehicle.

Moreover, the vehicle, or a separated wheel, performs in our example motion on the horizontal floor for simplicity. Thus, the wheel being embedded into the vehicle in the simplest case should be aligned vertically. To express such an alignment analytically we can connect with the wheel the base $\{\mathbf{i}, \mathbf{j}, \mathbf{k}\}$ originating from the wheel center. Both unit vectors $\mathbf{i}, \mathbf{j}$ lie in the wheel plane, and unit vector $\mathbf{k}$ is normal to it. Thus the vertical alignment of the wheel is equivalent to horizontal alignment for the vector $\mathbf{k}$. Analytical condition for this is

$$\mathbf{k} \cdot \mathbf{n}_A = 0,$$

where unit vector $\mathbf{n}_A$ is vertical, or normal to the floor. In other words, let $T \in SO(3)$ be the matrix of transformation from base $\{\mathbf{i}, \mathbf{j}, \mathbf{k}\}$ to the inertial absolute coordinate system. Then components of vector $\mathbf{k}$ are exactly the components of the matrix $T = (t_{ij})_{i,j=1}^{i,j=3}$ third column. Thus one can express condition of the wheel vertical alignment in the form

$$t_{23} = 0.$$

This latter equation shows that the omni wheel multibody system undergoes the geometrical servo constraint. It is easy to see that this constraint may be implemented via control effort, rotating torque $\mathbf{M}$ directed such as to prevent rotation of the wheel plane w. r. t. horizontal line belonging to this plane.

For details of the torque vector $\mathbf{M}$ computation note that this vector has to be directed along horizontal line passing through the wheel center and belonging to its plane. Directing unit vector $\mathbf{l}$ for this line has to satisfy the equation

$$\mathbf{l} = \mathbf{k} \times \mathbf{n}_A / |\mathbf{k} \times \mathbf{n}_A|.$$

Hence

$$\mathbf{M} = \lambda \mathbf{l}$$

and the multiplier λ is simply a value of torque balancing the wheel vertical orientation. In the wheel model torque $\mathbf{M}$ has to be added to other torques applied to the wheel under simulation. The value λ is exactly the Lagrange multiplier corresponding to the servo-constraint above.

It is easy to see the servo-constraint plays here a role of the virtual testbench for investigating the omni wheel dynamics. The remainder of the whole vehicle model is replaced simplistically by the wrench being applied to the wheel. The whole omni wheel dynamics visual model is seen in Figure 5

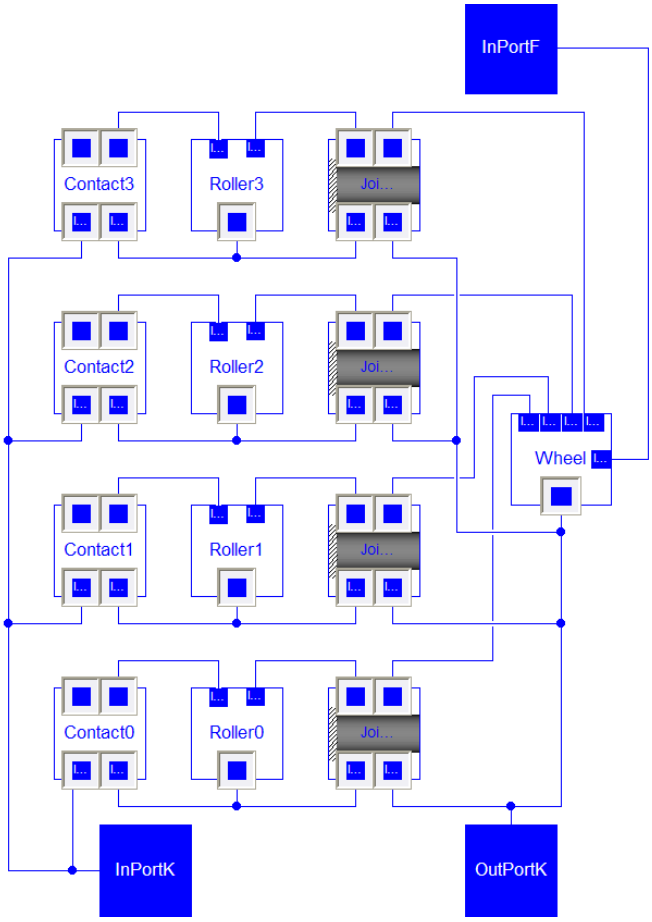

Figure 5: The omni wheel dynamics visual model.

As one can detect here the model of the omni wheel multibody system has been implemented using original multibody dynamics class library developed previously [7, 9]. One can use this library independently or with help of the knowm Modelica Standard Multibody class library or with any other Modelica library. The better way being recommended for such use is the following one. Firstly, one can implement mechanical subsystems of the whole system under implementation. For instance, mechanisms having tree structure are modeled in a better way using Modelica Standard Multibody Library while mechanical subsystems including unilateral constraints with friction are better implemented using the aforementioned library of classes. Secondly, the only issue remained is to implement proper interfaces using models of ports mapping corresponding signals being tranferred from one subsystems to another.

5 IMPROVED CONTACT TRACKING ALGORITHM

5.1 Implicit contact tracking algorithm

We will assume in the further course that the wheel plane keeps its vertical orientation permanently. We have to introduce auxiliary orthonormal bases: $b_1 = \{\mathbf{i}_1, \mathbf{j}_1, \mathbf{k}_1\}$ and $b_2 = \{\mathbf{i}_2, \mathbf{j}_2, \mathbf{k}_2\}$. Intermediate base b_2 characterises partially position and orientation of the roller, while the base b_1 relates to the omni wheel.

The base b_2 coordinate system has its origin O_B at the roller central point. The unit vector $\mathbf{i}_2$ is directed along the roller axis of rotation, see Figure 6, fragment (a). The unit vector $\mathbf{j}_2$ is directed orthogonally to $\mathbf{i}_2$ and lies simultaneously in the vertical plane. The third unit vector $\mathbf{k}_2$ of the base b_2 is defined in a natural way as

$$\mathbf{k}_2 = \mathbf{i}_2 \times \mathbf{j}_2.$$

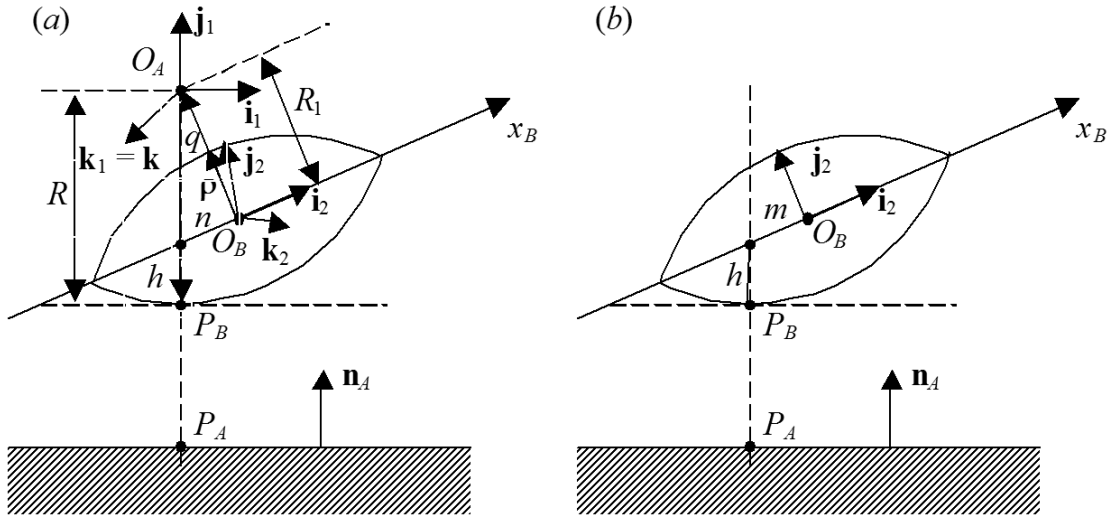

Figure 6: Contact tracking scheme: (a) lateral view of the omni wheel with a roller has been rotated about line O_AO_B by the angle ψ, (b) lateral view of the individual roller.

Remind here that all unit vectors are computed w. r. t. given fixed (absolute) coordinate system. We assume that positions and orientations are known for all bodies belonging to the multibody system for any instant $t \in [t_0, t_1]$ of simulation process. Therefore, we have

$$\mathbf{i}_2 = T_B \cdot (1,0,0)^T, \quad \boldsymbol{\rho} = (\mathbf{r}_{O_A} - \mathbf{r}_{O_B}) \,/\, |\mathbf{r}_{O_A} - \mathbf{r}_{O_B}|\,,$$

where T_B is the roller current orientation matrix.

Origin of the base b_1 coordinate system is located at the point O_A ($= O$ in Figure 4) of the wheel center. The unit vector $\mathbf{i}_1$ is oriented horizontally and belongs to the wheel plane. The unit vector $\mathbf{k}_1$ is orthogonal to the wheel plane and is identical to one of the wheel connected base vectors. We assume that using a controller the vector $\mathbf{k}_1$ permanently maintains its horizontal state. Supposing vector $\mathbf{k}_1(t)$ known we also have $\mathbf{j}_1(t) = (0,1,0)^T$ and $\mathbf{i}_1(t) = \mathbf{j}_1(t) \times \mathbf{k}_1(t)$.

Consider now relations providing base b_2 construction. Unit vector $\mathbf{i}_2$ has been built above. During roller and the floor contact the vector $\mathbf{i}_2(t)$ can not become vertical. Moreover, if the

roller distortion takes place, its angle of rotation $\psi > 0$ about axis $O_A O_B$ is fixed non-zero, then the condition $\mathbf{i}_2 \neq (0,1,0)^T$ is fulfilled permanently. So we can assume that the condition

$$\mathbf{c} = \mathbf{i}_2 \times (0,1,0)^T \neq \mathbf{0}$$

is also fulfilled.

Thus, we can define $\mathbf{k}_2 = \mathbf{c}/|\mathbf{c}|$. And after this we can set $\mathbf{j}_2 = \mathbf{k}_2 \times \mathbf{i}_2$. Geometrical constraints, conditions of orthogonality to be exact, play important role in the omni wheel kinematics

$$\boldsymbol{\rho} \cdot \mathbf{i}_2 = 0, \quad \boldsymbol{\rho} \cdot \mathbf{k}_1 = 0.$$

These equations actually apply to computing the unit vector $\boldsymbol{\rho}$ and we have their differential versions

$$\frac{d}{dt}\boldsymbol{\rho} \cdot \mathbf{i}_2 + \boldsymbol{\rho} \cdot \frac{d}{dt}\mathbf{i}_2 = 0, \quad \frac{d}{dt}\boldsymbol{\rho} \cdot \mathbf{k}_1 + \boldsymbol{\rho} \cdot \frac{d}{dt}\mathbf{k}_1 = 0.$$

The value $c_\beta = \cos\beta = \mathbf{i}_2 \cdot (0,1,0)^T$ of cosine for the angle β of the roller axis inclination to vertical $(0,1,0)^T$ plays also an important role in the contact tracking algorithm. If current value of the variable c_β is less than some limiting parameter $c_{\beta\max}$, and simultaneously if an altitude of the point O_B defining position of the roller center is less than value R of the wheel radius then the contact takes place. Otherwise no contact occurs.

Note here that in order to arrange the unilateral constraint in the multibody system dynamics model the developer usually has to implement something like hybrid automata construct. In our omni wheel model, on the contrary, this is not the case. It turned out sufficient to implement "simple" "`if`" construct to switch states "contact" and "no contact" for each individual roller, and simultaneously to advance forward "contact" state from one roller to its neighbour. The whole picture looks like from time to time neighbouring rollers mutually exchange their states. One can find details of the unilateral constraint implementation in [1]. Merely note that "`if`"-alternatives are the following: (a) "contact" state corresponds to zero-valued relative acceleration of two contacting surfaces at the point of contact, (b) "no contact" branch corresponds to the zero-valued reaction mutual for both bodies at contact. All this is according to the Signorini rule. "`if`"-condition depends on the roller orientation variables.

Essential role in all these computations plays a contact tracking algorithm. Generally, its implementation reduces to computation of the contact point/patch which enables computing forces at contact. Usually, one considers contact of two surfaces participating in rigid/elastic interaction of two massive bodies. As a rule, such algotithms are pretty expensive and noticeably slow the whole simulation process. Fortunately, in case of omni wheels we found here the simplest way to make this computation as fast as possible using "elementary" geometric considerations.

We can also easily see from the Figure 6 that the point P_B of contact between roller and floor is obtained using formula

$$\mathbf{r}_{P_B} = \mathbf{r}_{O_B} + R_1\boldsymbol{\rho} - R\mathbf{j}_1 + \mu\mathbf{k}_1,$$

where the scalar μ is to be computed. Here the value R_1 is the distance between points O_A and O_B. The scalar μ can be computed if we multiply the last equation by $\mathbf{k}_2$ using dot-product. Thus we have

$$\mu = \left[R\mathbf{j}_1 \cdot \mathbf{k}_2 - R_1\boldsymbol{\rho} \cdot \mathbf{k}_2\right] / \mathbf{k}_1 \cdot \mathbf{k}_2$$

since the vector $\mathbf{r}_{P_B} - \mathbf{r}_{O_B}$ lies in vertical section of axis-symmetrical surface of the roller, and the vector $\mathbf{k}_2$ by construction is orthogonal to this section. As a result the position $\mathbf{r}_{P_B}$ of the contact point P_B is uniquely computed.

5.2 Explicit contact tracking algorithm

Yet another way to obtain current position $\mathbf{r}_{P_B}$ of the contact point P_B, or more accurately: the roller point closest to the floor, is an application of the following chain of equations. This chain is simply understood from geometrical scheme shown in Figure 6, (a) and (b).

$$\mathbf{r}_{P_B} = \mathbf{r}_{O_B} - m\mathbf{i}_2 - h\mathbf{j}_1,$$

where $m = R_1 \sin q / \cos q / \cos\psi$, $h = R - R_1 / \cos q$, q is the current value for angle of deviation of the vector $\boldsymbol{\rho}$ from direction of the vector $\mathbf{j}_1$. So we have

$$\cos q = \boldsymbol{\rho} \cdot \mathbf{n}_A, \quad \sin q = (\mathbf{n}_A \times \boldsymbol{\rho}) \cdot \mathbf{k}_1.$$

Here we give explanations of some details of Figure 6. Fragment (a) corresponds to the lateral projection of the wheel and likewise the distorted roller projection. This latter object is shown here in a general position. Furthermore, P_B is the current contact point between the roller and the horizontal floor, n is a projection of the roller axial line segment onto the wheel plane. We can see easily that this projection is computed by the formula $n = m\cos\psi$ because the roller axis is turned about $O_A O_B$ by the angle ψ, see fragment (b) for the roller axial vertical lateral section. Thus, we have to pass two straight line segments from the roller center O_B to reach the point P_B: (a) the segment of the roller axis of length m; (b) the segment down the vertical of length h. As we already mentioned above all variables needed are computed through known variables using explicit formulae.

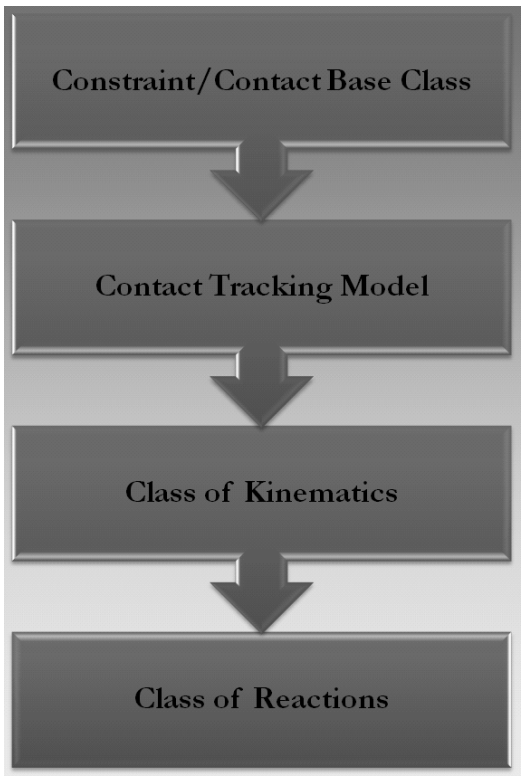

Figure 7: Contact model by stages of inheritance.

In case of $\psi > 0$, distortion exists, for both implicit and explicit algorithms not all the length of the roller surface generatrix is necessarily in contact. So really we have to cut tips of rollers

to provide regular simulation process. Length of the tip to be cut we can obtain for instance empirically or compute it explicitly. Indeed, one can easily see from Figure 6 that the real roller length should be computed by the formula

$$L = 2R \sin\alpha / \cos\psi.$$

"Ideal" switching of contact takes place in this case: exactly at the instant of contact loss for current roller a contact immediately arises for the "next" roller in direction of the wheel rolling.

5.3 Computer implementation

Model of the omni wheel testbench virtual prototype is a container class including the following objects instantiated: (a) disk of the wheel; (b) objects of rollers mounted along the wheel rim; (c) objects of joints connecting rollers and the wheel disk; (d) objects of contacts connecting objects of rollers and the object of the horizontal floor surface; (e) model of base body as a horizontal floor.

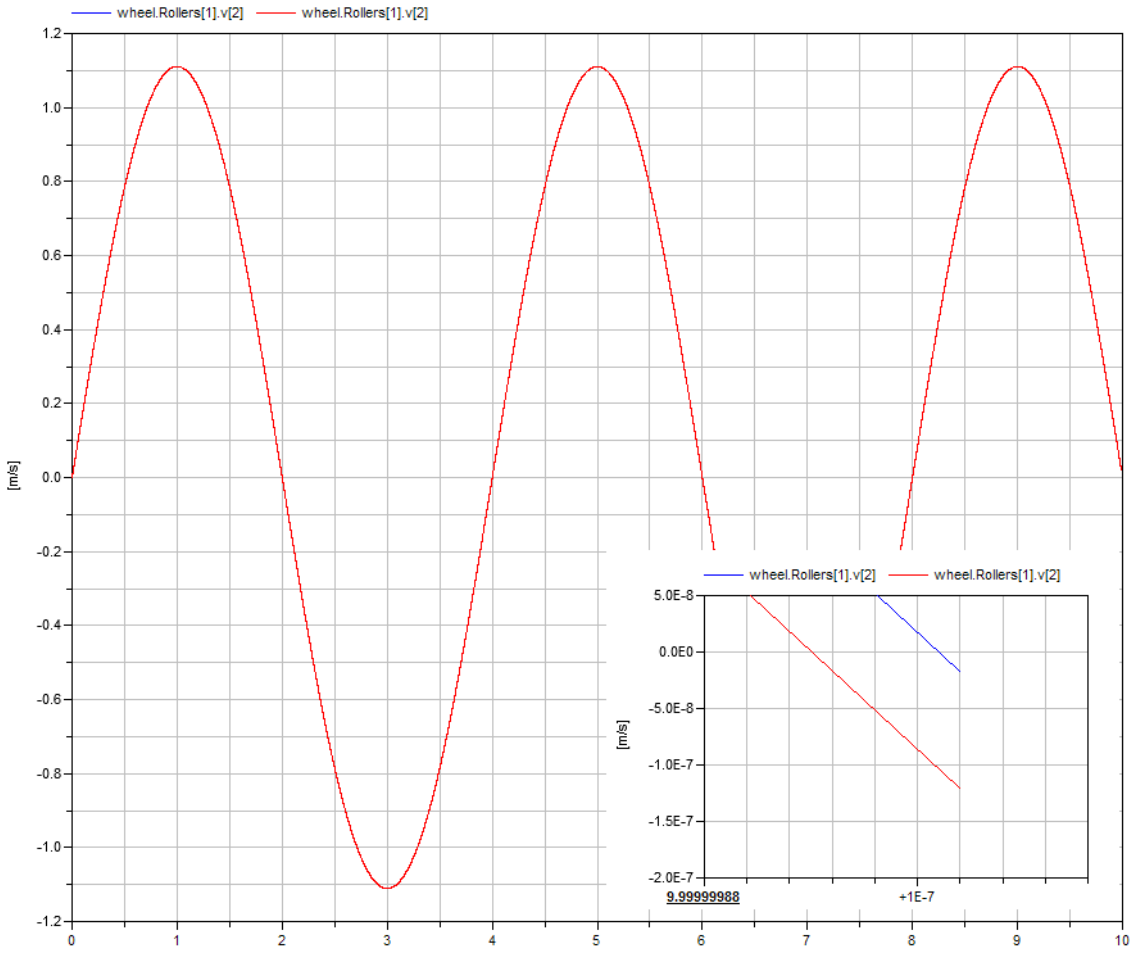

Figure 8: Comparison of dynamics for the roller No. 1 central point, its velocity y-coordinate, for cases of: explicit (blue curve) and implicit (red curve) algorithm of contact tracking.

Let us analyse in more details a structure of contact model. This model has many similarities with contact models previously considered [7]. Nevertheless important differencies exist. One of them mentioned above with regard to organization of the contact class using simple and

efficient construct [1]. Note that in case of $\psi > 0$ the point of contact creates a curve with discontinuities at instances of rollers changes. However, this circumstance does not prevent the process of regular simulation.

Finally, we apply rigid point contact model as part of the simplest omni wheel model. For this we use the base class for constraint/contact models having only equations of Newton's third law as a behavioral section [9].

We use class of the contact tracking model on the second stage of inheritance, see Figure 7. Cases of this class organization have been analysed above. Coordinates of nearest points P_A and P_B at contact for each pair (floor, roller) are computed as a result for this class functionality.

Class for computing all kinematical characteristics at contact needed "works" in case of contact existence on the next stage of inheritance. On the third stage class for computing the reactions at contact is "turned on". Reactions are the following: (a) normal reaction; (b) tangent force of friction; (c) torque of reactions (zero in the current consideration though it is not difficult to compute torque for several contact models).

To verify an approach for building up the models under analysis we compare the omni wheel dynamics in cases of implicit and explicit algorithms. The wheel performs free motion (combining rotation and sliding) with the only restriction: keep vertical alignment of the wheel disk.

Roller No. 1 central point, its mass center, altitude was analyzed and verified. More accurately we examine y-coordinate of the point velocity. Both models turned out almost identical: in the worst case we have a divergence: in accelerations of order 10^{-8}, in velocities of order 10^{-7}, in position of order 10^{-6} over the time span being equal to 10 units of time. Results of simulation for velocities are shown in Figure 8. Other divergencies for the roller No. 1 central point acceleration and position at time = 10units are shown in Figure 9 and 10 respectively. As expected the model with explicit contact tracking algorithm is faster approximately in 1.5 times.

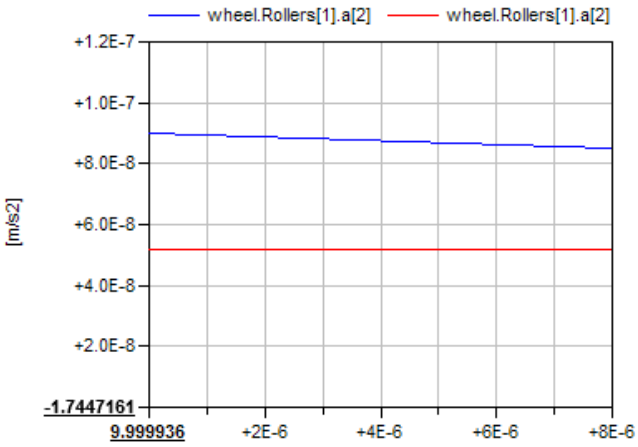

Figure 9: Divergence for y-components of acceleration.

6 CONCLUSIONS

- Two contact tracking algorithms were proposed: implicit and explicit. As expected the second algorithm turned out to be faster almost in 1.5 times. Both algorithms are simple (and efficient) even in simpler case of rollers without any distortion.

- In case of distorted rollers contact curve becomes discontinuous at instants of rollers

Figure 10: Divergence for y-components of position.

change. But simulation process maintains its regularity.

- Both algorithms generate identical dynamics.
- Process of the contact model design using technology of "vertical separation" outlined above has an evident motivation and allows a simple generalization both for the normal force computation and for the tangent friction force model.

7 ACKNOWLEDGMENT

The investigation was performed in MAI under financial support provided by RSF, project 14-21-00068.

Keywords: Solid System, Internal Movers, Dry Friction, Mathematical Modeling, Tracking.

Abstract. *In this paper we investigate the solid system with internal rotating eccentrics as a movers. The system moves in plane with dry friction. Massive eccentrics rotating with variable angular velocity convert rotational motion into uneven translational. The motion is caused by inertia forces and friction between the system and the rough surface and occurs in short steps or slides. The equations of motion are derived under assumption of decreasing linear dependence of electric motor torque on angular velocity. We consider the motion of the platform and the pendulum, and then the resulting system is presented in a convenient form for numerical integration in MatLab. Runge–Kutta fourth-order method is used. Tracking of labels applied to the system is performed using time-lapse video and Adobe After Effects. The results of numerical integration of math model are presented and compared with experimental data obtained using a tracking program.*

1 INTRODUCTION

An interest in solid systems driven by inner movements of masses without outer movers, such as wheels, chain tracks, or legs, arises in last decade. A new class of mechanisms (robots, mechatronic systems) able to move in a resisting medium without external movers due to movement of internal bodies attracts attention [1-12].

In study [1] there is a very simple mechanical model: an absolutely rigid body that can move along a horizontal line; inside the body, there is a movable mass that also moves horizontally. Such a motion realized as a result of the specific periodic relative motions of a material point inside the body. The internal motion parameters providing for a maximum average velocity of the system as a whole are determined.

In paper [2] they deal with a class of vibration-driven models that simulate the dynamics of vibration-driven mobile robots, which mean autonomous mechanisms consisting of a body and movable internal masses. Moving under the action of drives, the internal masses interact with the robot body and the body, in turn, interacts with the external environment. By controlling the motion of internal masses, they can control the force of reaction of the external environment acting on the robot body, providing its motion in the desired direction and regulating the velocity. Vibration-driven robots are simple in design and do not require special limbs, such as wheels, chain tracks, or legs. In particular, this makes them promising for movement not only on surfaces but also within dense media resisting pressure (e.g., in soil), as well as in pipes. Presumably, micro robots of this type can be applied in medicine in order to deliver drugs or a diagnostic sensor to an affected area.

In work [3] the controlled horizontal motion of a body in the presence of dry friction forces is investigated. Control is accomplished by means of a movable mass that can move within the body in a bounded range.

In study [4] for three forms of resistance forces they have calculated the periodic translational motion of a two-mass system consisting of the main body (the container), interacting with the medium, and an internal moving mass. They have considered simple motions of the internal mass with respect to the container, called two-phase motion, and a corresponding piecewise-constant relative velocity of the internal mass. They have shown that as a result of simple motions of the internal mass with respect to the body, the system is displaced as a whole. The principle of motion considered in this paper was realized in a number of experimental models. The internal displacements were obtained by means of a pendulum system and a rotating mass. Mobile mini-robots, moving inside a tube, have been designed and successfully tested. Experiments have confirmed the practical realizability of the principle described above for displacing bodies in resistant media.

In paper [5] the dynamical system consisting of a rigid body and an internal mass is investigated. The rigid body can move along a rough horizontal plane with a piece-wise linear resistance law due to the special periodic internal motions. A three-phase control is constructed and the motion of the body relative to the environment is controlled by varying the relative acceleration of the internal mass. The relationships between the control parameters for the realization of a directed velocity-periodic motion of the rigid body are established through both theoretical and numerical methods. Optimal and practical parameters of the internal motion, at which the maximal mean velocity of the body is reached, are determined.

In work [6] a periodic motion of the internal body relative to the main body, which generates the motion of the main body with periodically changing velocity and the maximum displacement for the period, is constructed for a wide class of laws of resistance of the environment to the motion of the main body. The principle of motion considered is appropriate for mobile mini- and micro-robots. The body (housing) of such robots can be hermetically

sealed and smooth, without protruding parts, which enables these robots to be used for the non-destructive inspection of miniature engineering structures such as thin pipe-lines, as well as in medicine.

In study [7], optimal control problems are solved for two types of vibrationally excited mobile systems. First, a three-body articulated system moving in a horizontal plane is considered. The system consists of a rigid body (main body) to which two links are attached by revolute joints. All three bodies interact with the environment with the forces depending on the velocity of motion of these bodies relative to the environment. The system is controlled by highfrequency periodic angular oscillations of the links relative to the main body. This system models the swimming of some animals. The equation of motion of this system is derived and analyzed. Second, a two-body system moving along a horizontal line in a nonlinear resistive medium is considered. One of the bodies (the main body) interacts with the environment and with the other body (internal body), which interacts with the main body but does not interact with the environment. The environment resists the motion of the main body with a force that depends on the velocity of the main body relative to the environment. A periodic optimal motion of the internal body relative to the main body is defined by solving an optimal control problem.

In paper [8] they investigate two systems consisting of a spherical shell rolling without slipping on a plane and a moving rigid body fixed inside the shell by means of two different mechanisms. In the former case the rigid body is attached to the center of the ball on a spherical hinge. They show an isomorphism between the equations of motion for the inner body with those for the ball moving on a smooth plane. In the latter case the rigid body is fixed by means of a nonholonomic hinge. Equations of motion for this system have been obtained and new integrable cases found.

Paper [9] is concerned with the motion of a cubic rigid body (cube) with a rotor, caused by a sudden brake of the rotor, which imparts its angular momentum to the body. This produces an impulsive reaction of the support, leading to a jump or rolling from one face to another. The robot, called by them M-block, is 4 cm in size and uses an internal flywheel mechanism rotating at 20 000 rev/min. Initially the cube rests on a horizontal plane. When the brake is set, the relative rotation slows down, and its energy is imparted to the case.

This paper [10] deals with the problem of a spherical robot propelled by an internal omniwheel platform and rolling without slipping on a plane. The problem of control of spherical robot motion along an arbitrary trajectory is solved within the framework of a kinematic model and a dynamic model. A number of particular cases of motion are identified, and their stability is investigated. An algorithm for constructing elementary maneuvers (gaits) providing the transition from one steady-state motion to another is presented for the dynamic model. A number of experiments have been carried out confirming the adequacy of the proposed kinematic model.

In work [11] they consider the motion of a system consisting of a rigid body and internal movable masses on a rough surface. The possibility of rotation of the system around its center of mass due to the motion of internal movable masses is investigated. To describe the friction between the body and the reference surface, a local Amontons-Coulomb law is selected. To determine the normal stress distribution in the contact area between the body and the surface, a linear dynamically consistent model is used. As examples they consider two configurations of internal masses: a hard horizontal disk and two material points, which move parallel to the longitudinal axis of the body symmetry in the opposite way. Motions of the system are analyzed for selected configurations.

In work [12] the two-dimensional motion of a system consisting of a hollow rigid body, resting on a rough plane, and two internal mobile point masses, capable of moving parallel to

the longitudinal axis of symmetry of the body is considered. Friction in the contact area is modelled by a local Amontons–Coulomb law. A dynamically matched linear model is used to describe the normal stress distribution. The possibility of achieving rotation of the system by a certain relative motion of internal masses is investigated. Two control laws for the movable masses are considered: piecewise-linear and harmonic, for which the equations of motion are integrated numerically for different values of the parameters of the control laws.

In our work we consider solid system consisting of a rigid nesting frame with two internal masses in the form of eccentrics (unbalanced massive wheels). Eccentrics rotate with variable angular velocity and have no contact with external medium. Nesting frame has a contact with a rough surface with dry friction and moves short steps (or slides) in plane due to rotating eccentrics.

2 EXPERIMENTS

We constructed a model of solid system with two unbalanced wheels in Moscow Institute of Physics and Technology at the Chair of Theoretical Mechanics.

The solid system was designed in SolidWorks program. From a practical point of view, we decided to use open-source building platform (Makeblock, mechanical parts and motors). The result of modeling is presented on Fig.1.

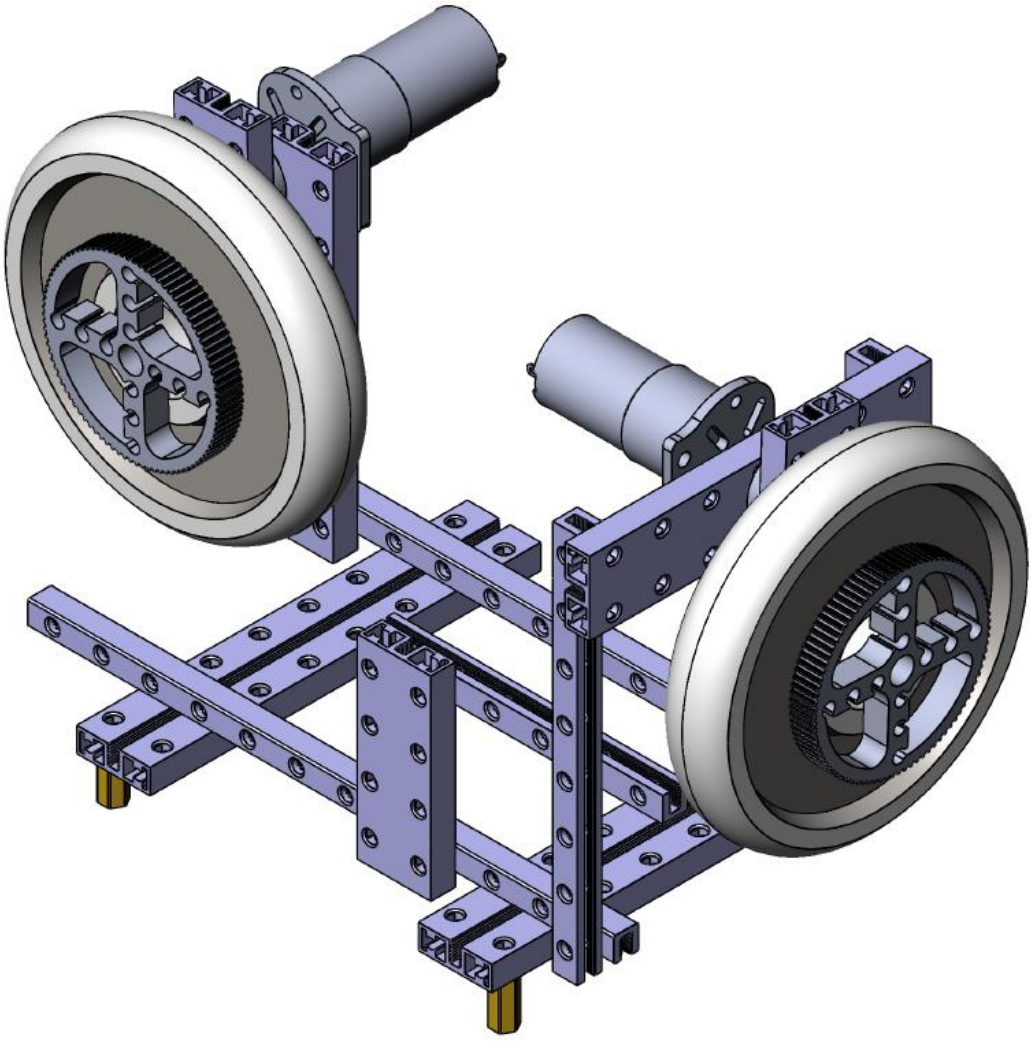

Figure 1: CAD-model of the solid system.

Assembly of the system has led to the result shown in the Fig. 2. Open-source microcontroller (Arduino) sets the velocities of motors rotating two eccentrics. Rigid nesting frame stays on four legs with rounded plastic foots.

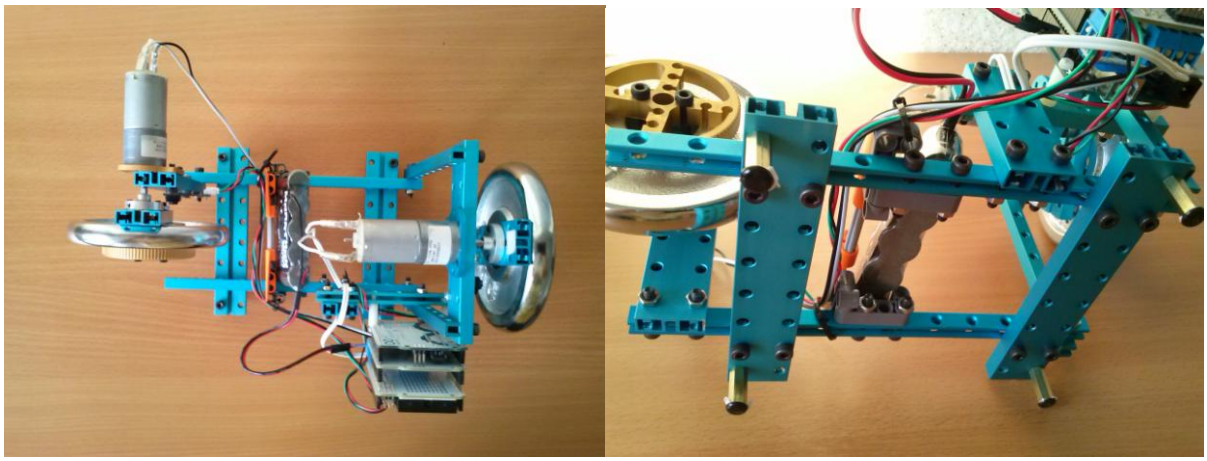

Figure 2: Experimental-model of the solid system (view from above, bottom view).

One of the wheels is placed along the longitudinal axis of symmetry, another one – in transversal position. The main parameters of the model are presented in Table 1.

Characteristics	Value
Total weight	1.825 kg
Weight of wheels	0.5 kg
Average angular speed of the wheels	125 rpm
Eccentricity of longitudinal wheel	3.5 cm
Eccentricity of transversal wheel	2.5 cm
The longitudinal distance between the points of contact with the surface	13.1 cm
The transversal distance between the points of contact with the surface	11.3 cm

Table 1: Parameters of the model.

First part of experiment was devoted to testing of the system on different rough surfaces. Characteristics of surfaces are presented in Table 2.

№	Type	Characterisation	Coef. of friction
1	Laminated chipboard 1	Smooth, with microscopic uniform embossing	0.31
2	Glass	Smooth	0.52
3	Laminated chipboard 2	Smooth, with the moth-eye pattern "under the tree"	0.35
4	Plywood	Very rough, non-uniform	0.34
5	Plastic	Slightly rough, uniform	0.32

Table 2: Characteristics of surfaces.

Two series of experiments were conducted. First, the longitudinal motion of the body was studied (the transversal wheel does not rotate) for two types of rotation (back and forth). The results are shown in Fig. 3, where all measurements were made for 11 revolutions of the

wheel with average angular velocity 125 rpm. In the second series, the rotational motion was experienced (only the transversal wheel is rotating) in similar conditions. The results are presented in Fig. 4.

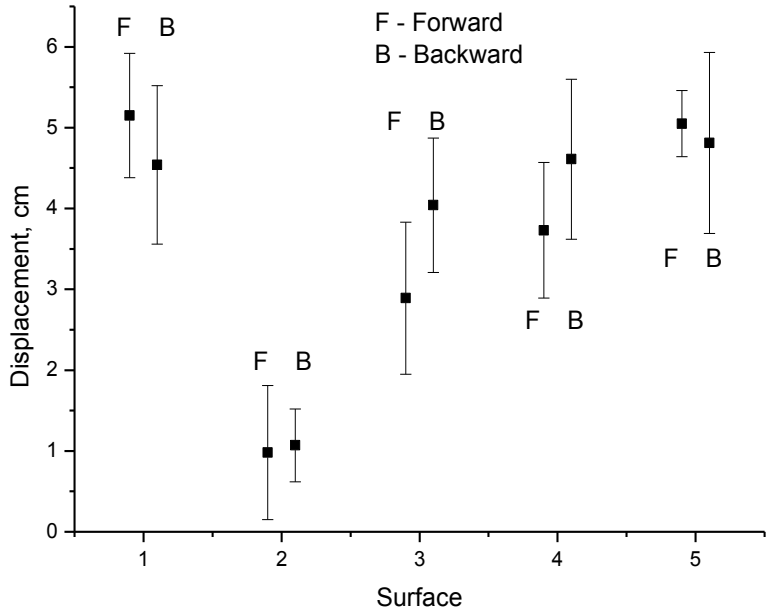

Figure 3: Longitudinal displacement of the body (back and forth) on different surfaces.

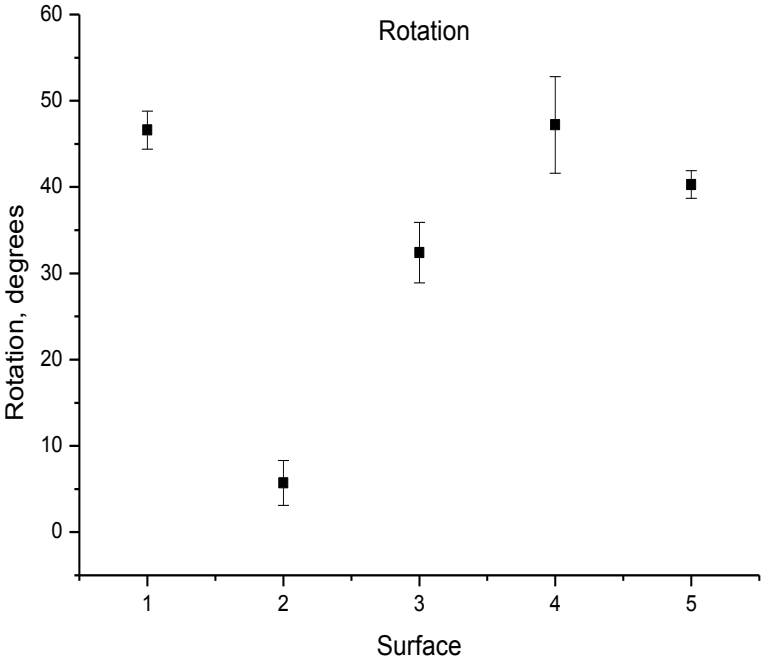

Figure 4: Rotational motion of the body on different surfaces.

It can be seen that both displacement and rotation angle are diminishing with increasing of the coefficient of friction. Note that if this coefficient were zero, no displacement would occur.

In this series of experiments the glass was the most difficult material in terms of repeatability – relative measurement error was the highest compared to other materials. Conversely, the most predictable was the laminated chipboard surface. That is why in the second part of experiments, we decided to use laminated chipboard only.

Second part of experiment was devoted to tracking of the system on the rough surface. The longitudinal motion of the body was studied (the transversal wheel does not rotate) for one type of rotation (forth).

Tracking of labels applied to the system is performed using time-lapse video and Adobe After Effects program. Video frame rate was 60 frames per second. The results of tracking experiments are presented on Fig. 5 (displacement of the system body in meters, time in seconds). Observation of the movement is accomplished by means of contrasting markers on the system components. Recording is done on camera. The resulting video is processed in the software. It uses the standard function "Tracking". In the case of tracking robot position output data are contingent pixels that are converted into millimeters (60 px = 10 mm). To control the time periods and synchronization in the experiment it was used a stopwatch accurate to hundredths of a second.

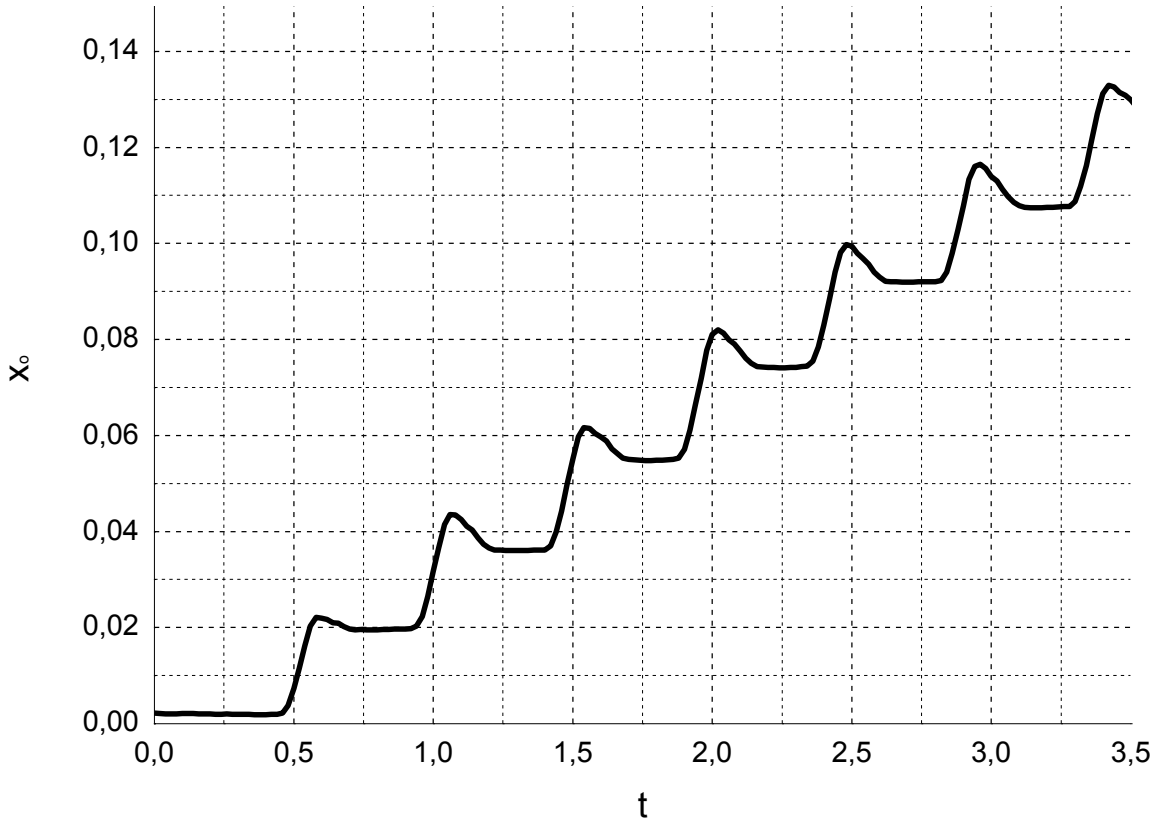

Figure 5: Experimental data obtained using a tracking system in Adobe After Effects program, displacement of body in dependence of time

As we can see, the movement takes place at a constant average speed. Approximately periodic movement occurs sliding forward with some setback.

Such movement can be explained qualitatively as follows. Wheel rotates with variable angular velocity. There are two phases: first, when wheel moves same direction as acceleration of gravity; and the second, vice versa. In first case wheel is accelerated, in second – slows down. Uneven rotational movement of the wheel is converted into a non-uniform translational movement of the base frame, since there are unequal movement pulses differently compensated by friction forces between foots and surface.

The nature of the movement is in good agreement with the results of mathematical modeling, which are presented in the next section.

3 MATHEMATICAL MODELING

First consider the simplified system, shown in Fig.6. A hollow case of mass *m* with flat basement carries a mathematical pendulum of mass m_1 and length *a*, suspended at the point O'. The external forces include normal reaction *N*, friction force *F*, and moment *M*, applied to the pendulum. Note that while the reaction forces *N* and *F* have passive character, the moment *M* is created by a motor, attached to the case, and ensures the movement of the system.

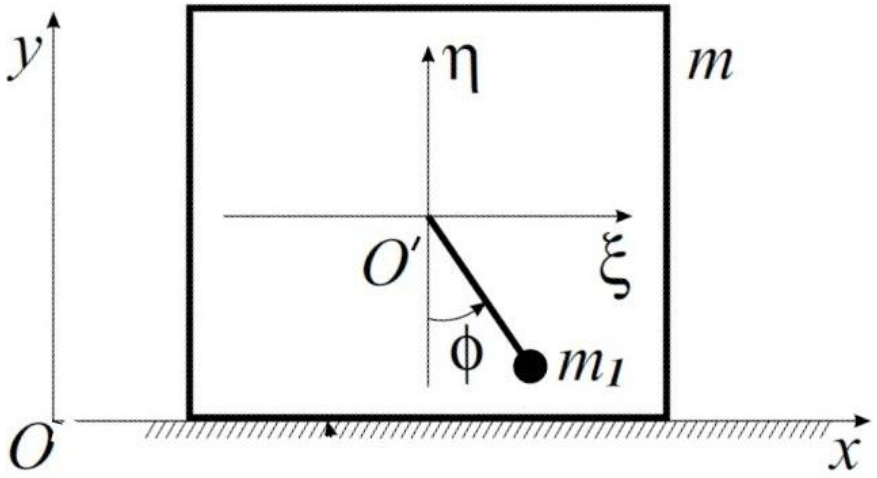

Figure 6: Mechanical model of the system with single unbalanced wheel.

We set coordinates *x* and *y* of point O' and angle ϕ between the pendulum axle and vertical as generalized coordinates. The equations of motion in the Lagrangian form are:

$$\frac{d}{dt}\left(\frac{\partial T}{\partial \dot{x}}\right)=F,\ \frac{d}{dt}\left(\frac{\partial T}{\partial \dot{y}}\right)=N-(m+m_1)g,\quad \frac{d}{dt}\left(\frac{\partial T}{\partial \dot{\phi}}\right)-\frac{\partial T}{\partial \phi}=-\frac{\partial \Pi}{\partial \phi}+M,$$

$$T=\frac{1}{2}(m+m_1)\left(\dot{x}^2+\dot{y}^2\right)+\frac{1}{2}m_1\left(a^2\dot{\phi}^2+2a\dot{x}\dot{\phi}\cos\phi+2a\dot{y}\dot{\phi}\sin\phi\right), \tag{1}$$

$$\Pi=-m_1 ag\cos\phi,\quad F=-\mu N\operatorname{sign}\dot{x}.$$

Since *y=const*, the second equation (1) follows:

$$N=(m+m_1)g+am_1\left(\ddot{\phi}\sin\phi+\dot{\phi}^2\cos\phi\right). \tag{2}$$

A physically plausible form of system (1) is:

$$(m+m_1)\frac{dv_0}{dt}=F,\quad \frac{d}{dt}(T+\Pi)=F\dot{x}+M\dot{\phi},\quad v_0=\dot{x}+a\xi\dot{\phi}\cos\phi,\quad \xi=\frac{m_1 a}{m+m_1}, \tag{3}$$

where v_0 is velocity of the centre of gravity.

We will make the assumption of a decreasing linear relationship between torque of the motor and the angular velocity of its rotation (Fig. 7):

$$M=M_0-k|\omega|,\quad M_0,k=const,\quad M_0,k>0. \tag{4}$$

This kind of dependence usually takes place in direct current motors as in our work.

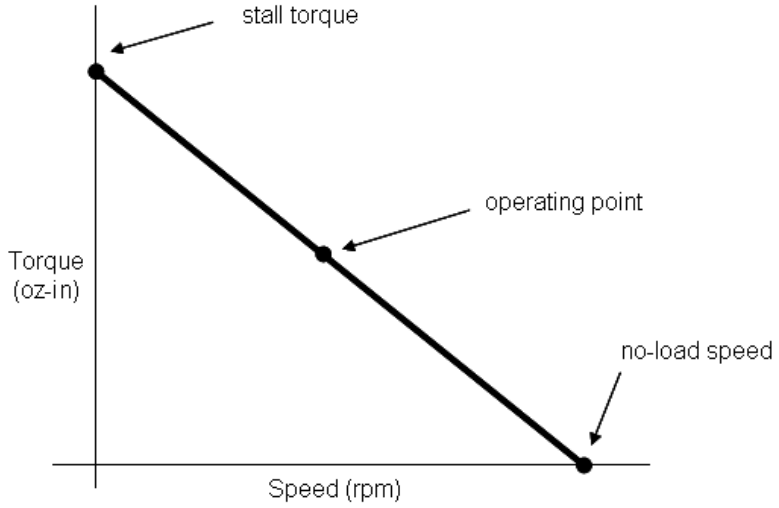

Figure 7: The dependence of the torque of the motor from its angular velocity.

As a result, we obtain the following system of equations for the motion of the platform and the pendulum:

$$\begin{gathered}\left(m+m_1\right)\dot{\upsilon}+am_1\left(\ddot{\varphi}\cos\varphi-\dot{\varphi}^2\sin\varphi\right)=-\mu N\frac{\upsilon}{|\upsilon|},\\ N=\left(m+m_1\right)g+m_1a\left(\ddot{\varphi}\sin\varphi+\dot{\varphi}^2\cos\varphi\right),\\ m_1a^2\ddot{\varphi}+m_1a\dot{\upsilon}\cos\varphi=M_0-k|\dot{\varphi}|-m_1ag\sin\varphi.\end{gathered}\tag{5}$$

The system is represented as (if $\upsilon\neq 0$):

$$\dot{\upsilon}=\frac{\Delta_1}{\Delta},\quad \ddot{\varphi}=\frac{\Delta_2}{\Delta},\tag{6}$$

where:

$$\begin{gathered}\Delta=mm_1a^2+a^2m_1^2\sin^2\varphi-\mu a^2m_1^2\sin\varphi\cos\varphi\frac{\upsilon}{|\upsilon|},\\ \Delta_1=\left(-\mu\left(m+m_1\right)g\frac{\upsilon}{|\upsilon|}+am_1\dot{\varphi}^2\left(\sin\varphi-\mu\cos\varphi\frac{\upsilon}{|\upsilon|}\right)\right)m_1a^2-\\ -am_1\left(\cos\varphi+\mu\sin\varphi\frac{\upsilon}{|\upsilon|}\right)\left(M_0-k|\dot{\varphi}|-m_1ag\sin\varphi\right),\\ \Delta_2=\left(m+m_1\right)\left(M_0-k|\dot{\varphi}|-m_1ag\sin\varphi\right)-\\ -\left(-\mu\left(m+m_1\right)g\frac{\upsilon}{|\upsilon|}+am_1\dot{\varphi}^2\left(\sin\varphi-\mu\cos\varphi\frac{\upsilon}{|\upsilon|}\right)\right)m_1a\cos\varphi.\end{gathered}\tag{7}$$

Then the system (6, 7) (taking into account also the case $\upsilon=0$) is solved numerically in MatLab program. Runge–Kutta fourth-order method is used. The results are shown in Fig. 8.

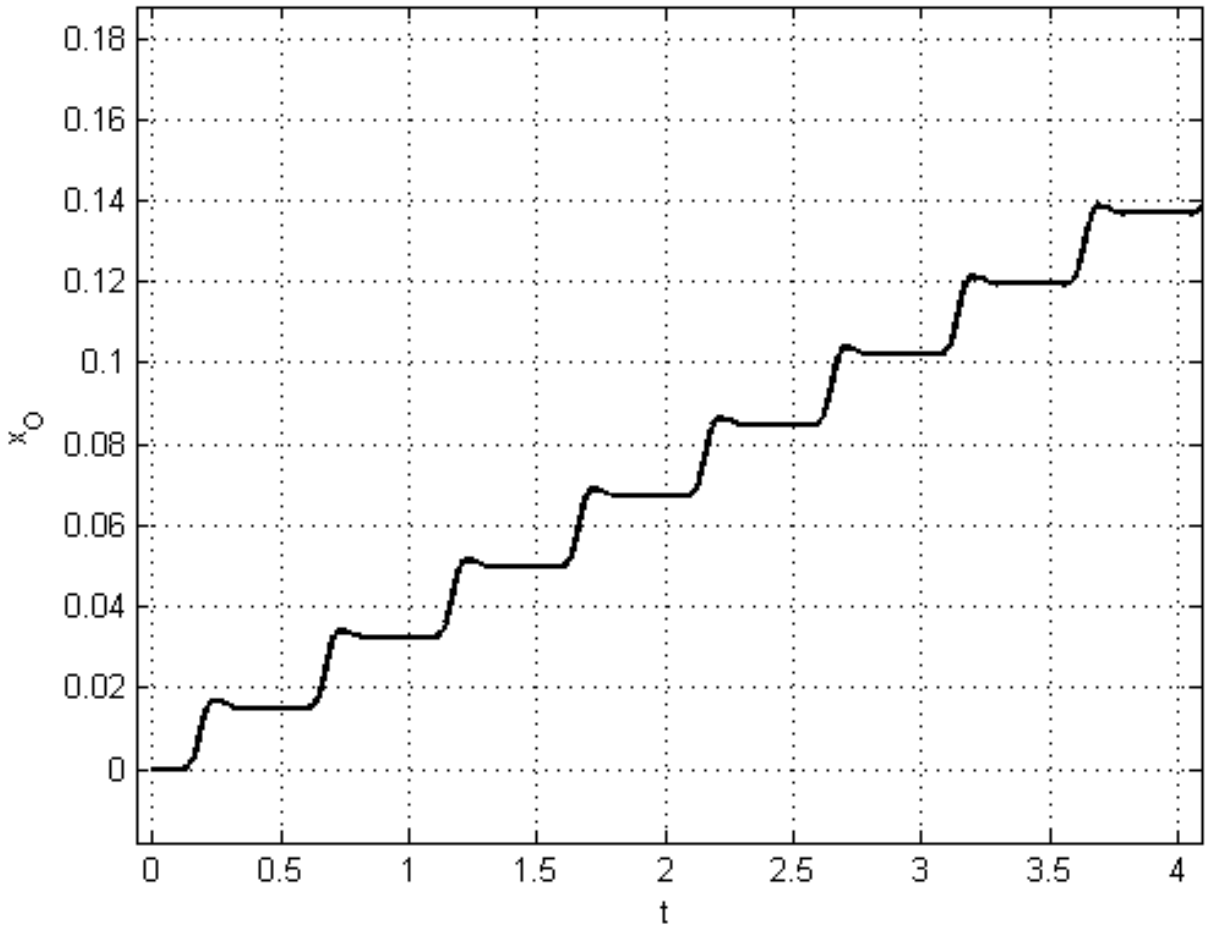

Figure 8: Numerical integration in MatLab, displacement of body in dependence of time.

Graph of body diplacement x (meters) from the time t (seconds) in Fig. 8 is obtained by numerical integration at the following conditions (Table 3):

Parameter	Value
The reduced length of the pendulum	0.06 m
Body weight (without pendulum)	1.325 kg
The pendulum weight	0.5 kg
The coefficient of friction	0.3
Acceleration of gravity	9.8 m/s^2
M_0	0.341 N·m
k	0.020 N·m·s

Table 3: Parameters in numerical integration.

Though this model can move, it has visible shortcomings. First of all, the rectilinear trajectory is unstable: due to unaccounted disbalances the body will deviate. Obviously, in practice, it is impossible to attach a cargo to the body, keeping ideal symmetry. Further, the practical needs are not restricted by rectilinear motion: usually mobile devises move along a prescribed curve. Our aim is to create a robot which could perform stable rectilinear or curvilinear motion. The key problem is to let the body move more accurately and to adapt to the surfaces with different coefficients of friction. This problem can be described in next paper.

4 CONCLUSIONS

- The motion of body with rotating internal wheels in interaction with external environment in form of rough surface can be used as the principle for the motion of mobile robots.
- Robotic mechanisms of this class, being isolated from external environment in shell, can be used in extreme conditions, with strong pollution of surrounding space, in aggressiveness of environment (for example, on another planet or in chemically active environment).
- The movement of the system is studied with the help of mathematical modeling and numerical integration and is compared with experimental data obtained by tracking method.

Abstract. *The principal aim of this paper is to evaluate the non-regular dynamic behavior of a vehicle involved in a collision with a fixed obstacle. Firstly, the model used for the wheels/ground interaction is the linear model. In addition, we established the constraints equations relating to holding contact with the ground and those concerning conditions of Ackermann. The obtained results had been compared with those given by the Pc-Crash software. We noted a good correlation for various scenarios. After validation, we used this model in the case of collision vehicle/fixed obstacle. A comparison of the simulation and experimental results confirmed the good agreement between the model and the real system of Crash-Test.*

1 INTRODUCTION

The modeling and simulation of the dynamic behavior of vehicle today are a scientific theme that has progressed rapidly under the impetus of vehicles industries. Thanks to their potential, this discipline has become an indispensable tool for improving the performance of vehicle.

However, in some situations, particularly those characterized by a non-regular vehicles dynamics (rollover, crash, sudden change in certain parameters of the roadway, demining operation by an intervention vehicle ...), the equations governing the movement of system lead to differential and algebraic equations are difficult to solve.

Most mechanical systems subjected to non-permanent excitations can be modeled by non-smooth dynamical systems. This non-regularity can originate in the batch-term control, in the interaction of the environment with the system and in problems of sudden change in system parameters. This loss of regularity, in the late 1970s, Michelle Schatzman [1] and Jean Jacques Moreau [2] started researching a mathematically consistent formulation for modeling the dynamic behavior of non-regular mechanisms.

In the case of vehicle, the non-regular dynamic situations can be classified into three categories:

i) Non-regular dynamic situations caused by discontinuities of control parameters (sudden change of steering angle, sudden braking action...).

ii) Non-regular dynamic situations caused by discontinuities in the system/environment interaction (collision vehicle/fixed barrier, collision vehicle/vehicle, rollover, skidding, ground roughness, slope change in a way, sudden change in the parameters road…).

iii) Non-regular dynamic situations caused by discontinuities of some parameters of the vehicle (sudden change of the damping coefficient or stiffness of the suspension system ...).

The objective of this work is the development of a comprehensive approach to dynamic behavior modeling of the vehicle taking into account the problems of irregular dynamics in collision between the vehicle and a fixed obstacle. In addition, the validation of the results of this approach compared with those given by appropriate software.

2 VEHICLE DYNAMIC MODEL

2.1 Geometric description of the system

In the present study, the structure of the considered mobile robot is composed of a vehicle (Figure 1) which is supposed rigid body fixed to the chassis and suspended via the suspension system composed of a spring and damper (*ki* is the stiffness and *bi* is the damping coefficient). Unsuspended masses are negligible compared to the suspended masse. In addition, the caster, toe and tilt angles of the kingpin are not considered. The anti-roll bar is not modeled. The braking is applied to all wheels and the load transfer is considered.

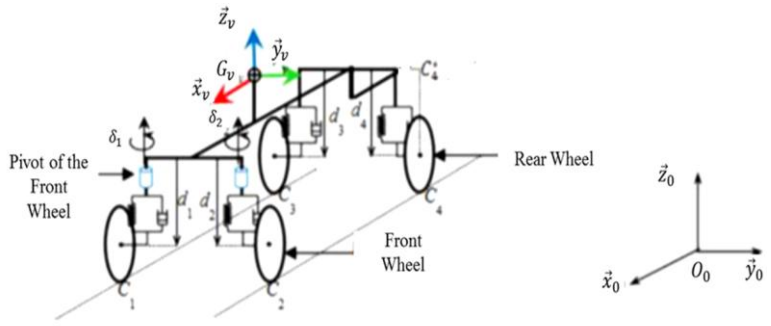

Figure 1: Vehicle model.

The system is moving on a road to which is attached a frame $\Re_0 = \left(O_0, \vec{x}_0, \vec{y}_0, \vec{z}_0\right)$. Let $\Re_v = \left(G_v, \vec{x}_v, \vec{y}_v, \vec{z}_v\right)$ be the mobile frame linked to the robot chassis, G_v the original center of gravity of the robot. The axis $\vec{x}_v$ is perpendicular to the plane of longitudinal symmetry of the vehicle, facing the left side, the axis is perpendicular to $\vec{y}_v$ and directed towards the front of the vehicle.

The configuration of the vehicle frame versus the fixed reference $\Re_0$ is defined by six parameters: three cartesian coordinates (x, y, z) of the center of gravity and the three angles (φ_1: roll, φ_2: pitching and φ_3: yaw) orientation of the $\Re_v$ with respect to reference $\Re_0$. The rotation matrix of $\Re_v$ relatively to $\Re_0$ is:

$$ {}^{0}P_{v} = \begin{bmatrix} c_2c_3 & s_1s_2c_3 - c_1s_3 & c_1s_2c_3 + s_1s_3 \\ c_2s_3 & s_1s_2s_3 + c_1c_3 & c_1s_2s_3 - s_1s_3 \\ -s_2 & s_1c_2 & c_1c_2 \end{bmatrix} \tag{1} $$

With: $c_i = \cos\left(\varphi_i\right), s_i = \sin\left(\varphi_i\right), i = 1..3$.

The kinematic wrenches of the vehicle frame relative to the reference, expressed in the vehicle frame are given by the following relationships:

$$ {}^{v}\vec{V}_{Gv} = {}^{v}P_0 \begin{pmatrix} \dot{x} \\ \dot{y} \\ \dot{z} \end{pmatrix} \text{ and } {}^{v}\vec{w}_v = \begin{pmatrix} w_{xv} \\ w_{yv} \\ w_{zv} \end{pmatrix} = \begin{bmatrix} 1 & 0 & -s_2 \\ 0 & c_1 & s_1c_2 \\ 0 & -s_1 & c_1c_2 \end{bmatrix} \begin{pmatrix} \dot{\varphi}_1 \\ \dot{\varphi}_2 \\ \dot{\varphi}_3 \end{pmatrix} \tag{2} $$

In order to take into account the efforts of wheels/ground interaction, we attach to each wheel, a frame $\Re_i = \left(C_i, \vec{e}_{xi}, \vec{e}_{yi}, \vec{e}_{zi}\right)$ placed at the wheel/ground contact point. The unit vectors of $\Re_i$ are defined, according to the normal $\vec{n}_i$ of the wheel i contact with the ground plane and its steering angle, by the following expressions:

$$For\ \ i=1...4\ \left\{\begin{array}{c} {}^{0}\vec{e}_{zi}={}^{0}\vec{n}_i \\ {}^{0}\vec{e}_{xi}=\dfrac{({}^{0}P_v\cdot{}^{v}\vec{v}_i)\wedge{}^{0}\vec{e}_{zi}}{\left|({}^{0}P_v\cdot{}^{v}\vec{v}_i)\wedge{}^{0}\vec{e}_{zi}\right|} \\ {}^{0}\vec{e}_{yi}={}^{0}\vec{e}_{zi}\wedge{}^{0}\vec{e}_{xi} \end{array}\right\} \tag{3}$$

With $\vec{n_i}$ the vector normal to the wheel plane. These vectors are defined by ${}^{v}\vec{v}_i=\begin{pmatrix}-\sin\delta_i & \cos\delta_i & 0\end{pmatrix}^T$ for the front wheels of the vehicle and ${}^{v}\vec{v}_i=\begin{pmatrix}0 & 1 & 0\end{pmatrix}^T$ for the other wheels.

The transition matrix of the wheel/ground interaction frame ($\mathcal{R}_i/\mathcal{R}_0$) is defined by the following relationship:

$${}^{0}P_i=\left[\begin{array}{c|c|c} {}^{0}\vec{e}_{xi} & {}^{0}\vec{e}_{yi} & {}^{0}\vec{e}_{zi} \end{array}\right]\quad for\ \ i=1...4 \tag{4}$$

In this, the elongations of the springs are modeled by the variables d_i, for i = 1...4. The vector of the generalized coordinates $\vec{q}$ contains the kinematic variables of translation and orientation of the vehicle, the variables characterizing the elongation of the springs and the two front wheels steering angles δ_1 and δ_2. The vector $\vec{q}$ is thus defined as follows:

$$\vec{q}=\left(x,y,z,\varphi_1,\varphi_2,\varphi_3,d_1,d_2,d_3,d_4,\delta_1,\delta_2\right)$$

2.2 Constraints equations

The constraints equations of a vehicle are defined by the conditions linked to Ackermann steering system and the wheels/ground holding contact conditions of the vehicle. They are developed bellows.

2.2.1 Ackermann Conditions

During the movement of the vehicle along a curve, the steering angles are linked to the existing of yaw speed w_{zv} and the radius of curvature of this curve by the following equations:

$$\begin{array}{l} if\ \ w_{zv}=0\Rightarrow\left\{\begin{array}{l}\delta_1=0\\ \delta_2=0\end{array}\right. \\ if\ \ w_{zv}\neq 0\Rightarrow\left\{\begin{array}{l}\delta_1=\tan^{-1}\left(\dfrac{L_v}{R+L_w/2}\right)\\ \delta_2=\tan^{-1}\left(\dfrac{L_v}{R-L_w/2}\right)\end{array}\right. \end{array} \tag{5}$$

With: L_v: vehicle wheelbase; L_w: rear track; $R=V_{xv}/w_{zv}$ The curvature radius calculated on the rear track of the robot center and V_{xv}: longitudinal velocity.

2.2.2 Wheels/ground holding contact conditions (WGHCC)

WGHCCs of a vehicle are defined by the following algebraic equations:

$$\left({}^{0}\overrightarrow{O_0C_i} - {}^{0}\overrightarrow{O_0G_v} - {}^{0}\overrightarrow{G_vC_i}^{*} + r_w\,{}^{0}\vec{n}_i \right) {}^{0}\vec{z}_v + d_i = 0 \quad for\ i = 1...4 \tag{6}$$

With r_w: the radius of the wheels.

The conditions (6), derived twice with respect to time, can be expressed as follows:

$$\left[J_v \right] \cdot \ddot{\vec{X}} + \overrightarrow{B_{cv}} = \vec{0} \tag{7}$$

With: $\left[J_v \right]$ is the Jacobean matrix inherent to the **WGHCC** of the vehicle;

$\overrightarrow{B_{cv}}$ are the acceleration constraints vector of **WGHCC** of the vehicle.

$$\ddot{\vec{X}} = \left(\ddot{x}, \ddot{y}, \ddot{z}, \dot{w}_{xv}, \dot{w}_{yv}, \dot{w}_{zv}, \ddot{d}_1, \ddot{d}_2, \ddot{d}_3, \ddot{d}_4 \right)^T \tag{8}$$

$$\left[J_v \right] = \begin{bmatrix} {}^{0}\overrightarrow{n_1}^{T} & -{}^{0}\overrightarrow{n_1}^{T}\left({}^{0}P_v \left[* {}^{v}\overrightarrow{G_vC_1} \right] \right) & -{}^{0}\overrightarrow{n_1}^{T}\,{}^{0}\overrightarrow{z_v} & 0 & 0 & 0 \\ {}^{0}\overrightarrow{n_2}^{T} & -{}^{0}\overrightarrow{n_2}^{T}\left({}^{0}P_v \left[* {}^{v}\overrightarrow{G_vC_2} \right] \right) & 0 & -{}^{0}\overrightarrow{n_2}^{T}\,{}^{0}\overrightarrow{z_v} & 0 & 0 \\ {}^{0}\overrightarrow{n_3}^{T} & -{}^{0}\overrightarrow{n_3}^{T}\left({}^{0}P_v \left[* {}^{v}\overrightarrow{G_vC_3} \right] \right) & 0 & 0 & -{}^{0}\overrightarrow{n_3}^{T}\,{}^{0}\overrightarrow{z_v} & 0 \\ {}^{0}\overrightarrow{n_4}^{T} & -{}^{0}\overrightarrow{n_4}^{T}\left({}^{0}P_v \left[* {}^{v}\overrightarrow{G_vC_4} \right] \right) & 0 & 0 & 0 & -{}^{0}\overrightarrow{n_4}^{T}\,{}^{0}\overrightarrow{z_v} \end{bmatrix} \tag{9}$$

$$\overrightarrow{B_{cv}}(i) = {}^{0}\overrightarrow{n_i}^{T}\left[{}^{0}P_v \left(2 \cdot {}^{v}\overrightarrow{w_v} \wedge \left(-\dot{d}_i \cdot {}^{v}z_v \right) + {}^{v}\overrightarrow{w_v} \wedge \left({}^{v}\overrightarrow{w_v} \wedge {}^{v}\overrightarrow{G_vC_i} \right) \right) \right] \quad for\ i = 1...4 \tag{10}$$

$\left[* {}^{0}\overrightarrow{G_vC_i} \right]$: The operator of the vector cross product.

2.3 Motions equations

The main forces acting on a vehicle in motion are wheels/ground interaction forces, the dynamic forces, gravity and the aerodynamic forces. In this model, we consider only the dynamic forces, gravity, and wheel/ground interaction efforts for simplification reasons.

Interaction efforts applied to each wheel of the system are represented in the reference related to wheels by the vector $\left(F_{xi} \quad F_{yi} \quad F_{zi} \right)$. These three components are linked together by a dependency relationship defined by the wheels/ground interaction efforts of the linear model [3] [4] [5] [10] [22]. Taking account of the forces applied on the vehicle, the twelve following equations of motion is obtained as follows:

$$\begin{cases} m \begin{pmatrix} \ddot{x} \\ \ddot{y} \\ \ddot{z} \end{pmatrix} = m \cdot {}^{0}\vec{g} + \sum_{i=1}^{4} {}^{0}\vec{F}_i + {}^{0}\vec{F}_{out} \\ {}^{v}\mathbb{I}_{Gv}\,{}^{v}\overrightarrow{\dot{w}_v} + {}^{v}\overrightarrow{w_v} \wedge \left({}^{v}\mathbb{I}_{Gv}\,{}^{v}\overrightarrow{w_v} \right) = \sum_{i=1}^{4} {}^{v}\overrightarrow{G_vC_i} \wedge {}^{v}\vec{F}_i + {}^{v}\vec{M}_{out} \end{cases} \tag{11}$$

With ${}^{0}\vec{g}$: the gravitational acceleration; ${}^{v}\overrightarrow{\dot{w}_v}$: Angular acceleration of the vehicle expressed in $\mathcal{R}_v$ frame; ${}^{v}\mathbb{I}_{Gv}$ is the tensor of inertia of the robot; m_v is the mass.

and:

$$\left({}^{v}P_i \cdot {}^{i}\vec{F}_i \right) \cdot {}^{v}\vec{z}_v = -k_i \left(d_i - L_{0i} \right) - b_i \cdot \dot{d}_i \qquad for\ i = 1...4 \tag{12}$$

With L_{0i}: Initial spring length of the wheel *i*.

By grouping the various equations of constraints and motion of the system (car-like robot), we obtain the following differential-algebraic system describing the dynamics of our system:

$$[A]\cdot\ddot{\vec{X}} = \vec{B} \tag{13}$$

$$[A] = \begin{bmatrix} [M_v]_{6\times10} \\ [J_v]_{4\times10} \end{bmatrix} with: [M_v] = \begin{bmatrix} m\cdot I_{3\times3} & 0_{3\times3} & 0_{3\times4} \\ 0_{3\times3} & {}^{v}\mathbb{I}_{Gv} & 0_{3\times4} \end{bmatrix}$$

$$\vec{B} = \begin{pmatrix} \vec{B}_{mv} \\ -\vec{B}_{cv} \end{pmatrix}, \text{ with}: \vec{B}_{mv} = \begin{pmatrix} m\cdot\vec{g} + \sum_{i=1}^{4}\left({}^{0}P_i\cdot{}^{i}\vec{F}_i\right) + {}^{0}\vec{F}_{out} \\ -{}^{v}\vec{w}_v \wedge \left({}^{v}\mathbb{I}_{Gv}\cdot{}^{v}\vec{w}_v\right) + \sum_{i=1}^{4}{}^{v}\overrightarrow{G_vC_i} \wedge \left({}^{0}P_i\cdot{}^{i}\vec{F}_i\right) + {}^{v}\overrightarrow{M}_{out} \end{pmatrix}$$

The numerical integration equations, with the consideration of the initial conditions, describe the dynamic behavior of the vehicle for a given time history of acceleration (or braking) and steering data. In this work, we used the Euler method for integrating these differential equations.

3 RESULTS

To discuss the reliability of obtained results we will validate them by comparison with those given by Pc-crash® accidents simulator [21]. Then, we will present some examples of applications of the modeling approach for different complex scenarios. In these examples, the applied geometrical and inertial parameters of the vehicle are summarized in Table 1.

Parameters	Car like robot
Mass *m*	950 *Kg*
Moment of inertia *Ixx*	1072 *Kg/m²*
Moment of inertia *Iyy*	1342 *Kg/m²*
Moment of inertia *Izz*	1342 *Kg/m²*
Height of center of gravity	0.50 *m*
Front track	1.41 *m*
Rear track	1.41 *m*
front wheelbase	1.04 *m*
Rear wheelbase	1.50 *m*
Front suspension stiffness	9.97 *KN/m*
Rear suspension stiffness	6.79 *KN/m*
Front dumping	897.28 *N.s/m*
Rear dumping	611.01 *N.s/m*
Coefficient of friction	0.70
Radius wheel	0.25 m

Table 1: Geometrical and inertial parameters of the vehicle.

Scenario 1: Acceleration and deceleration on a straight path:

This scenario is described as follows (Figure 2): *i)* an acceleration phase for 4 seconds; *ii)* a constant speed phase for 2 seconds and *iii)* a deceleration for 4 seconds (the braking is distributed on the front and rear wheels). The simulation results by the developed application and those given by PC-Crash are illustrated in figures 3 and 4. These figures show a good correlation between the results obtained by the dynamic model developed and those given by the software of Pc-Crash.

Scenario 2: Dynamics of the robot during the course of a turn:

This scenario is described as follows: *i)* linear movement for 2 seconds at constant speed $S = 15\ m/s$ and *ii)* turning for 8 seconds with 100m of curvature radius. The obtained simulation results are illustrated in figures 5 to 6. The curves plotted in these figures show a very satisfactory correlation between the results of our developed model and those given by Pc-Crash.

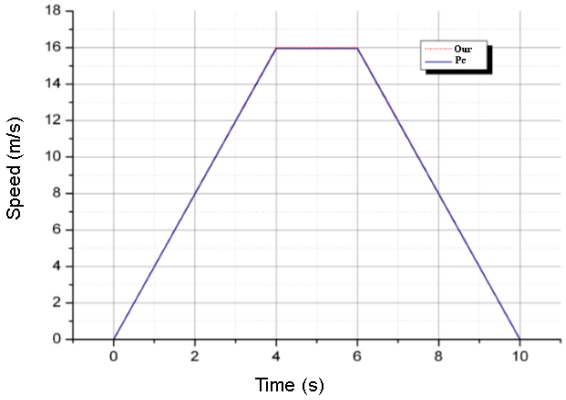

Figure 2: Speed of the vehicle.

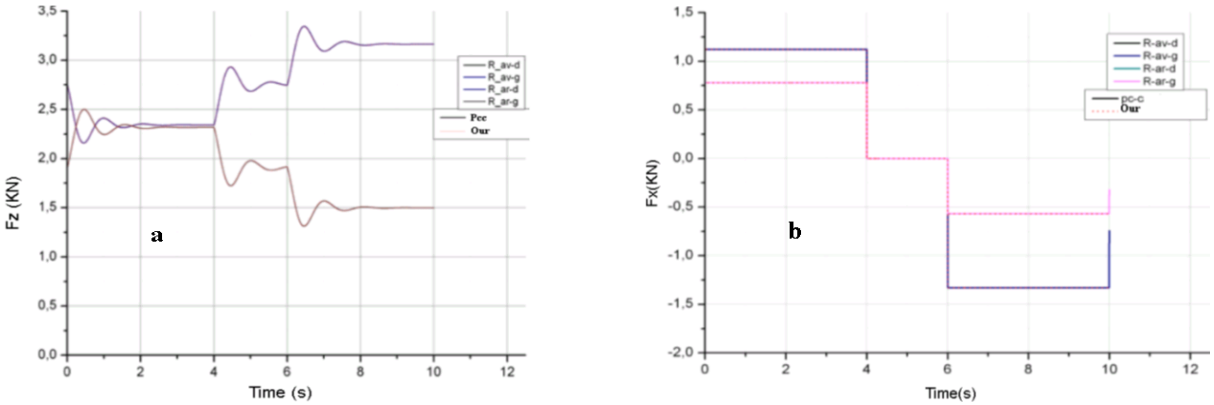

Figure 3: (a) Vertical and (b) longitudinal forces wheels

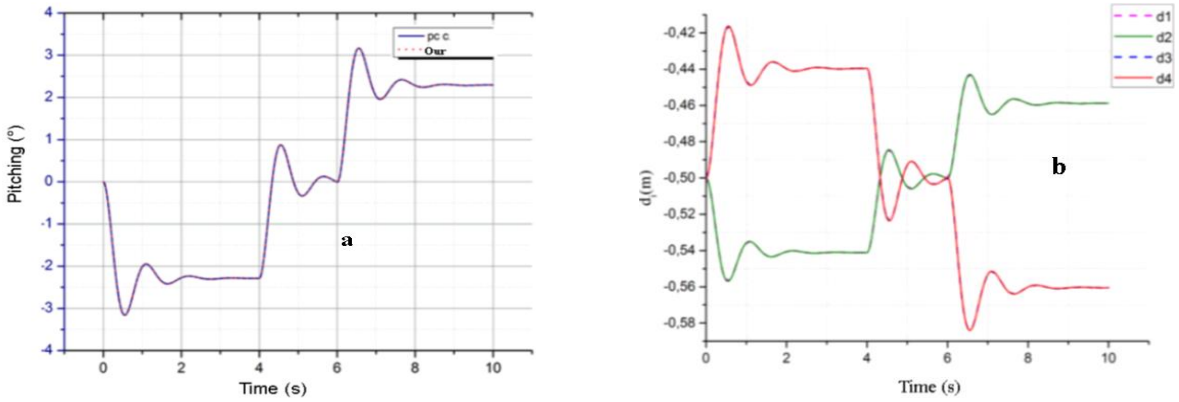

Figure 4: (a) Pitching angle and (b) elongation of spring of suspension

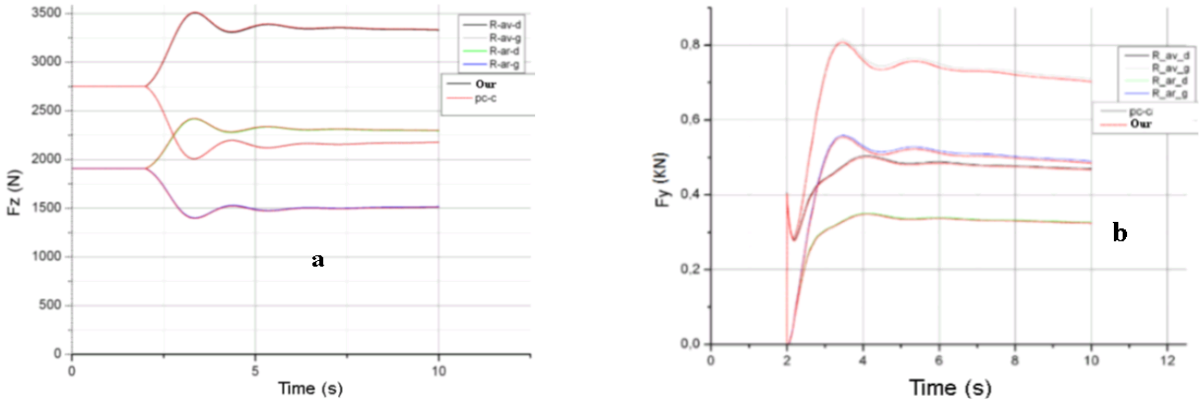

Figure 5: (a) Vertical and (b) longitudinal forces wheels

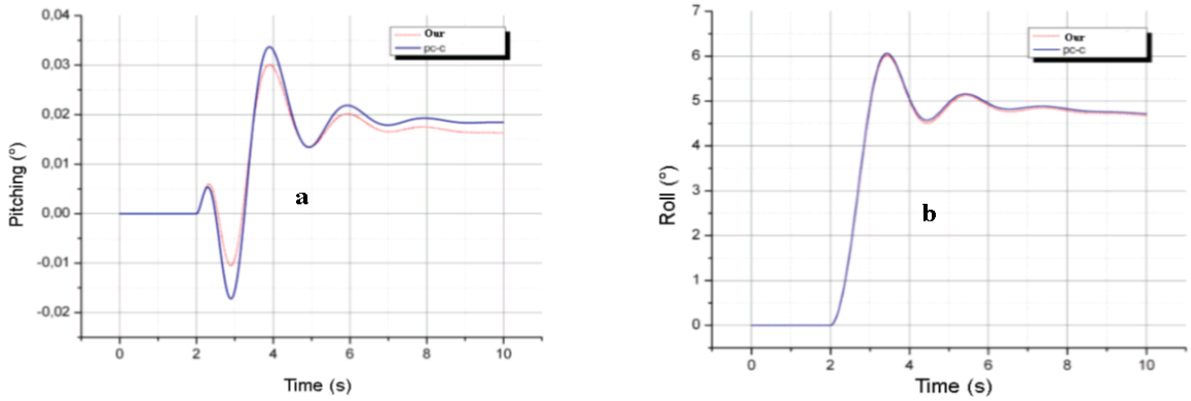

Figure 6: (a) Pitching angle and (b) roll angle

In the results for these two scenarios, we have already met with non-regularities of certain parameters (Figure 3b and 5b). In the first scenario, the irregular dynamic is caused by discontinuities of longitudinal acceleration, while for the second scenario; is approved by the sudden change in curvature radius.

4 APPLICATION TO COLLISION

Vehicle dynamic in normal operating mode remains predominant in the literature because it is usually sufficient to study a wide operating range, for this; we found a very little literature treating the irregular dynamic of the vehicle. However, the modeling of non-regular dynamic

behavior of the vehicle will explain the phenomena which are introduced into the phase of an accident (the investigation of road accidents), and the operation of these models in vehicle construction or in mission planning an intervention autonomous vehicles.

To find a solution to our problems, we will be simply made to realize, first, an analytical study of the constraints equations and motions equations and, secondly, the resolution process. The approach should ensure convergence and allow the user to obtain the desired response at the instants for any case.

Simulate a collision type of accident is to replicate the response of the vehicle involved in the accident, before, during and after the collision. This simulation requires the development and implementation of three models:

i) The collision detection model.
ii) The collision force calculate model.
iii) The model of the dynamic behavior of objects (vehicle, pedestrians ...) colliding.

In this work, we opted for a representation, not polyhydric, very simple based on modeling of vehicle and obstacles in the form of rectangular objects. The algorithm that we used for collision detection is based on the calculation of the distance between the rectangular objects. The distance between parallelepipeds is the smallest between the edges of the facets with respect to each other. The distance in the configuration illustrated in Figure 7, is given by:

$$L_{i/j} = \left({}^{j}R_i \cdot {}^{i}P_2 - {}^{j}P_5 \right) \cdot z_i \tag{14}$$

Either $L_{i/j}$ the smallest distance between the two parallelepipeds, whichever is negative, the objects collide. Otherwise, the objects are separated.

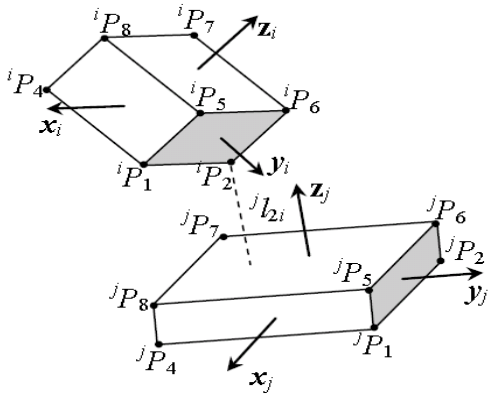

Figure 7: Calculating the distance between two parallelepipeds.

The second step of processing a collision problem is to calculate the collision forces. The methods used to assess these forces can be classified into three categories: the constraints methods, pulse-based methods and penalties methods. We chose a penalty method for the following reasons: *i)* penalties methods are implemented in several simulation software and *ii)* simplicity implementation. In this method, the collision force applied by the object *i* on the *j* item to the collision point, is given by:

$$F_{i/j} = -\left(k_{i/j} \cdot l_{i/j} + b_{i/j} \cdot \dot{l}_{i/j} \right) \left(\vec{n}_{i/j} - \mu_{i/j} \frac{\vec{v}_{i/j}}{\left\| \vec{v}_{i/j} \right\|} \right) \text{ and } F_{i/j} = -F_{j/i} \tag{15}$$

With $\vec{n}_{i/j}$ the common normal to the contact surfaces; $k_{i/j}$ and $b_{i/j}$ are the coefficients of stiffness and damping of the two objects at the point of collision; $\vec{v}_{i/j}$ the relative sliding velocity

at the contact point; $\dot{l}_{i/j} = l_{i/j}/dt$: is the velocity of interpenetration. The value of this speed is calculated by a numerical derivation of $l_{i/j}$.

$$l_{i/j}(t+dt) = \left(l_{i/j}(t+dt) - l_{i/j}(t)\right)/dt \tag{16}$$

4.1 Simulation algorithm of vehicle's collision

The simulation process starts with the initial conditions (position, orientation and vehicle velocity). During its movement, the vehicle is subjected to the force of gravity, the wheels/ground interaction efforts and inertia forces. The collision forces are not taken into account if there is a collision between the vehicle and its environment. It is therefore necessary to detect whether there is a collision or not. In a collision, it is necessary to calculate the impact point, the normal to the surfaces in this point and the interpenetration distance, and evaluate the collision forces. Then, these forces are taken into account in the vehicle dynamics. Once the full dynamic is calculated, the overall configuration system is updated.

4.2 Simulation of collision vehicle/fixed obstacle

To simulate the non-regular dynamic behavior of a vehicle collision phase. The vehicle in rectilinear motion with constant speed, it collides with a fixed obstacle (a wall) considered a perfectly rigid body. The angle α is the orientation between the vehicle speed and the normal to the wall (Figure 8), we considered two cases of collision:

Case 1: a frontal collision for α = 180 °

Case 2: an oblique collision for α = 170 °.

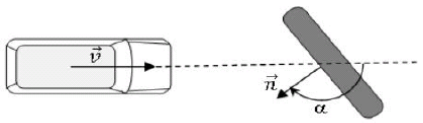

Figure 8: Collision of a vehicle with the wall.

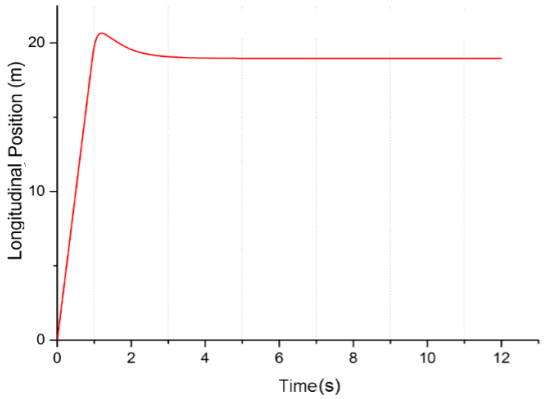
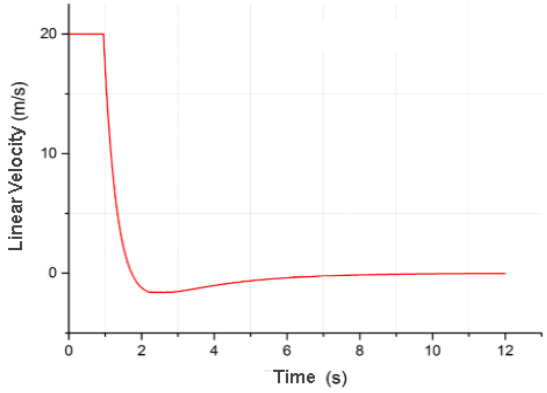
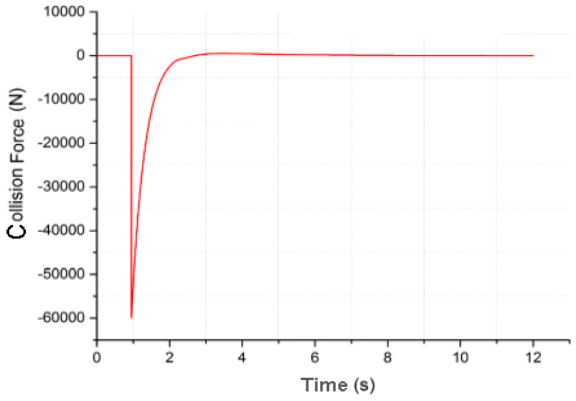


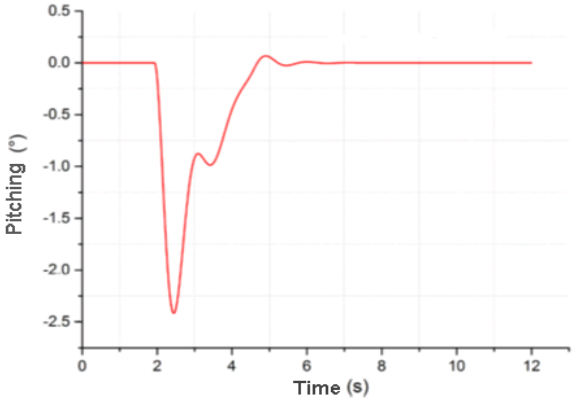
a) Longitudinal position



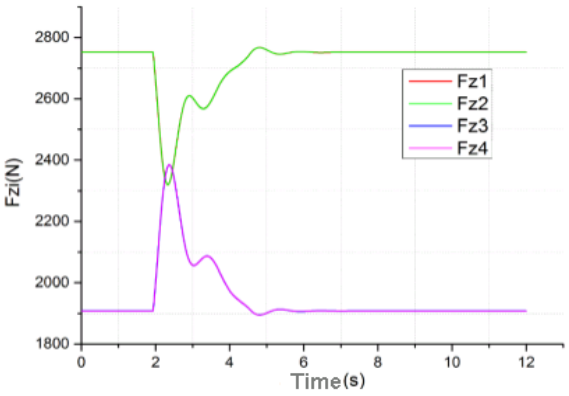
b) Linear velocity



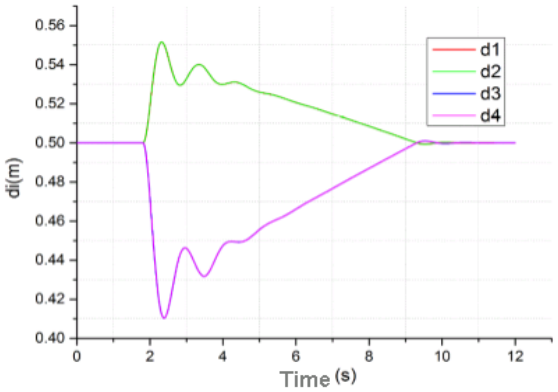
c) Collision forces



d) Pitching angle

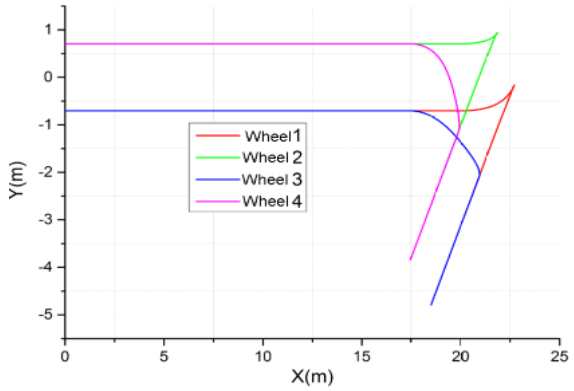


e) Vertical forces

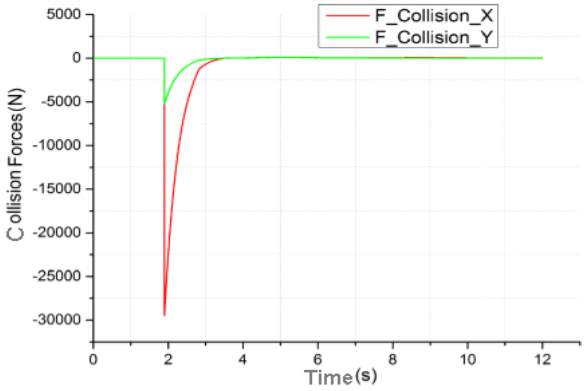


f) Elongation of springs

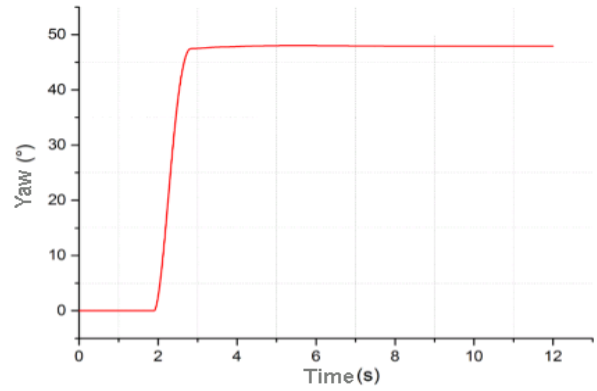
Figure 9**:** Results obtained of frontal collision vehicle/wall.



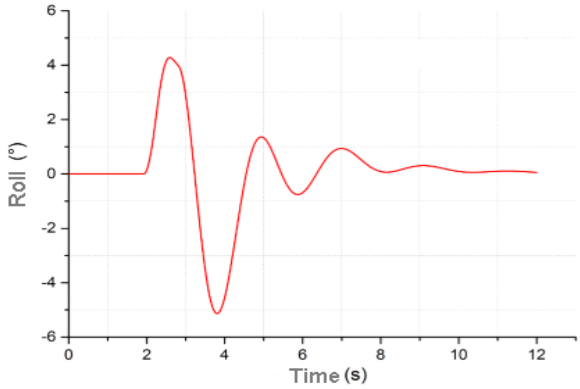
a) Vehicle trajectory



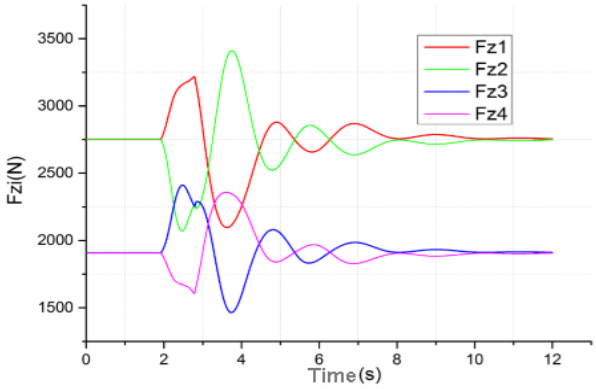
b) Collision forces



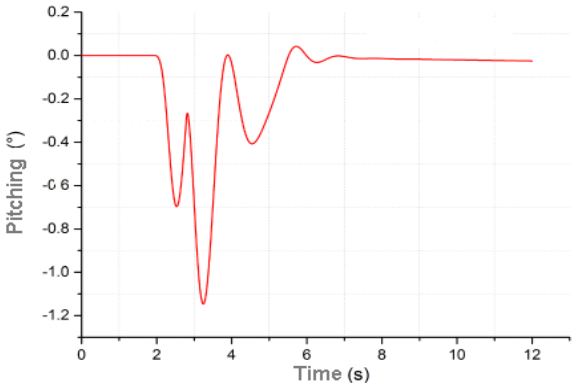
c) Yaw angle



d) Roll angle



e) Vertical forces



f) Pitching angle

Figure 10: Results obtained of an oblique collision vehicle/wall.

The results obtained for the first case are illustrated in Figure 9. We note, in phase collision, a sharp decrease of the robot speed (Figure b). Then after the crash phase, a movement of the vehicle to the rear until the stoppage of vehicle (Figure 9a). This frontal collision, causes an inclination of the vehicle backward (change in the negative pitch angle (Figure 9d)), which causes an increase of the vertical forces applied to the rear wheel and a decrease in those front wheels (Figure 9f).

In the second case, the vehicle changes its direction after the collision (Figure 10a) and obviously, the longitudinal component of force is higher than that of the transversal component (Figure 10b). The vehicle is moving at an angle of 50 ° with respect to the yaw axis and then stabilizes at that angle (Figure 10c), and unlike the first case, we observe a change in the roll angle due to the orientation of the wall (Figure 10d).

Before the collision, the vertical forces applied on the same axle are identical. After that, we find that the vertical forces on the right side conversely increases the left side (Figure 10f), which shows that the point of application of the collision is in the driver's side.

4.3 Validation results of the frontal collision vehicle/wall

The validation of the collision model was performed by comparison with those given experimentally Crash-test [24]. For this, we have considered a vehicle of mass m = 2000 Kg in rectilinear motion with constant velocity v = 13.42 m/s. In this validation, we considered that the collision vehicle/wall is composed of two phases:

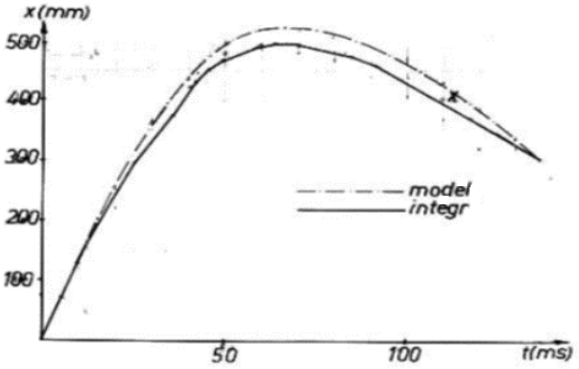
i) A deformation phase with stiffness $K_1 = 1.243\ 10^6\ N/m^2$.

ii) A restitution phase with a stiffness $K_2 = 896.6\ 10^3\ N/m^2$.

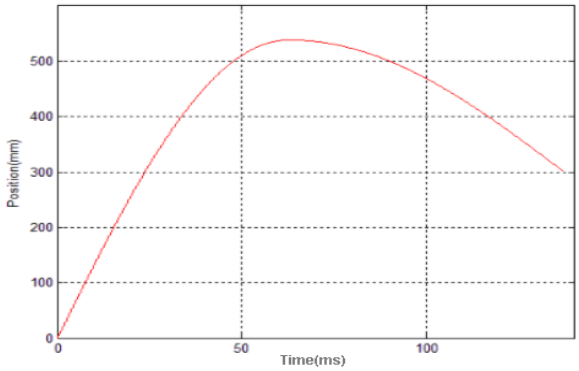
The collision force applied by the wall on the vehicle, is defined by the following relationship:

$$F_{w/v} = \begin{cases} -\left(k_1 \cdot l_{w/v}\right) x_v & if\ \dot{l}_{w/v} > 0 \\ -k_2 \cdot \left(l_{w/v} - l_p\right) x_v & if\ \dot{l}_{w/v} \le 0 \end{cases} \quad (17)$$

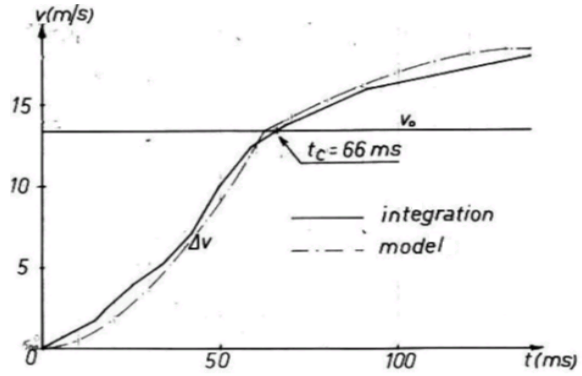
With $l_{w/v}$ the penetration distance of the vehicle in the wall; l_p : Distance from permanent deformation.



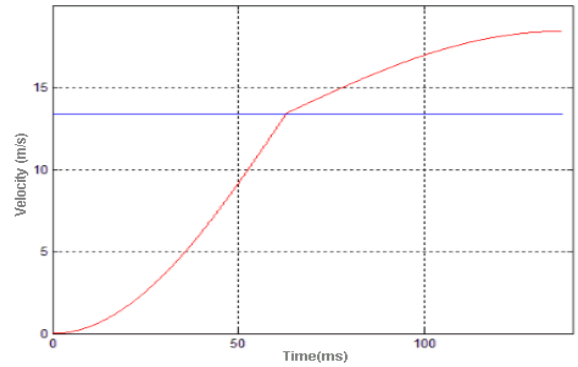
a) Penetration distance (Crash-test) **[24]**



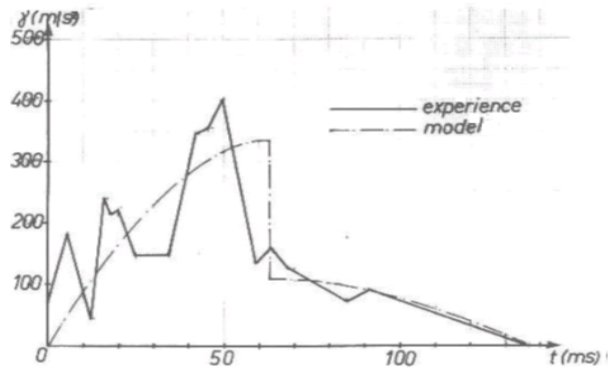
b) Penetration distance (our model)



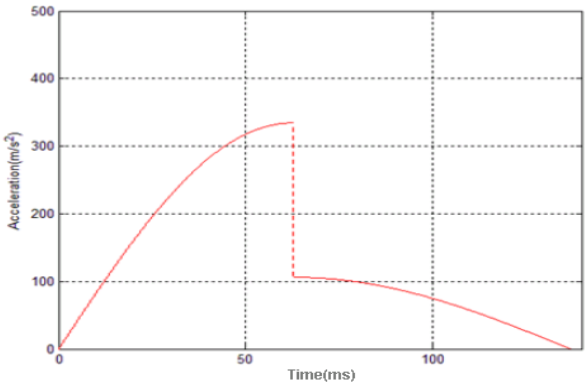
c) Penetration velocity (Crash-test) **[24]**



d) Penetration velocity (our model)



e) Penetration acceleration (Crash-test) **[24]**



f) Penetration acceleration (our model)

Figure 11: Validation results of the collision model vehicle/wall.

Our simulation results and those given by experimental measurement Crash test are presented in Figure 11. We find, from these results, that the curves of the displacement, velocity and

acceleration of penetration are substantially the same compared with those of the experiment. We can say that the modeling of the head-on collision of a vehicle against a wall is correct.

5 CONCLUSION

In this work, we introduced the steps necessary for dynamic modeling of the vehicle. The first step relates to the mechanical system description. In this step, the vehicle is considered as a rigid body connected to the ground via the suspension system. The second step is devoted to the generation of system constraints equations to know the wheels/ground holding contact conditions and the Ackermann steering. The third step relates to the generation of the motions equations. While the final step is devoted to solving the system of differential and algebraic equations by the Euler explicit method. The validation results of the developed dynamic model was carried out by comparison with those given by the PC-Crash software. We show that the results are very satisfactory. Subsequently, we focused our study on the non-regular behavior of a vehicle during a collision with a fixed obstacle. We have proposed a method based on the evaluation of the distance to vehicle /obstacle interpenetration. The collision force is calculated, thereafter, via a penalty method. The results of this method are validated experimentally with those given by Crash-test. These results show the affinity of the developed model. Moreover, the choice of model validation was not trivial but rather conditioned by the availability of middle address the same problems.

Keywords: under-platform damper, friction, damping, contact parameters

Abstract. *Underplatform dampers (UPDs) are widely used as a source of friction damping and are frequently incorporated into compressors and turbines for both aircraft and power-plant applications to mitigate the effects of resonant vibrations on fatigue failure.*
The need for reliable models of UPDs has led to a considerable amount of literature in the last three decades. The standard approach is to fine-tune and experimentally validate the UPDs models by comparing measured and calculated vibration response of blade pairs. With this approach one cannot investigate the damper behaviour directly and no measurements of the contact parameters can be undertaken. The experimental-numerical method proposed by these authors overcomes this problem through the combined use of purposely developed tools:

- *a test rig capable of measuring directly the damper working parameters (i.e. damper hysteresis cycle and kinematics);*
- *error estimates of measured and derived forces and displacements ;*
- *a numerical routine representing the damper between the platforms solved either in the time or in the frequency domain;*
- *a robust procedure for the estimation of friction and stiffness parameters at the contact from experimental data.*

These tools combined together offer concrete prospects of success in damper simulation and design. On one hand, they allow mapping the values of contact parameters under different working conditions (i.e. frequency, centrifugal load and presence/absence of damper rolling), thus ensuring valuable predictions both at the design and at the simulation stage. On the other hand the experimental-numerical method offers a clear understanding of all contact events (stick, slip, lift) which take place during the cycle, and on how they influence the damping performance. This deeper insight is the basis to actual design and optimization criteria.
Purpose of the paper is to illustrate the tools and methods through the analysis of a family of rigid bar dampers with a curved-flat cross section. A series of diagrams fit to describe the damper behaviour will be presented and used to estimate relevant friction contact parameters.

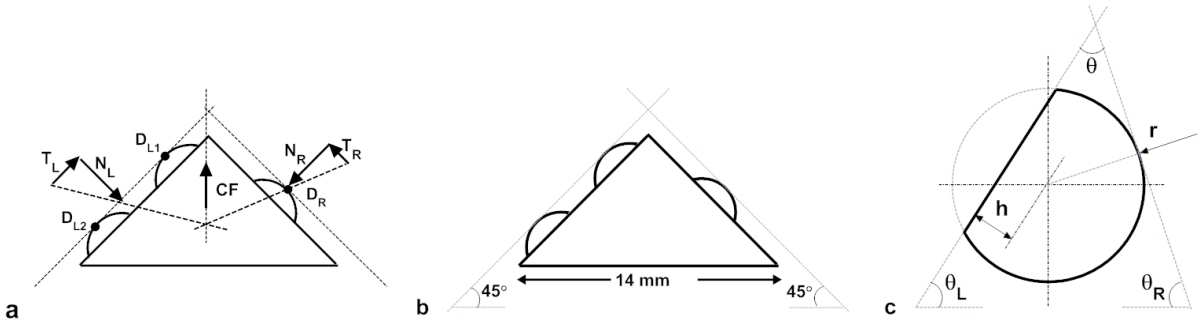

Figure 1: Laboratory three-point damper a- IP hysteresis cycle b- Tangential/Normal force ratio during the cycle c- Contact Forces Diagram

1 INTRODUCTION

The dedicated damper routine developed by the AERMEC group [1, 2, 3] combines numerical simulation with a trustworthy experimental approach for these reasons:

- experimental observations can be used as a benchmark to draw the appropriate values of contact parameters (local friction coefficients and contact stiffness) to be used as input to a numerical model which represents the dynamics of the damper between the two platforms.
- the validated routine becomes a design and optmization tool.

The outcome of the design and optimization tool are highly dependent on friction interface parameters, as demonstrated in [4]. Trustworthy predictions cannot prescind from the experimental investigation of friction interface parameters, and studies on the measurement of friction coefficients and contact stiffness values appear in the literature to this day [5].
The first part of the paper will illustrate the test rig and the numerical model applied to a three-point laboratory damper shown in Fig. 1a-b. It will be shown how experimental data can be used to understand the damper behaviour and then to estimate friction contact parameters. Moreover, it will be highlighted how the simplified configuration of the three-point laboratory damper (three equal non-conforming contacts with known positions) makes the tuning process easier.
The second part of the paper will instead focus on two real optimized curved-flat dampers, whose configurations (i.e. angles and depth of cut) were chosen following the pre-optimization technique presented in [6]. The purpose of the paper is to highlight the additional effort necessary to correctly model differenct contact interfaces (both conforming and non-conforming) and to propose a robust data-processing technique to estimate contact parameters.

2 THE TEST RIG

The experimental investigation here summarized takes advantage of a test rig (Fig.2) purposely developed at the AERMEC lab [1] representing a damper between two platforms.
The damper is loaded by a deadweight simulating the centrifugal force. The cable holes are properly oriented and pass through the damper center of mass: their sections shrink down to match the cables' diameter in correspondence of the center of mass to exactly reproduce the loading conditions encountered on a bladed disk.

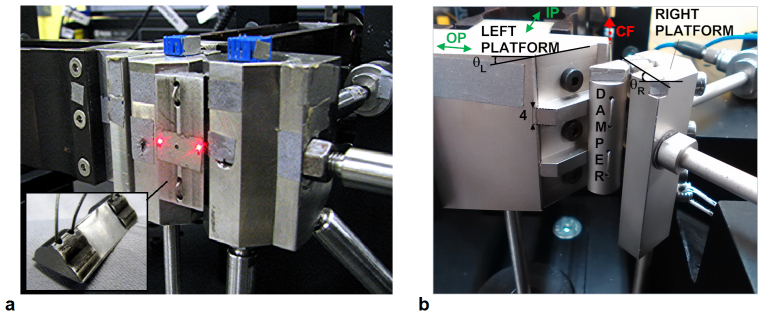

Figure 2: Experimental setup featuring a- the three point laboratory damper and b- a curved-flat damper

Table 1: Uncertainty on experimental data

Quantity	Standard deviation
Right contact force (N_R,T_R)	$3\%(0.5N)$
Left contact force (N_L,T_L)	$3-5\%(0.7-0.9N)$
Left c. force application point	0.5 mm
Platforms relative movement ($w_{LP}-w_{RP}$)	$0.08\mu m$
Rotation (β)	$5\%(0.6\cdot 10^{-4}rad)$

The left blade platform, which serves as input motion to the system, is connected to two perpendicular piezoelectric actuators. The actuators are capable of reproducing any in-plane periodic displacement, however the cases analyzed in this paper all reproduce the typical blades' In-Phase (IP) motion. The right blade platform, connected, by means of a tripod, to two force sensors measures the contact forces transmitted between the platforms, through the damper. A laser head measures the platforms' relative displacement and damper kinematics.
The forces transmitted between the platforms through the damper are measured and related to the measured relative platform movement in order to record the damper hysteresis loop (e.g shown in Fig.3).
A complete description of the test rig components, calibration procedures and the error estimation techniques can be found in [1, 7]. Table 1 lists all the measured and derived quantities together with their level of uncertainty. These results led the authors to believe that the accuracy of force and kinematic measurements offers a trustworthy basis on which to build the contact parameter estimation technique.

3 UNDERSTANDING AND SIMULATING A LABORATORY THREE-POINT DAMPER

3.1 Relevant Diagrams

The hysteresis cycle in Fig.3a plots the force (vertical componentin the I-P case) transmitted to the right platform plotted as a function of the corresponding component of the relative displacement between platforms. Reference points on the hysteresis loop have been marked by a symbol and a number, repeated on the corresponding points on other diagrams: they are useful to guide the analysis of the cycle by cross-comparison.
For each hysteresis cycle (Fig.3a) a set of experimental diagrams can be produced to investigate the damper behavior. Numerical results (dashed line) are shown together with their experimental match (solid line). The experimental results allow to validate the numerical model (by

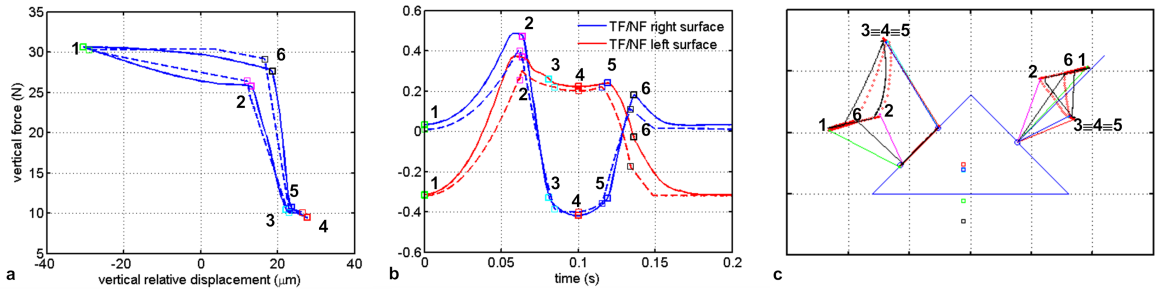

Figure 3: Laboratory three-point damper a- IP hysteresis cycle b- Tangential/Normal force ratio during the cycle c- Contact Forces Diagram

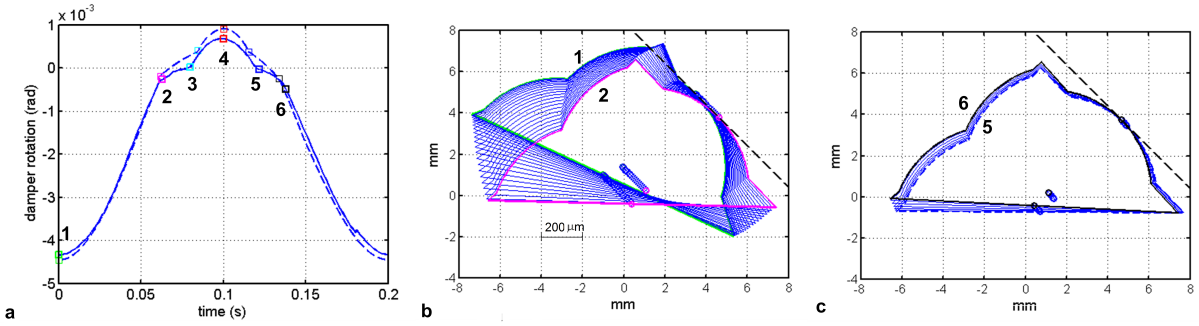

Figure 4: Laboratory three-point damper a- Rotation against time. b- Kinematic reconstruction from marker 1 to 2 . c- Kinematic reconstruction from marker 5 to 6

comparing the two sets of results) and to estimate the contact parameters used to obtain the simulated cycle. These diagrams are:

- T/N force ratios (Fig. 3b) : it represents the ratio of the total tangential and normal force components on the left and right contact surfaces plotted as a function of time. The flat portions of each line may indicate a slip phase subject to cross-confirmation by other diagrams - on an interface: in such case the ratio T/N will represent a friction coefficient.
- Contact forces diagram (Fig. 3c): it represents -) the vectors of forces transmitted between the platforms -) the damper surfaces and their points of application.
- Damper rotation (b) against time (Fig. 4a).
- Damper kinematic reconstruction (i.e. Fig. 4b-c): a visual representation of damper positions with magnified (x 100) displacements and rotation.

3.2 The damper numerical routine

The interpretation of experimental results is quite complex because it requires to relate the behaviour of forces and motions in order to assess the working mode in each part of the hysteresis cycle. A numerical model is then necessary to analyze each tract of the hysteresis cycle by precisely identifying stick or slip conditions and the related exchanged forces, as shown in

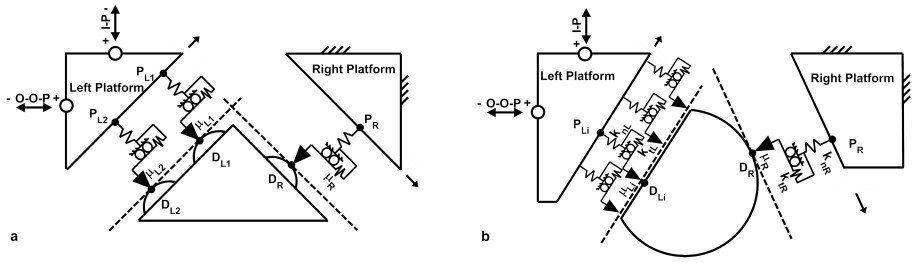

Figure 5: Damper numerical routine featuring a Laboratory damper b Curved-flat damper

Table 2: Step by step analysis of the cycle in Fig. 3-4

Stage	T_L/N_L	N_L position	D_{L1}	D_{L2}	T_R/N_R	D_R
1-2	Varying	on D_{L2}	Separation	Stick	Varying	Stick
2-3	$\approx$ Constant	b/w D_{L1} and D_{L2}	Slip_+	Slip_+	Varying	Stick
3-4	Constant	on D_{L1}	Slip_+	Separation	Constant	Slip_-
4-5	Constant	on D_{L1}	Slip_+	Separation	Varying	Stick
5-6	Varying	b/w D_{L1} and D_{L2}	Slip_+	Stick	Varying	Stick
6-1	Constant	on D_{L2}	Separation	Slip_+	Varying	Stick

Table 2. A functional scheme of the numerical model adapted to both damper configurations is shown in Fig. 5. All contact interfaces are modeled using an Iwan-type contact model which requires three contact parameters: normal and tangential contact stiffness and friction coefficient. A complete description of the damper numerical routine, which can be solved either in the time or in the frequency domain, can be found in [1] and [2].

3.3 Estimation of contact parameters

3.3.1 Friction coefficients

Friction coefficients are estimated using the T/N force ratios (Fig. 3b). The right one poses no problem since there is only one contact point on that side of the damper. The left surface is, on the other hand, the result of the combination of the two contact points. Initially $\mu_{L1} = \mu_{L2}$ is assumed, and by considering in addition another tract where only one of the left contact points is actually in contact and is slipping (e.g. stage 3-4 for μ_{L1} and stage 6-1 for μ_{L2} referring to Fig. 3b-c) μ_{L1} and μ_{L2} can be determined. The resulting values of friction coefficients are in this case : μ_{L1} = 0.22, μ_{L2} = 0.34 and $\mu_R = 0.4$.

3.3.2 Contact stiffness values

Since all contact points share the same geometry it is here assumed that they all share the same normal and tangential stiffness values k_n and k_t. The **normal contact stiffness** k_n was estimated using the normal displacement-normal force curve of a cylinder pressed against a plane[9]-[10].
The **tangential contact stiffness** was estimated using the full-stick (all contact points in contact and in stick) cycle slope of the OP hysteresis cycles (here not shown)[1]. It shold be noted that this slope is the same in all investigated cases and does not change when the platform starts closing. This due to the fact that during that stage all contact points are repeatably in the same

contact condition. The cycle slope is a composite effect of normal and tangential stiffness values at all contacts. The resulting values of contact stiffness are in this case : $k_n = 2.4N/\mu m$, $k_t = 1.6N/\mu m$.

4 LIMITS OF THE CURRENT PRACTICE ON LABORATORY UPDs INVESTIGATION

The methods developed for the three-point laboratory damper are successful in exploring and understanding its behaviour, however several shortcomings still remain to be tackled.

1. The laboratory damper here analyzed is a non-optimized configuration (i.e. large rolling motion caused by contact point lift-off minimizes the dissipated energy per cycle).

2. In order for the design tool to be effective, its simulation capabilities have to include dampers with other geometries (i.e. curved-flat damper as shown in Fig.1)

These authors have tackled point 1 in [6], by proposing a pre-optimization method for curved-flat UPDs. This method was successful in identifying and excluding those damper configurations (choice of θ_L, θ_R and h shown in Fig. 1c) leading to undesirable damper behaviour (contact point lift-off, jamming etc.).
Concerning point 2, a few successful attempts to model curved-flat UPDs have been presented by these authors [2, **?**]. However some of the assumptions made for the three-point laboratory damper are not valid for other damper geometries, for instance:

- number of contact points on the flat side;
- position of the contact points on the flat side;
- contact stiffness values of the flat side are potentially different from those representing the cylindrical contact point.

These differences make the tuning procedure described in 3.3 not completely suitable when estimating contact parameters relative to the curved-flat dampers-platforms interface. The purpose of this paper is to overcome these shortcomings by proposing a new method with a solid experimental basis and a fine data processing technique.

5 EXPLORING CURVED-FLAT DAMPERS

5.1 Selected configurations

As mentioned before the selected damper configurations are the result of a pre-optimization process which aims at maximizing the dissipated energy [6]. The parameters which influence the damper behaviour are (see Fig.1):

- the non-dimensional "residual radius" h/r;
- the angles of the platforms θ_R and θ_L.
- the value of the friction coefficients μ_R and μ_L;

The selected damper configurations are:

- A: $\theta_L = 55^0$, $\theta_R = 65^0$, $h/2 = 0.2$

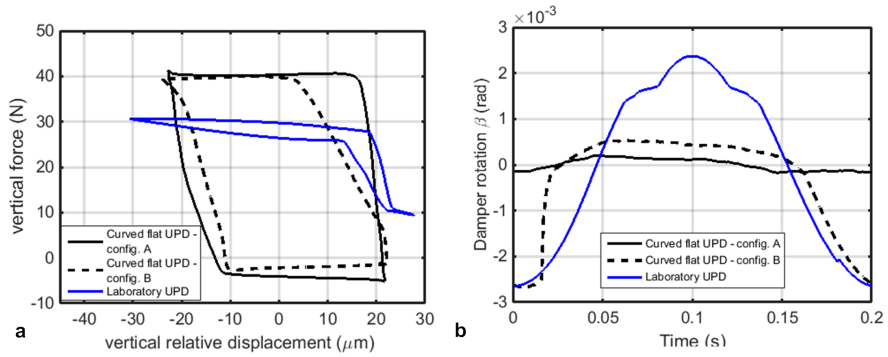

Figure 6: a Hysteresis cycles and b Damper rotation signals for an applied centrifugal load of $CF = 4.65kg$ and a 5 Hz $\pm 30\mu m$ IP imposed displacement

- B: $\theta_L = 35^0$, $\theta_R = 65^0$, $h/2 = 0.2$

While h/r,θ_L and θ_R are parameters the designer can act upon, friction coefficients are unknown constraints measured a-posteriori.
Figure 6 shows the hysteresis cycles and the rotation signals for the two curved-flat damper configurations and for the above mentioned laboratory damper. The boundary conditions imposed to the dampers (i.e. centrifugal load, imposed displacement and frequency) are the same for all three cases. The results shown here were produced by a 5 Hz excitation because the signals are cleaner and easier to manipulate. However, it should be noted that contact stiffness values did not change for all investigated frequencies (i.e. up to 160 Hz).
Severe differences are noted among the three configurations:

- **force levels**: the curved-flat damper which display a set of friction coefficients ($\mu_R = 0.65$, $\mu_L = 0.5$) and ($\mu_R = 0.78$, $\mu_L = 0.5$) for configurations A and B respectively, ensure slip force levels higher than those encountered for the laboratory damper ($\mu_R = 0.4$, $\mu_L \approx 0.3$).

- Configuration A (i.e. choice of angles and parameter h/r) manages to avoid lift-off completely, as shown by the rotation signal in Fig. 6, and thus to maximize the dissipated energy.

- Configuration B does encouter some lift-off and therefore a larger rotation, it is however a significant improvement if compared to the laboratory damper.

6 CONTACT PARAMETERS ESTIMATION FOR CURVED-FLAT DAMPERS

Both the pre-optimization technique presented in [6] and the damper numerical routine itself need a robust model of contact interfaces. The purpose of this section is to present the new configuration introduced in the numerical routine to model a curved-flat damper and the new experimental capabilities developed at AERMEC to estimate the relevant contact parameters.
This section will focus on the contact point position and on the contact stiffness values. The technique to estimate friction coefficients developed for the three-point laboratory damper can be applied without further modifications to any other damper configuration.

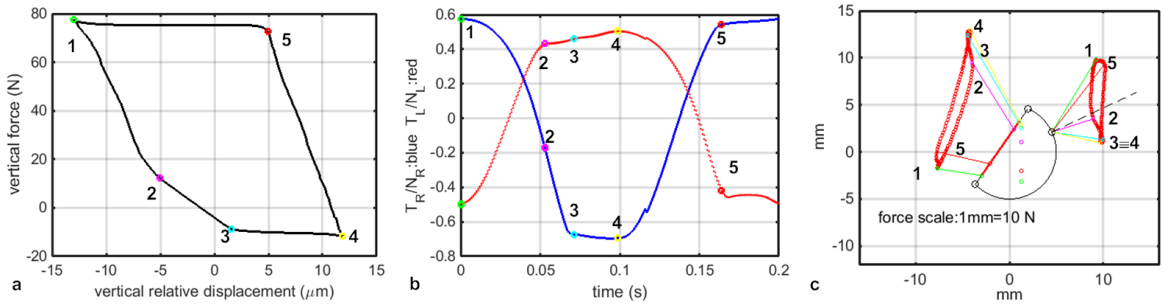

Figure 7: Curved-flat damper a- IP hysteresis cycle b- Tangential/Normal force ratio during the cycle c- Contact Forces Diagram

6.1 Contact points number and position

While the number and position of contact points used to model the laboratory UPD (see Fig. 5a) was determined by the damper configuration itself, while the flat portion of the curved-flat damper requires additional attention. A few successful attempts to model a curved-flat UPD using only two contact points on the left side have been carried out in the past [2]. However, without additional experimental evidence the system is under-determined and selecting the position of the contact points and the contact stiffness values requires a cumbersome case-by-case fine-tuning procedure. Section 6.1.2 proposes a novel method to estimate the normal contact stiffness per unit length. Therefore it is sensible to envision a series of contact points uniformly distributed over the contact interface, the higher the number of contact points, the finer the representation of the interface.

6.1.1 Contact stiffness values

As mentioned before the contact stiffness tuning technique developed for the laboratory damper is not valid anymore. While the normal contact stiffness on the right (i.e. cylindrical) side can still be deduced using the normal displacement-normal force curve of a cylinder pressed against a plane[9]-[10], the remaining unknowns (k_{tL}, k_{tR} and k_{nL}) need additional information which can only be provided by a robust experimental basis.

6.1.2 Normal contact stiffness at the flat interface

Referring to Fig. 8 it is possible to write the expression of the rotation β at a given instant in time as:

$$\beta = \frac{n(x)}{x - (\frac{L}{2} - 3a)} \tag{1}$$

where $n(x)$ is the displacement in the normal direction at a given position x of the flat interface. The reference system x is parallel to the contact and its origin lies in the middle of the flat interface. Let us divide the flat interface into k segments each Δx long. If the normal stiffness is uniformly distributed the normal stiffness pertaining to one of these segments is:

$$k_{ni} = \frac{dk_{nL}}{dx} \cdot \Delta x \qquad 1 \leq i \leq k \tag{2}$$

If the force per unit length q(x) is known, e.g. $q(x) = \frac{q_{max}}{3a} \cdot (x - (\frac{L}{2} - 3a))$, it is possible to substitute the expression of $n(x)$ inside Eq. 1.

$$\beta = \frac{q(x) \cdot \Delta x}{\frac{dk_{nL}}{dx} \Delta x \cdot (x - (\frac{L}{2} - 3a))} \tag{3}$$

where a represents the distance between N_L application point and the nearest flat surface edge, as shown in Fig. 8b. If the force is uniformly distributed $q(x)$ will act on a portion of flat surface 3a long.
It is possible to express $q(x)$ as a function of the moment M produced by the resultant N_L around the origin shown in Fig. 8a.

$$\begin{aligned} M &= \int_{\frac{L}{2}-3a}^{\frac{L}{2}} \frac{q_{max}}{3a}(x - (\frac{L}{2} - 3a)) \cdot x \cdot dx \\ &= \frac{3}{2} q_{max} \cdot a \cdot (\frac{L}{2} - a) \end{aligned} \tag{4}$$

Substituting Equ. 4 in Equ. 3, it is possible to express $\frac{dk_{nL}}{dx}$ as:

$$\frac{dk_{nL}}{dx} = \frac{q(x)}{\beta} \tag{5}$$

$$= \frac{2M}{9a^2 \cdot (\frac{L}{2} - a)} \tag{6}$$

Figure 8c plots $2 \cdot M$ against $9a^2 \cdot (\frac{L}{2} - a)$ for the case shown in Fig. 7. The slope highlighted in the figure is the normal contact stiffness per unit length. The shape is slightly distorted:

- for low values of rotation/moment: this is due to the fact that the assumption made in Equ. 3 (i.e. that rotation and moment signals in time are synchronous) is not perfectly true due to minor distorsions caused by spurious movements of the left platform;
- close to markers 1/5: during those stages the left contact force resultant N_L application point is close to the lower edge, a situation similar to lift-off where the length of $a- > 0$.

The resulting values of $\frac{dk_{nL}}{dx}$ for both configurations of curved-flat UPDs are reported in Table 6.1.2. The results have been repeated on both tracts (i.e. ascending and descending) of the shape in Fig. 8c and repeated using repeated independent measurements.

6.1.3 Tangential Contact Stiffness values

The tangential contact stiffness values are derived directly from experimental data. The available laser heads are pointed on damper and platform protrusions purposely machined to be perpendicular to the contact surfaces, as shown in Fig. 9a.
The laser signal is then plotted against the corresponding tangential force (T_R or T_L respectively), as shown in Fig. 9 b and c for the curved-flat damper (configuration A). It should be noted that the tangential force on the cylindrical side T_R is measured using the load cells, while the tangential force resultant on the flat side T_L is reconstructed using the procedure described

Table 3: Flat interface normal contact stiffness per unit length

Damper configuration	Centrifugal Load	Repetition	$\frac{dk_{nL}}{dx}$ (N/mm^2)	$\sigma(N/mm^2)$
A	4.65 kg	1	18900	1387
A	4.65 kg	2	19004	1831
A	8.65 kg	1	18054	847
A	8.65 kg	2	19393	669
B	4.65 kg	1	1334	362
B	4.65 kg	2	1231	79
B	8.65 kg	1	6412	558
B	8.65 kg	2	6586	581

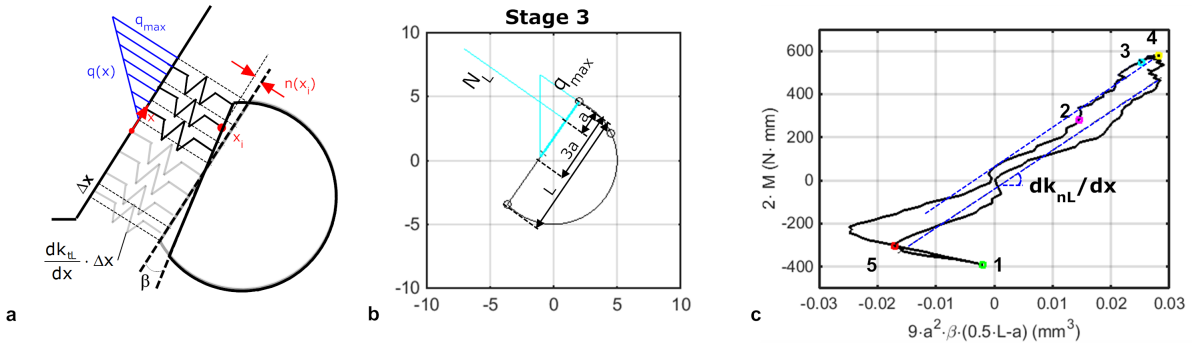

Figure 8: a- Scheme representing the flat surface model. b- Force component N_L and corresponding force per unit-length on the flat surface at marker 3 for the cycle in Fig. 7a. c- Flat interface normal contact stiffness per unit length relative to the cycle shown in Fig. 7.

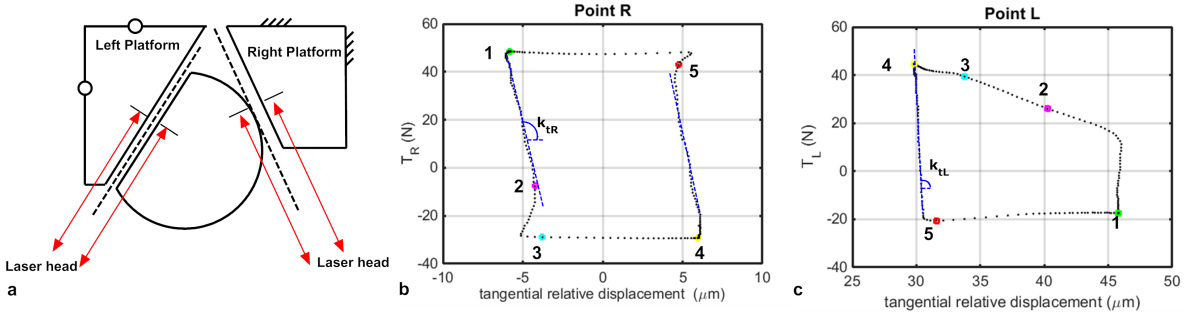

Figure 9: a- Functional scheme representing the experimental procedure used to estimate the tangential contact stiffness values b- Hysteresis at the right contact c- Hysteresis at the left interface

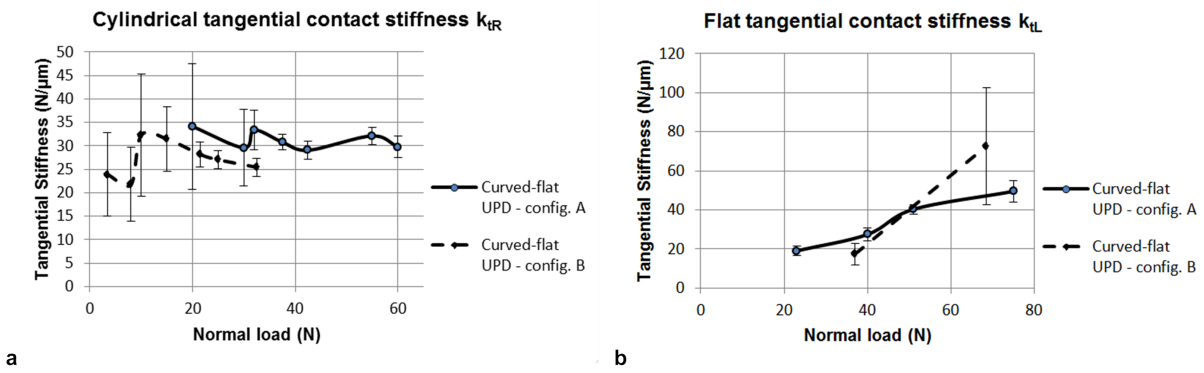

Figure 10: Curved-flat damper a- IP hysteresis cycle b- Tangential/Normal force ratio during the cycle c- Contact Forces Diagram

in Fig.1a.

For each contact interface the stages corresponding to a stick state are identified using the Tangential/Normal force ratio diagram (i.e. in Fig. 7b). The stages are "1-3" and "4-5" for the right interface and "1-2" and "4-5" for the left one. Out of these tracts only those highlighted in Fig. 9 b-c are used to estimate the tangential stiffness values. In particulare stage $2-3$ for the right interface and stage "1-2" for the left one are neglected due to spurious platforms' movements.
For each identified tract the central portion of the slope is singled out and fitted using a least square method. The resulting values are plotted against their respective normal load levels at the interface (see Fig. 10) , together with their standard deviation.
It should be noted how the right tangential stiffness (i.e. on the cylindrical side) is not influenced by variations of the normal load, while the one on the flat side increases with increasing normal load. This may be due to the conforming nature of the flat contact interface.

7 CONCLUSIONS

This paper focuses on a coupled experimental-numerical approach to investigate, simulate and understand under-platform dampers behaviour. The paper highilights the strengths of this method, but also its limits concerning the estimation of friction contact parameters, with a particular emphasis on contact stiffness values.
A novel procedure and data processing technique is therefore proposed to overcome these limits and give reliable indications to the damper designer concerning the values of contact parameters to be used as input to the damper numerical routine. A sample of results is discussed in order to show, in practice, the technique to estimate the contact parameters (tangential stiffness on the cylindrical side and both tangential and normal contact stiffness on the flat interface) starting from the experimental results. Each measured quantity is assigned a level of uncertainty and the data processing technique gives an indication of the reliability of each derived quantity. These authors believe that this work constitutes a reliable basis to build a design tool (i.e. validated damper numerical routine) capable of giving trustworthy predictions in the frame of asymmetrical damper design and optimization.

Abstract. *This work is devoted to the development of a new dynamic substructuring method inspired by classic fixed-interface component mode synthesis, in order to compute the steady-state vibrations of dissipative, nonlinear structures. For each substructure, the displacement field is sought as a multiharmonic oscillation made of standard static mode shapes, supplemented by the eigenvectors of the nonlinear complex modes of the substructure computed with fixed-boundary conditions. The method eventually leads to a strongly reduced nonlinear algebraic system, easily solved by iterative solvers. The procedure is tested on a lumped parameter model of bladed disk subjected to dry friction nonlinearities, with or without structural mistuning, and proves very efficient in terms of computational cost. These results emphasize the promising capabilities of this new reduced-order modeling technique to tackle such nonlinear systems exhibiting high modal density.*

1 INTRODUCTION

Reduced-order modeling has always been a key problematic in computational mechanics. Despite the soaring hardware and software capabilities offered by modern electronics and computing, finite element analysis of large scale industrial systems remains challenging when some complex and nonlinear phenomena are to be included in the design process. Component mode synthesis (CMS) methods [1, 2, 3, 4] have been widely used in structural dynamics, but can unfortunately prove ill-suited to the study of nonlinear systems when a large number of degrees-of-freedom (DOF) are impacted by strong nonlinear effects. For such systems, standard techniques may indeed fail to find a satisfying compromise between order-reduction and accuracy, due to the lack of representativity of the reduction basis. From this perspective, owing to their ability to capture the essence of the nonlinearities [5, 6], nonlinear complex modes are interesting candidates in devising new effective and efficient approaches to reduce nonlinear models.

In bladed-disk dynamics, the loss of cyclic symmetry of the structures, referred to as mistuning, has been a leading subject of research, first tackled by a few authors in the 1960s [7, 8, 9, 10] and widely studied since then [11]. This phenomenon mainly denotes the discrepancies between the blades of the assembly, resulting for instance from the manufacturing process and in-operation wear, but which can also be intentionally introduced in the nominal design. Even though the mistuning of cyclic structures is known to potentially induce a significant increase in the vibration level, it has also proved, indeed, to improve the robustness of the design against hazardous instabilities such as flutter. In order to perform quantitative analyses on industrial models, several mistuning dedicated reduced-order modeling techniques have been devised to efficiently handle large scale systems [12, 13, 14, 15]. Unfortunately, most of them are not applicable in the presence of nonlinearities, hence the need for further endeavours devoted to the reduced-order modeling of nonlinear, mistuned cyclic structures.

In the present paper, a new approach is proposed to build reduced-order models of nonlinear and dissipative systems. The method does not require any cyclic or nearly-cyclic symmetry assumption, and can thus be directly applied to the study of strongly mistuned bladed-disks. The procedure mimics a standard Craig-Bampton CMS, but makes use of the notion of nonlinear complex modes to build nonlinear superelements, including all internal nonlinear DOFs in the reduction basis. The resulting algebraic system can thus be much smaller than that of a standard harmonic balance method (HBM), which requires to retain all nonlinear DOFs as master coordinates. The flexibility of nonlinear complex modes [5, 6, 16] makes this reduction technique suitable for the study of a broad range of nonlinearities, dissipative and non-smooth ones included.

In Section 2, the main steps of the computation of nonlinear complex modes are first reminded, and the nonlinear superelement equations are derived. A lumped-parameter model of bladed-disk exhibiting dry friction nonlinear elements is then used in Section 3 to illustrate the capability of this new technique. First, the method is tested on a tuned system, and is then used to synthesise the response after application of a random mistuning pattern. Section 4 presents the performance of the procedure, and its potential limitations.

2 NONLINEAR COMPONENT MODE SYNTHESIS

This section aims at summarizing the main steps to build a nonlinear superelement. The computation of nonlinear complex modes is briefly reminded in Section 2.1, and the notion is illustrated on a basic 2-DOFs system. In Section 2.2, the system of equations defining a nonlinear superelement are then derived. As mentioned in the introduction, this new reduced-order modeling procedure shares some similarities with classic CMS methods, and is hereafter referred to as CNCMS, for component nonlinear complex mode synthesis.

2.1 Nonlinear complex modes

The concept of nonlinear mode is nowadays well established in the community of nonlinear dynamicists. A comprehensive review listing all major contributions and techniques applicable to structural dynamics is proposed in [17]. Nonlinear complex modes are an extension of nonlinear normal modes to dissipative systems, that aims at taking advantage of numerical and frequency-based formulation such as the harmonic balance method to compute the free vibrations of damped nonlinear structures. First introduced in [5], they have proved tremendously interesting to study all sorts of nonlinear systems [6, 16, 18], and are fundamentals to the reduced-order modeling technique presented here. Only a brief reminder is provided here to introduce some notations, but more details can be found in [5, 6, 16, 18].

Nonlinear complex modes refer to pure or pseudo-oscillations of the system of nonlinear differential equations (1). The terms are defined in a classic manner, with $\mathbf{M}$ the mass matrix, $\mathbf{C}$ the viscous damping matrix, $\mathbf{K}$ the linear stiffness matrix, and $\mathbf{f}_{nl}$ a term of nonlinear restoring and dissipative forces.

$$\mathbf{M}\ddot{\mathbf{x}}(t) + \mathbf{C}\dot{\mathbf{x}}(t) + \mathbf{K}\mathbf{x}(t) + \mathbf{f}_{nl}(\mathbf{x}, \dot{\mathbf{x}}) = \mathbf{0} \tag{1}$$

The n-th mode $\mathbf{x}_n$ is approximated by a truncated series of damped oscillations of fundamental frequency ω_n and modal damping β_n, such that with $\lambda_n = -\beta_n + i\omega_n$ and $c.c.$ referring to the complex conjugate terms,

$$\mathbf{x}_n(t) = \frac{1}{2}\left\{\sum_{k=1}^{n_h} \hat{\mathbf{x}}_{n,k} e^{kt\lambda_n} + c.c.\right\} \tag{2}$$

Similarly to standard Galerkin methods, the approximation (2) is then substituted into the governing equations (1), and the orthogonality of the residual to the subspace spanned by the functions $\{e_k = e^{ikt\omega_n}\}$, $\forall k \in [\![1, n_h]\!]$, is enforced, with respect to the inner product (3) where $\overline{g(t)}$ is the complex conjugate of $g(t)$. In order to take advantage of the orthogonality property of the complex exponential functions, the solution is assumed to be undamped over the period T used in the inner product, which has proved to have a negligible effects on the accuracy of the results (see [5] for further information).

$$\langle f|g\rangle = \frac{2}{T}\int_0^T f(t)\overline{g(t)}dt \text{ , with } T = \frac{2\pi}{\omega_n} \tag{3}$$

The resulting algebraic system (4) is the eigenproblem corresponding to the nonlinear complex mode $\mathbf{x}_n$, where the term $\langle \mathbf{f}_{nl}|e_k\rangle$ potentially couples all the equations. This system is underdetermined and must be supplemented with two equations, classically in the form of a

phase condition and a continuation scheme, which are not detailed here. The interested reader is referred to [18] for further information.

$$\begin{aligned} &\forall k \in [\![1, n_h]\!] : \\ &\left[(k\lambda_n)^2\mathbf{M} + (k\lambda_n)\mathbf{C} + \mathbf{K}\right] \hat{\mathbf{x}}_{n,k} + \langle \mathbf{f}_{nl} | e_k \rangle = \mathbf{0} \end{aligned} \tag{4}$$

The flexibility of nonlinear complex modes arises, among other things, from their applicability to a broad range of nonlinearities, including non-smooth forces. This is made possible and easy to implement by means of the alternating frequency-time scheme (AFT) proposed in [19], and widely used in conjunction with harmonic balance methods [5, 16, 18]. This procedure uses direct ($\mathcal{F}$) and inverse ($\mathcal{F}^{-1}$) Fourier transforms to compute $\langle \mathbf{f}_{nl} | e_k \rangle$ from the time-domain definition of the nonlinear terms.

To exemplify nonlinear complex modes, let us now consider the academic system on Figure 1 subjected to a dry friction force, with the lumped-parameters taking their values in Table 1. Figure 2 shows the variations of the first natural frequency and corresponding modal damping as a function of the displacement amplitude $|x_1|$. These so-called backbones are thoroughly explained in previous papers [5, 6, 18] and will not be discussed here. However, it should be remembered in the following sections that nonlinear complex modes are functions of a parameter describing the intensity of the nonlinear effects, here the amplitude of vibration $|x_1|$, and that the modes of friction-damped systems exhibit an optimum damping point, corresponding to a maximum dissipation arising from the nonlinearity.

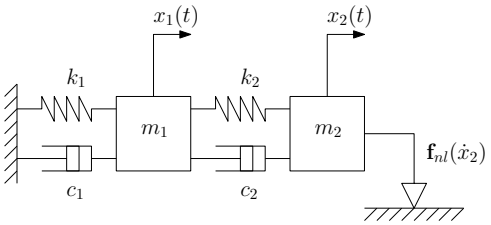

Figure 1: 2-DOFs dry-friction damped model

– (unit)	m (kg)	c (Ns/m)	k (N/m)

2.2 Nonlinear superelement

This section is dedicated to the derivation of the equations governing one superelement, built by means of nonlinear complex modes. Each substructure being treated indepedently, the nonlinear superelement could be perfectly used in conjunction with standard CMS superelements

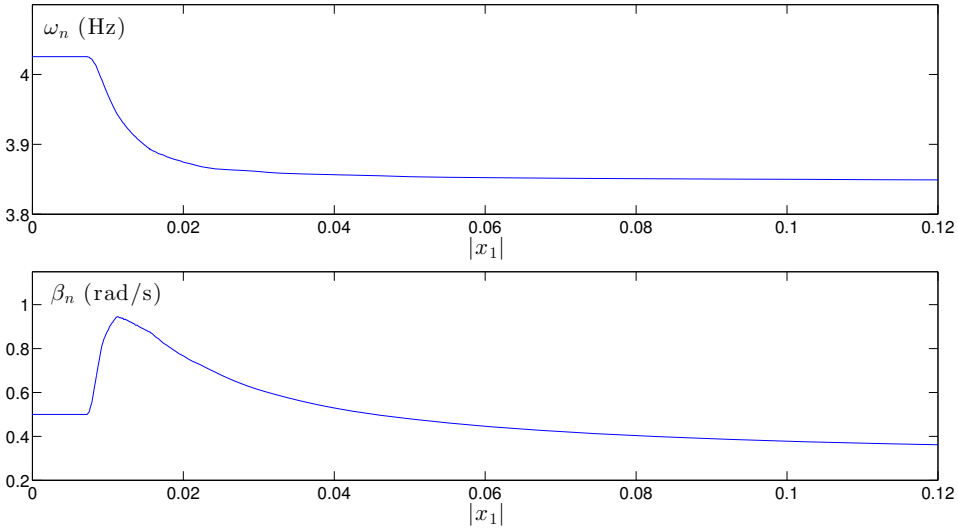

Figure 2: Nonlinear natural frequency and modal damping of the 2-DOFs model

using linear modes. This reduced-order model is devoted to the study of forced vibrations arising from harmonic or multi-harmonic excitations, of the form given in Eq. (5) where Ω is the fundamental forcing frequency.

$$\mathbf{f}_e(t) = \frac{1}{2}\left(\sum_k \langle \mathbf{f}_e | e_k \rangle e^{ik\Omega t} + c.c.\right) \tag{5}$$

The displacement of the substructure is sought as a multi-harmonic oscillation (6) made of nonlinear eigenvectors $\boldsymbol{\varphi}_{n,k}$ corresponding to fixed-interface nonlinear complex modes, supplemented by linear static modes $\boldsymbol{\psi}_{s,k}$ as in a standard fixed-interface CMS [1]. The generalized coordinates q_n and p_s corresponding to the nonlinear complex modes and static modes, respectively, are the new unknowns of the problem.

$$\mathbf{x}(t) = \frac{1}{2}\left(\sum_n q_n \sum_k \boldsymbol{\varphi}_{n,k}(|q_n|)e^{ik\Omega t} + \sum_s p_s \sum_k \boldsymbol{\psi}_{s,k} e^{ik\Omega t} + c.c.\right) \tag{6}$$

The relation between the nonlinear eigenvectors $\boldsymbol{\varphi}_{n,k}$ and the k-th harmonics $\hat{\mathbf{x}}_{n,k}$ in Eq. (2) is given by Eq. (7).

$$\hat{\mathbf{x}}_{n,k} = q_n \boldsymbol{\varphi}_{n,k} \tag{7}$$

In the following, the vectors $\boldsymbol{\psi}_{s,k}$ are all taken equal to the standard static modeshapes of a Craig-Bampton CMS, given by Eq. (8) when the DOFs are partitionned into a set of internal (subscript i) and boundary (subscript b) DOFs, although different vectors could be used.

$$\begin{aligned} &\forall k \in [\![1, n_h]\!] : \\ &\boldsymbol{\psi}_{s,k} = -\mathbf{K}_{ii}^{-1}\mathbf{K}_{ib} \quad \text{with} \quad \mathbf{K} = \begin{bmatrix} \mathbf{K}_{ii} & \mathbf{K}_{ib} \\ \mathbf{K}_{bi} & \mathbf{K}_{bb} \end{bmatrix} \end{aligned} \tag{8}$$

As mentioned in Section 2.1 for the 2-DOFs model, the modal parameters $\boldsymbol{\varphi}_{n,k}$ and λ_n are functions of a parameter describing the activation of the nonlinearity. In Eq. (6), this parameter is the amplitude $|q_n|$ of the coordinate of the corresponding mode. In theory, since the mode is complex, two variables should be used to describe its variations (*i.e.* the real and imaginary parts of q_n), but it was shown in [5] that chosing only the amplitude $|q_n|$ yields excellent results for dry-friction nonlinearities. In the following equations, the dependency of $\boldsymbol{\varphi}_{n,k}$ and λ_n on $|q_n|$ is implied.

In accordance with Galerkin methods, the approximation (6) is substituted into Eq. (1), after addition of the external forcing $\mathbf{f}_e$ from Eq. (5) on the right hand side, and the residual is orthogonalized to the subspace spanned by the functions $\{e_k = \mathrm{e}^{ik\Omega t}\}$ with respect to the inner product (3). The operation yields,

$$\begin{aligned} &\forall k \in [\![1, n_h]\!] : \\ &\left[(ik\Omega)^2\mathbf{M} + (ik\Omega)\mathbf{C} + \mathbf{K}\right] \left\{ \sum_n q_n \boldsymbol{\varphi}_{n,k} + \sum_s p_s \boldsymbol{\psi}_{s,k} \right\} + \langle \mathbf{f}_{nl} | e_k \rangle = \langle \mathbf{f}_e | e_k \rangle \end{aligned} \tag{9}$$

As performed in [6] in a modal synthesis procedure, the term $\langle \mathbf{f}_{nl} | e_k \rangle$ is replaced by the sum of the analogous vectors in the eigenproblem (4), which yields the set of equations (10), where the second line accounts now for $\langle \mathbf{f}_{nl} | e_k \rangle$. The matrix $\tilde{\mathbf{K}}$ differs from the matrix $\mathbf{K}$ owing to the fixed boundary conditions enforced during the computation of the modes.

$$\begin{aligned} &\forall k \in [\![1, n_h]\!] : \\ &\sum_n \left[(ik\Omega)^2\mathbf{M} + (ik\Omega)\mathbf{C} + \mathbf{K}\right] q_n \boldsymbol{\varphi}_{n,k} \\ -&\sum_n \left[(k\lambda_n)^2\mathbf{M} + (k\lambda_n)\mathbf{C} + \tilde{\mathbf{K}}\right] q_n \boldsymbol{\varphi}_{n,k} \\ +&\sum_s \left[(ik\Omega)^2\mathbf{M} + (ik\Omega)\mathbf{C} + \mathbf{K}\right] p_s \boldsymbol{\psi}_{s,k} \\ -&\langle \mathbf{f}_e | e_k \rangle \approx \mathbf{0} \end{aligned} \tag{10}$$

Finally, the residuals (10) are orthogonalized to the subspace spanned by the basis vectors $\boldsymbol{\varphi}_{n,k}$ and $\boldsymbol{\psi}_{s,k}$ with respect to the classic Hermitian form in $\mathbb{C}^n$. The whole process leads to the set of algebraic equations (11) governing the motion of a substructure, where $\bullet^\dagger$ refers to the Hermitian transpose.

$$\begin{aligned} &\forall k \in [\![1, n_h]\!] : \\ &\boldsymbol{\rho}_k = \begin{bmatrix} \boldsymbol{\Phi}_{n,k}^\dagger \left(\mathbf{Z}_k \boldsymbol{\Phi}_{n,k} - \boldsymbol{\xi}_k\right) & \boldsymbol{\Phi}_{n,k}^\dagger \mathbf{Z}_k \boldsymbol{\Psi}_{s,k} \\ \boldsymbol{\Psi}_{s,k}^\dagger \left(\mathbf{Z}_k \boldsymbol{\Phi}_{n,k} - \boldsymbol{\xi}_k\right) & \boldsymbol{\Psi}_{s,k}^\dagger \mathbf{Z}_k \boldsymbol{\Psi}_{s,k} \end{bmatrix} \begin{Bmatrix} \mathbf{q} \\ \mathbf{p} \end{Bmatrix} - \begin{Bmatrix} \boldsymbol{\Phi}_{n,k}^\dagger \langle \mathbf{f}_e | e_k \rangle \\ \boldsymbol{\Psi}_{s,k}^\dagger \langle \mathbf{f}_e | e_k \rangle \end{Bmatrix} = \mathbf{0} \end{aligned} \tag{11}$$

with $\mathbf{Z}_k = \left[(ik\Omega)^2\mathbf{M} + (ik\Omega)\mathbf{C} + \mathbf{K}\right]$ and $\boldsymbol{\xi}_k = \left[\mathbf{M}\boldsymbol{\Phi}_{n,k}\boldsymbol{\Lambda}_n^2 k^2 + \mathbf{C}\boldsymbol{\Phi}_{n,k}\boldsymbol{\Lambda}_n k + \tilde{\mathbf{K}}\boldsymbol{\Phi}_{n,k}\right]$ the dynamic stiffness matrix and the term arising from the substitution of each $\langle \mathbf{f}_{nl} | e_k \rangle$ from the eigenproblems, $\boldsymbol{\Phi}_{n,k}$ and $\boldsymbol{\Psi}_{s,k}$ the matrices made of the column vectors $\boldsymbol{\varphi}_{n,k}$ and $\boldsymbol{\psi}_{s,k}$, $\boldsymbol{\Lambda}_n$ a diagonal matrix made of the nonlinear eigenvalues distributed along the diagonal, and $\mathbf{q}$ and $\mathbf{p}$ the column vectors listing the general coordinates q_n and p_s respectively.

The reduced-order order model of the global system is eventually built by coupling the substructures through the generalized coordinates corresponding to the static modeshapes, p_s. If more than one harmonic is kept in the series expansion (2), which is typically the case for strong and non-smooth nonlinearities such as contact and friction, the resulting system is over-determined. However, one could, as a first approximation, discard the equations for which $\langle \mathbf{f}_e | e_k \rangle = \mathbf{0}$, which has proved to have a neglictible impact on the accuracy of the results. In the case of a mono-harmonic excitation, as in Section 3, the resulting system of equations is thus square.

Whether the system dealt with is over-determined or square, it is clearly nonlinear due to the dependency of the modes over the amplitude of their coordinates $|q_n|$, and must be solved iteratively by standard routines available in most commercial computing softwares. In practice, $\boldsymbol{\varphi}_{n,k}$ and λ_n are known for discrete values of $|q_n|$ from the nonlinear mode computation performed beforehand, and it requires now that they be interpolated at each iteration of the solver, which is readily achieved by linear or cubic interpolations.

3 NUMERICAL EXAMPLES

The dynamic substructuring method derived in Section 2 is now tested on a lumped-parameter model of bladed-disk, first on a tuned system, and then on the mistuned model, in order to demonstrate its efficiency in dealing with such complex and rich systems.

3.1 Lumped-parameter model

The cyclic model devised in this section aims at being representative of the phenomenology encountered in bladed-disk dynamics. It consists of identical sectors such as shown on Figure 3, with structural parameters taking the values reported in Table 2. The viscous damping parameters are defined so as to set the linear modal damping ratio of the first mode to 0.1%. Throughout the study, the maximum harmonic number n_h is set to 5, which has proved to provide a sufficient accuracy for the purpose of such analyses, and the nonlinear force arising from the dry-friction element is modeled by a hyperbolic tangent law [18].

– (unit)	Tip	Middle	Root	Disk	Ground
m (kg)	0.2	0.3	0.4	1.2	–
c (Ns/m)	1.3	0.7	26.7	33.3	0.4
k (10^6·N/m)	2	1	40	50	0.6

Table 2: Values of the parameters for the fundamental sector

In order to obtain clear and legible response curves for the mistuned system in Section 3.3, a model with only 12 sectors is used throughout Section 3.2 and Section 3.3. However, the performance of the method are appraised in Section 4.1 for 72 sectors, so as to deal with a more significant number of nonlinear DOFs, and thus assess the practical capabilities of the CNCMS.

3.2 Tuned system

The superelement of one sector is built from one nonlinear complex mode and two static modeshapes. Of course, for this tuned case, cyclic boundary conditions could have been applied

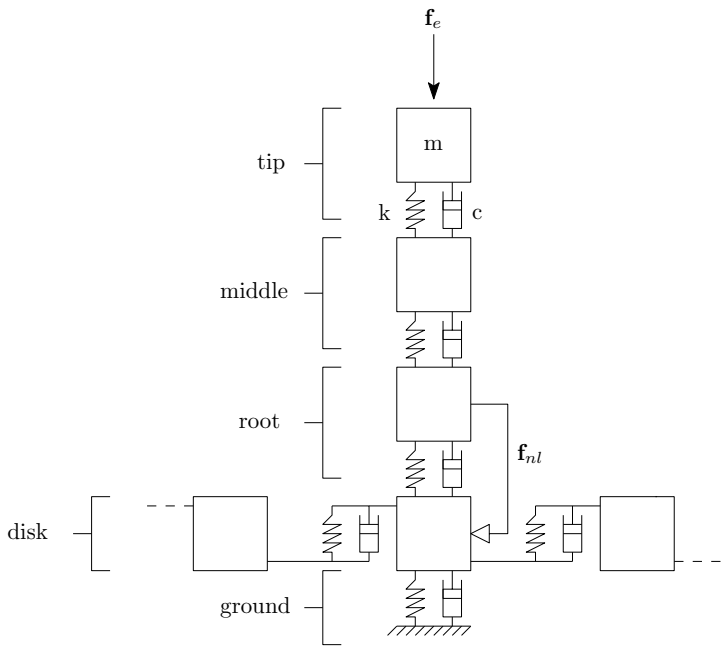

Figure 3: Fundamental sector of the cyclic model

to compute the mode, thus restricting the study to cyclic solutions. The system is first subjected at the blade tips to a travelling wave excitation, standard in bladed-disk dynamics, with 6 nodal parameters and for various excitation levels. In accordance with the linear theory of cyclic systems, the frequency response exhibits one resonance corresponding to the double mode with 6 nodal diameters. Figure 4 shows the perfect agreement of the solution obtained by CNCMS with the reference, computed by means of a classic harmonic balance method (HBM), even for a strong activation of the nonlinearities. The shift of the resonance toward lower frequencies as the amplitude of the response increases is characteristic of friction damped systems, and is a direct consequence of the evolution of the nonlinear natural frequencies that can be observed on Figure 2.

3.3 Mistuned system

An interesting application of the reduced-order modeling technique presented in this paper is the study of nonlinear and mistuned cyclic structures. In order to prove that the method can effectively handle such systems, the lumped-parameter model of Section 3.1 is modified by defining a new type of sector, with different tip and middle stiffness values, so as to shift the first natural frequency by 5% from that of the initial sector. The values taken by the structural parameters of this new sector are reported in Table 3. The fundamental sector A of the tuned model and this new sector B are then distributed according to a randomly generated pattern given in Table 4. The first nonlinear complex mode of each sector type is computed and used to build two different nonlinear superelements, which are then assembled in accordance with the mistuning pattern to build the reduced-order model.

The response of the mistuned system is computed for a travelling wave excitation with 6 nodal diameters, at a strong nonlinear level, and compared to the reference on Figure 5. As a consequence of the mistuning pattern, the response non longer exhibits one single peak, the

travelling wave exciting now all the modes in the frequency range. Even though some small differences can be observed, the accuracy of the solution synthesised by CNCMS is very satisfactory. The origin of these differences is adressed in Section 4.2, and should be put in perspective with the complexity of the response and the computational efficiency of the method, discussed in Section 4.1.

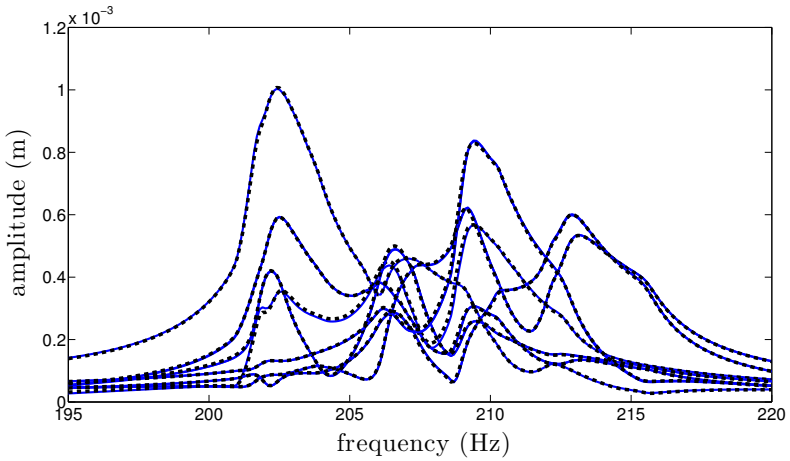

Figure 5: Response of all the blades of the mistuned system for a travelling wave excitation with 6 nodal diameters (CNCMS in blue solid lines, HBM black dashed lines)

4 DISCUSSION

This section briefly discusses the performance of the proposed reduced-order modeling technique. The efficiency of the method in terms of computational effort is first appraised, as well as the actual order-reduction obtained. The range of validity of the assumptions made is also adressed.

4.1 Performance

Figure 6 shows the ratio of the time required to compute the solution on a model with 72 sectors by HBM, normalized by the time required by CNCMS, for different excitation amplitudes F. Even close to the linear domain (F=1N), the CNCMS is about already 80 times faster than the HBM, and is up to 190 times faster when the system is extremely nonlinear (F=10N). Close to the optimum damping point (F=5N), mentioned in Section 2.1 and where it can be interesting to operate industrial systems, the ratio is close to 135, which highlights the outstanding potential of the CNCMS. The local maximum observed for F=4N also points out that the pattern of the nonlinear effects, besides the excitation level, can impact the performance of standard HBM methods when compared to the CNCMS.

The computational efficiency of the method clearly stands out in this study. It should however be pointed out that on the relatively small lumped-parameter model used here, the reduction capability of the CNCMS was not fully taken advantage of. On a larger model, the reduction arising from the use of nonlinear complex modes, allowing to drop all internal DOFs, would indeed be significantly more effective, and the computational performance of the method might prove even more impressive.

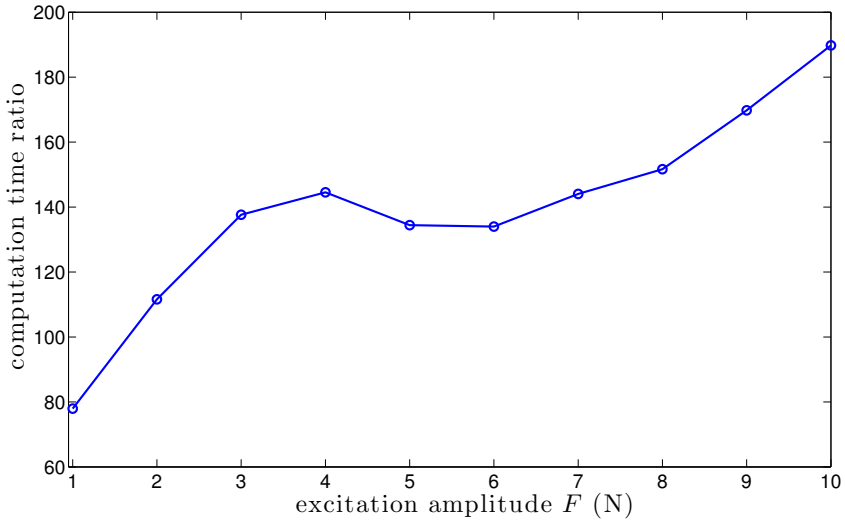

Figure 6: Computation time ratio between HBM and CNCMS

4.2 Limitations

In Section 3, some very small differences between the results obtained by CNCMS and the HBM reference could be observed. This could be explained by the fact that the model used here does not fully satisfy the assumptions made to derive the nonlinear superelement equations. In Eq. (6), the approximation of the displacement field for a given substructure uses indeed linear static modeshapes to account for the motion of the boundaries, which is quite understandable when it comes to actual blade-disk friction. On the lumped-parameter model of Section 3, however, the dry-friction elements are directly linked to the boundaries, which makes this approximation a bit bold. Nevertheless, the HBM reference curve is accurately approximated eventually, which allows to appraise the robustness of this new method.

5 CONCLUSION

The dynamic substructuring technique presented in this paper, the CNCMS, proved very promising for the study of forced vibrations in nonlinear structures. The method proved to handle quite well cases of neighboring resonant modes, and excellent computational performance has been obtained on a phenomenological model of mistuned bladed-disk, with a computation time about 135 times smaller than with standard and state-of-the-art HBM methods. Although devised initially in order to provide a new and efficient way to tackle problematics in bladed-disk dynamics, and allow to combine the presence of nonlinearities and mistuning, the procedure is flexible and could be applied to other types of nonlinear systems. Furthermore, the similarities between the CNCMS and the classic fixed-interface CMS perfectly allow to combine the two methods to build nonlinear and linear superelements, respectively, and build a hybrid reduced-order model by assembling these superelements.

Future prospects of this work could involve testing the procedure on other kind of nonlinearities, such as large deformation, or extend it to other CMS methods such as free-interface CMS. The implementation of the method on a large-scale 3D-model is an ongoing project of the authors, in view of assessing its potential for real, industrial structures.

Keywords: Time integrators, Rotordynamics, Model reduction, Nonlinear vibrations, FEM

Abstract. *This paper focuses on the application of time integration methods to rotor-stator assembly modeled by Finite Element Method. In particular the average acceleration method (which is implicit) and the central differences method (which is explicit) are examined. Both belong to the Newmark's time integrator family and are widely used. It is found that the first one is unstable due to the periodic kinematic constraints linking the rotating to the non rotating parts of the structure. A proposed remedy is to add numerical damping leading to the implicit HHT and α-generalized schemes. Concerning the integration with an explicit scheme, it is demonstrated that a classical implementation lead to a vanishingly small critical time step because of the strong gyroscopic effects. An exact implementation of this kind of scheme is proved to maintain the value of the critical time step.*

1 INTRODUCTION

The need to fully control the dynamical behavior of rotors is motivated by rotors machinery more and more complex operating in more and more severe conditions. Modeling capacities are often wished to ensure the lowest cost of design and maintenance and the highest safety margins.

To this end, this work focuses on the computation of the time response of a three-Dimensional Finite Element model (3D-FE model) enabling to represent the behavior of a complex rotor-stator assembly.

First, a three-Dimensional modelin the Finite Element software Cast3M [1] is considered, following the work of Combescure and Lazarus [2]. As pointed out by Geradin and Kill [3] and Chatelet *et al.* [4], compared to one-dimensional models (1D models), 3D-FE models exhibit better accuracy for evaluating stiffness of disc and wheel-shaft assembly. They are also required when dealing with non-axisymmetric geometry like bladed disc. They however imply an higher computational cost and some reduction techniques are necessary in industrial cases.

Time integration methods is widely viewed as the more direct manner to predict the dynamic response of a mechanical structure to a given loading in presence of some non-linearities. This general fact remains true in rotordynamics as pointed out by Genta [5] Alternatives in the frequency domain (like the Harmonic Balance Method for example) exist but their use is not always straightforward.

Hence, the present paper aims at presenting the specificity of time-integration methods when applied to a 3D rotor-stator assembly, exhibiting some little known numerical instabilities and their possible remedies.

2 MODELING 3D ROTOR-STATOR ASSEMBLY

2.1 Equation of motion of a 3D rotor-stator assembly

The more "natural" approach to model the vibrations of a rotor discretized by non-beam-element is to consider its motion in the rotating frame $\mathcal{R}' = \{O', \underline{e}'_1, \underline{e}'_2, \underline{e}'_3\}$. This one is represented on figure 1. A simple rotation defined by the angular velocity Ω around the first axis ($\underline{e}_1 = \underline{e}'_1$), links this frame to the non-rotating Galilean frame $\mathcal{R}$.

The position and displacement of a point P defined in the rotating frame by its relative coordinate can be expressed in the inertial frame by the rotation of angle $\underline{\Omega} t$ and the translation of the origin $\underline{s} = \underline{OO'}$. Following Argyris [6] for example, the position $\underline{y}$ of P is given by the coordinate $x + u$ in $\mathcal{R}'$, and the coordinate y of this point in $\mathcal{R}$ are expressed by:

$$\begin{aligned} \underline{y} &= \underline{OP} = \underline{OO'} + \underline{O'P} \\ y &= s + [R](x + u) \end{aligned} \tag{1}$$

where $[R] = \begin{bmatrix} \underline{e}'_1 & \underline{e}'_2 & \underline{e}'_3 \end{bmatrix}$ is the orthonormal matrix of the basis vectors of $\mathcal{R}'$ expressed in $\mathcal{R}$, and s is the coordinate of $\underline{OO'}$ in $\mathcal{R}$.

To deal with vibrations, velocity and acceleration have to be computed. The derivation of basis vector is simply:

$$\dot{\underline{e}}'_i = \underline{\Omega} \wedge \underline{e}'_i \tag{2}$$

Then velocity and acceleration in the inertial frame can be derived as:

$$\begin{aligned} \dot{\underline{y}} &= \dot{\underline{s}} + \dot{\underline{x}} + \dot{\underline{u}} \\ \dot{y} &= \dot{s} + [R]\dot{u} + \underline{\Omega} \wedge ([R]\,(x + u)) \end{aligned} \tag{3a}$$

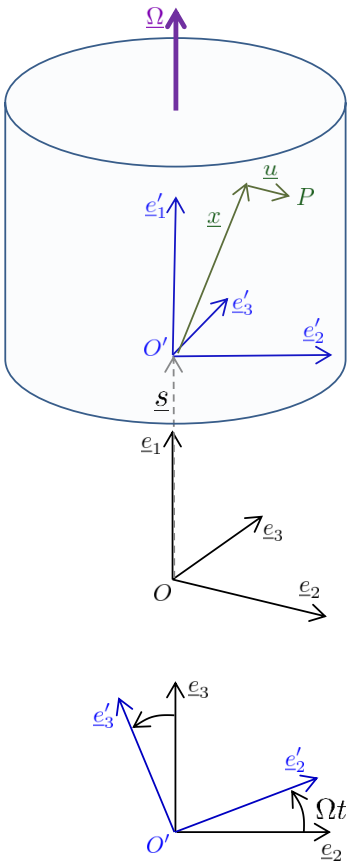

Figure 1: Definition of non-rotating (also called inertial) and rotating frames

$$\begin{aligned} \ddot{y} =& \ddot{s} + [R]\ddot{u} + \dot{\underline{\Omega}} \wedge ([R]\,(x+u)) + \underline{\Omega} \wedge \underline{\Omega} \wedge ([R]\,(x+u)) + 2\underline{\Omega} \wedge ([R]\dot{u}) \\ [R]^T\ddot{y} =& [R]^T\ddot{s} + \ddot{u} + \dot{\Omega}\wedge(x+u) + \Omega \wedge \Omega\wedge(x+u) + 2\Omega\wedge\dot{u} \end{aligned} \tag{3b}$$

The third term of the Right-Hand-side of Eq. (3b) is the Euler term and is zero as long as the spin speed is constant. The fourth term refers to the centrifugal effect acting in the radial direction. The last therm of the RHS is the probably the most characteristic of Rotordynamics as it refers to the Coriolis effect which produces a pseudo-acceleration in a direction perpendicular to the relative velocity.

The geometry of the rotor is discretized in the rotating frame with standard finite element shape functions:

$$\underline{x} = \sum_i N_i(x)\underline{x}_i \tag{4}$$

Isogeometric element are considered and displacements, velocity and acceleration are approximated in the same space of functions:

$$\begin{aligned} \underline{u}(\underline{x},t) &= \sum_i N_i(x)\underline{u}_i(t) \\ \dot{\underline{u}}(\underline{x},t) &= \sum_i N_i(x)\dot{\underline{u}}_i(t) \\ \ddot{\underline{u}}(\underline{x},t) &= \sum_i N_i(x)\ddot{\underline{u}}_i(t) \end{aligned} \tag{5}$$

The weak form of the mechanical problem for the domain $\mathcal{D}$ of boundary $\partial\mathcal{D} = \partial\mathcal{D}_F \cup \partial\mathcal{D}_u$ is given by Eq. (6).

$$\begin{aligned} &\forall \delta\underline{v} \in V^0 = \{\delta\underline{v}, \text{ so that } \delta\underline{v} = 0 \text{ sur } \partial\mathcal{D}_u\}, \\ &\int_{\mathcal{D}} \rho\underline{\ddot{u}} \cdot \delta\underline{v}\, d\mathcal{D} + \int_{\mathcal{D}} \underline{\underline{\sigma}} : \delta\underline{\underline{e}}(\underline{v})\, d\mathcal{D} = \int_{\mathcal{D}} \underline{f}_d \cdot \delta\underline{v}\, d\mathcal{D} + \int_{\partial\mathcal{D}_F} \underline{F}_d \cdot \delta\underline{v}\, d\Gamma \end{aligned} \tag{6}$$

Injecting the kinematic of the rotor in the weak form of the problem, supposing that equilibrium due to centrifugal forces is verified by a static motion generating a constant state of stress σ^0, and using the discretized approximation of these quantities, dynamic equilibrium is obtained:

$$[M]\underline{\ddot{u}}' + [\Omega G + C_{visc}]\underline{\dot{u}}' + [K_{elas} + \Omega^2 K_{cent} + K(\sigma^0)]\underline{u}' = F'_{ext} \tag{7}$$

where the Coriolis effect is G.

For the non-rotating part (i.e. the stator), the geometry and displacement are expressed in the inertial frame. Then, the discretized equations of motion reduce to :

$$[M]\underline{\ddot{u}} + [C_{visc}]\underline{\dot{u}} + [K_{elas}]\underline{u} = F_{ext} \tag{8}$$

2.2 Linking the rotating to the non-rotating frame

As depicted by figure 1, a simple change of frame enables to establish the constraint equation between the degrees of freedom of the rotor and ones of the stator. to equal their relative displacements :

$$\begin{pmatrix} U1 \\ U2 \\ U3 \end{pmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos\Omega t & -\sin\Omega t \\ 0 & \sin\Omega t & \cos\Omega t \end{bmatrix} \cdot \begin{pmatrix} U1' \\ U2' \\ U3' \end{pmatrix} \tag{9}$$
$$U \quad = \quad R(\Omega t) \quad \cdot \quad U'$$

A Lagrange multiplier Λ is introduced to recast the constraint :

$$\begin{pmatrix} 0 & -I & R \\ -I^T & 0 & 0 \\ R^T & 0 & 0 \end{pmatrix} \cdot \begin{bmatrix} \Lambda \\ U \\ U' \end{bmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix} \tag{10}$$
$$\text{soit} \qquad L(\Omega t) \quad \cdot \quad q \quad = \quad 0$$

3 NEWMARK TIME INTEGRATION SCHEMES

3.1 Basic equations of the Newmark scheme

A large number of literature exists about time integration scheme and the Newmark's scheme that seems to be one of the most used in structural dynamic community (see the books of Hughes [7], Géradin [8], Argyris [6] or Zienkiewicz [9] for example). It is often presented as a truncated Taylor development of local quantities which is not presented here for sake of clarity.

A recurrence formula links displacement, velocity and acceleration at time t_{n+1} :

$$\begin{aligned} \ddot{u}_{n+1} &= \frac{1}{\beta\Delta t^2}(u_{n+1} - u_n) - \frac{1}{\beta\Delta t}\dot{u}_n + (1 - \frac{1}{2\beta})\ddot{u}_n \\ \dot{u}_{n+1} &= \frac{\gamma}{\beta\Delta t}(u_{n+1} - u_n) + (1 - \frac{\gamma}{\beta})\dot{u}_n + \Delta t(1 - \frac{\gamma}{2\beta})\ddot{u}_n \end{aligned} \tag{11}$$

Introducing these expressions in the dynamic equilibrium, one gets :

$$\left[\frac{1}{\beta\Delta t^2}M + \frac{\gamma}{\beta\Delta t}C + K\right](u_{n+1} - u_n) = F^{ext}_{n+1} - Ku_n \\ - C\left((1-\frac{\gamma}{\beta})\dot{u}_n + \Delta t(1-\frac{\gamma}{2\beta})\ddot{u}_n\right) \\ - M\left(-\frac{1}{\beta\Delta t}\dot{u}_n + (1-\frac{1}{2\beta})\ddot{u}_n\right) \tag{12}$$

3.2 Properties of the Newmark scheme

The accuracy and stability of the Newmark scheme depend on the value of the parameters γ and β. Table 1 sums up the stability conditions of some different schemes for a 1-dof system subjected to no external loading.

Scheme	γ	β	$\Delta t_c/\Delta t^e$
Central difference	$1/2$	0	2
Fox and Goodwin	$1/2$	$1/12$	2.45
Linear acceleration	$1/2$	$1/6$	3.46
Average acceleration	$1/2$	$1/4$	∞
Modified average acceleration	$1/2+\alpha$	$1/4(1+\alpha)^2$	∞
Runge-Kutta 4	-	-	$2\sqrt{2}$
Fu-De Vogelaere	-	-	$2\sqrt{2}$

Table 1: Critical time step of some time integration schemes

where $\Delta t^e = \frac{min(\Delta x^e)}{\sqrt{E/\rho}}$ is the caracteristic time of an element of Young modulus E, density ρ and internodal distance Δx^e.

The application of the central difference method to rotordynamic will be presented in the next section. Then, the average acceleration method will be considered in section §5.

4 AN EXPLICIT SCHEME : THE CENTRAL DIFFERENCE METHOD

4.1 Classical approximation of the central difference method

Choosing $\gamma = \frac{1}{2}, \beta = 0$, the displacement at time $n+1$ only depends on quantities at time n :

$$u_{n+1} = u_n + \Delta t\dot{u}_n + \frac{\Delta t^2}{2}\ddot{u}_n \tag{13}$$

Introducing the velocity at the mid step :

$$\dot{u}_{n+\frac{1}{2}} = \frac{u_{n+1} - u_n}{\Delta t} \tag{14}$$

which enables to write :

$$\dot{u}_{n+1} = \frac{\Delta t}{2}\ddot{u}_{n+1} + \dot{u}_{n+\frac{1}{2}} \tag{15}$$

the equation of motion to solve at each time step is simply :

$$\left[M + \cancel{\frac{\Delta t}{2}C}\right] \ddot{u}_{n+1} = F^{ext}_{n+1} - Ku_{n+1} - C\dot{u}_{n+\frac{1}{2}} \tag{16}$$

A very common practice in code implementation is to neglect the term $\frac{\Delta t}{2}C$ on the Left-Hand-Side of equation (16). This leads to the "classical" central difference scheme. This assumption is generally justified by the relatively low effect of damping compared to the inertial one and to the stiffness. Combined to a lumping technique, it has the advantage to keep the operator diagonal, so that no matrix has to be inverted.

However in the case of rotordynamics, the matrix C includes viscous and gyroscopic (Coriolis matrix) effects. That is why it is proposed here to consider the "Full" central difference scheme which does not neglect the participation of this term and compute the inverse of $\left[M + \frac{\Delta t}{2}C\right]$. This strategy is adopted only in the case where the spatial description is reduced by modal approach.

The effect on the performance of the scheme is evaluated on the basis of the following example.

4.2 Application to a rotor modeled by 3D FE

A rotor constituted of a shaft and four short blades is considered (see figure 2.

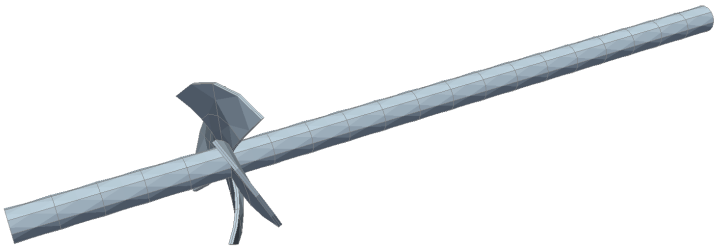

Figure 2: 3D mesh of the rotor test case

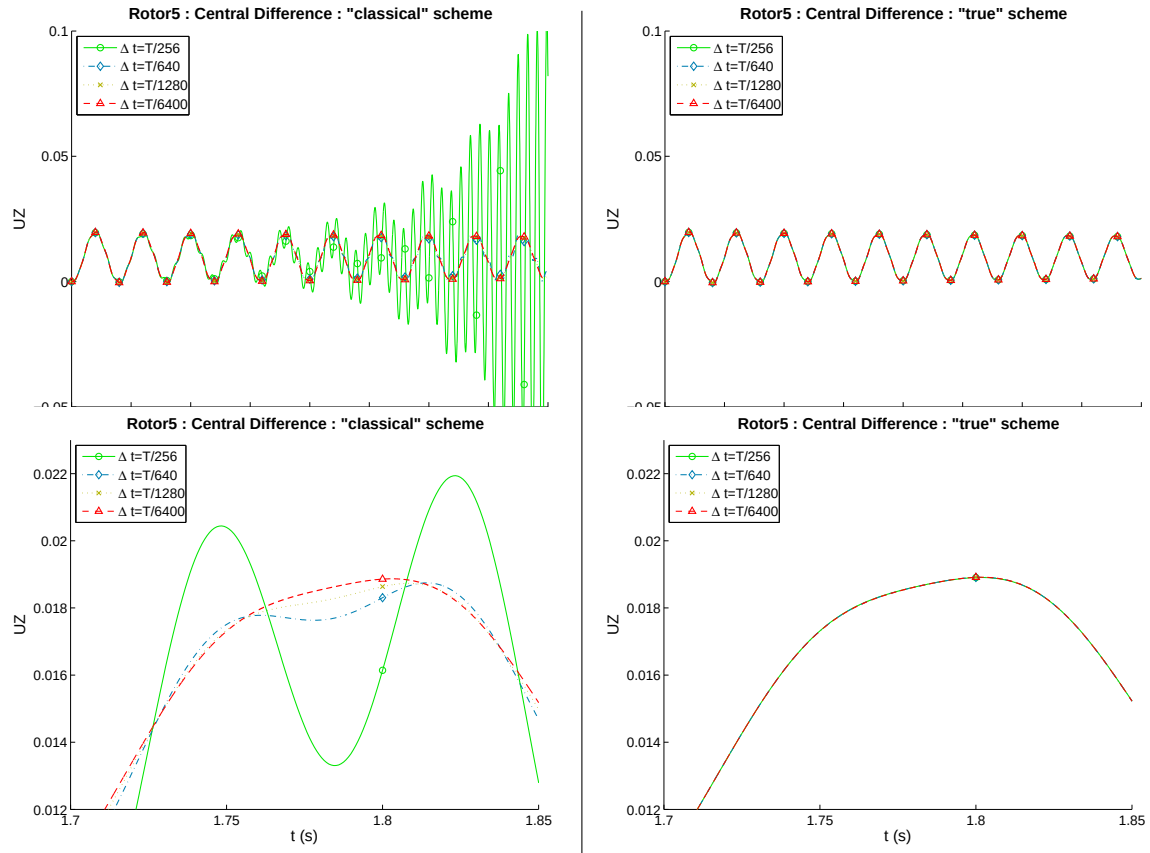
An unbalance excitation generated by a blade loss is simulating by applying an equivalent force to the model. Displacement evolution with time for different time step Δt are given figure 3a.

Figure 3a demonstrates that the application of the "Full" central difference scheme maintain the critical time step to an acceptable value, whereas the "classical" assumption that neglect C on the LHS drastically decrease it and causes unstable behavior for $\Delta t \geq \frac{T}{256}$ (where $T = 2\pi/\Omega$).



(a) "Classical" central difference scheme

(b) "Full" central difference scheme

Figure 3: Displacement evolution with time for various time step and the explicit central difference method

5 AN IMPLICIT SCHEME : THE AVERAGE ACCELERATION METHOD

5.1 Application to a 4 degree of freedom problem

A very simple model with 4 degree of freedom is presented here to illustrate the behavior of the average acceleration scheme when used to compute the response of a rotor-stator assembly. The model is depicted on figure 4.

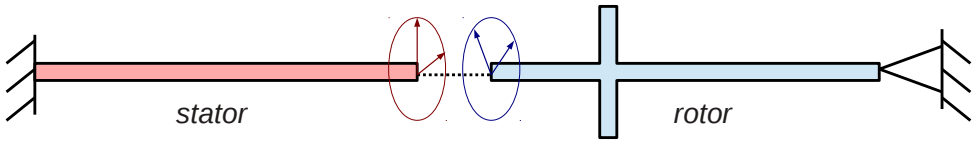


Figure 4: 4 dof rotor-stator system

Only the first modes are considered for the rotor and the stator (respectively the first flexural modes along y and z and the rigid body mode along y' and z'). The introduction of the two kinematic constraints linking rotating to non-rotating parts adds two Lagrange multipliers to the system. Hence, the vector of unknown is :

$$q^T = \begin{pmatrix} \lambda_y & \lambda_z & u_y & u_z & u'_y & u'_z \end{pmatrix} \tag{17}$$

and the equation of motion is :

$$Kq + C\dot{q} + M\ddot{q} = F \tag{18}$$

$$\text{with } K = \begin{bmatrix} 0 & 0 & 1 & 0 & -\cos\Omega t & \sin\Omega t \\ & 0 & 0 & 1 & -\sin\Omega t & -\cos\Omega t \\ & & k & 0 & 0 & 0 \\ & & & k & 0 & 0 \\ & & & & k' & 0 \\ \textit{sym} & & & & & k' \end{bmatrix} \quad C = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ & 0 & 0 & 0 & 0 & 0 \\ & & c & 0 & 0 & 0 \\ & & & c & 0 & 0 \\ & & & & c' & 0 \\ \textit{sym} & & & & & c' \end{bmatrix}$$

$$\text{and } M = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ & 0 & 0 & 0 & 0 & 0 \\ & & m & 0 & 0 & 0 \\ & & & m & 0 & 0 \\ & & & & m' & 0 \\ \textit{sym} & & & & & m' \end{bmatrix}$$

An unbalance loading is applied to the rotor along the y'-direction :

$$F = (2\pi\Omega)^2 \cdot r(t) \cdot \begin{pmatrix} 0 & 0 & 0 & 0 & f & 0 \end{pmatrix}^T \tag{19}$$

with a linear ramp variation during the half of the first period :

$$r(t) = \begin{cases} 2\Omega t & \text{if} \quad 0 \leq t < \frac{1}{2\Omega} \\ 1 & \text{else} \end{cases} \tag{20}$$

Numerical values used in for this test case are given table 2.

m	m'	k	k'	c	c'	f	Ω
1E3	1E3	6E6	0	31E3	0	$\frac{1}{(2\pi\Omega)^2}$	5 Hz

Table 2: Numerical value of the 4-dof system

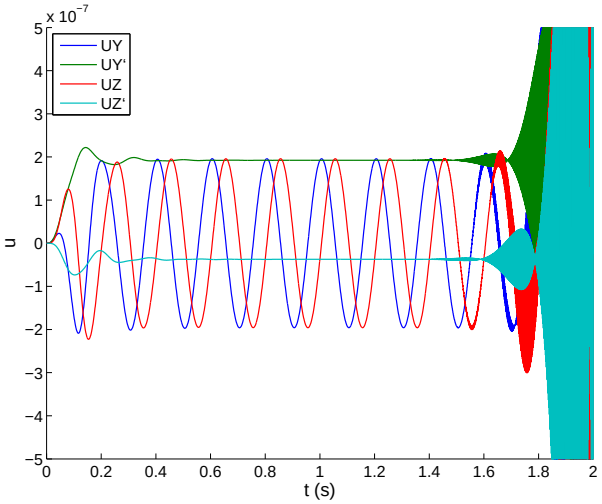
Solving equation (19) with the average acceleration method lead to the results of figure 5.

As there is no physical source of instability in the proposed model, the simple 4-dof example presented here proved the instability of the Newmark average acceleration method for this class of linear but with periodic constraints problem ! This is contradictory with the unconditionally stable reputation of this scheme for linear problem. Evolution of Lagrange multipliers suggests that the periodic constraint is the source of numerical divergence of the solution.

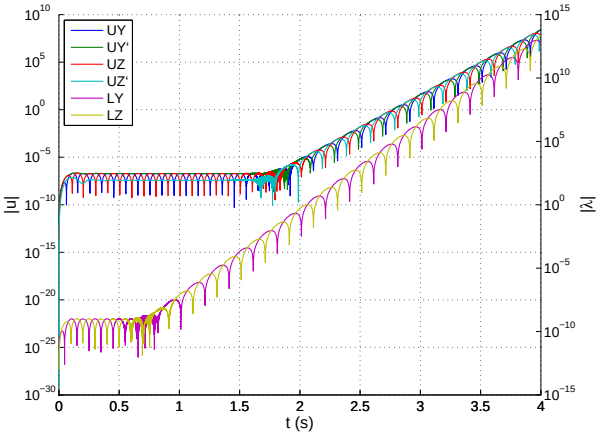
A single article of 1989 written by Cardona and Géradin [12] demonstrates that some kinematics constraints may lead to infinite eigenvalues of the amplification matrix. Time integration of systems with a relative important participation of kinematic constraints is then not an easy task. This explains why a great amount of literature can be found about time-integration in flexible multibody dynamics [13].

Three solutions can be adopted to treat this problem :

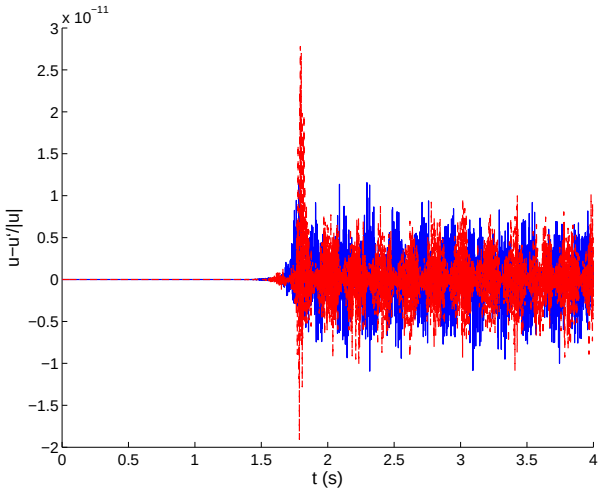
- When possible, eliminate the constraints (and the associated variables),
- Derive two times the constraint equation and add mass and damping terms so that the constraint becomes an overdamped system,



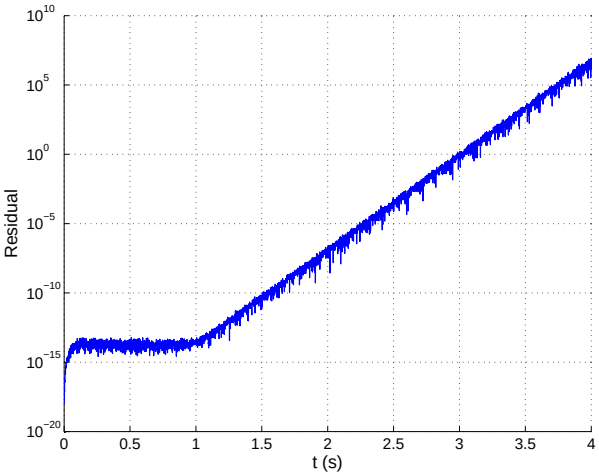
(a) Displacement time evolution up to 2 s



(b) Lagrange multipliers time evolution



(c) Relative validity of the constraint rotor-stator



(d) Evolution of the residual of the dynamic equilibrium

Figure 5: Results of the average acceleration method for the 4-dof system

- Use a scheme which presents naturally numerical damping.

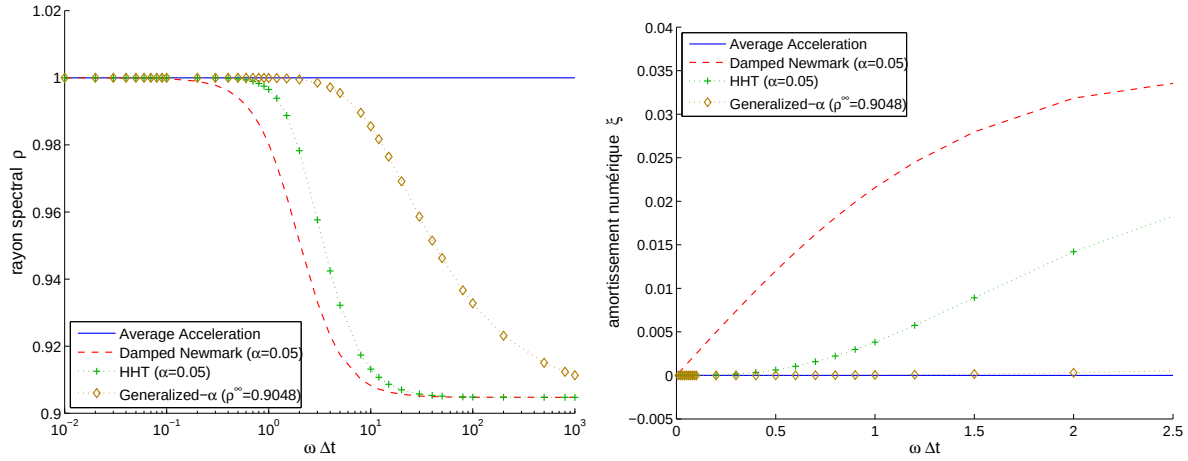
The last one will be discussed in the following subsection.

5.2 Adding numerical damping to the scheme

Three scheme with numerical damping have been implemented in Cast3M and tested on the 4-dof test case :

- Modified average acceleration with α=0.05
- HHT with α=0.05
- α-generalized with ρ_∞=0.9048

The spectral radius (identified as the highest eigenvalue of the amplification matrix) and the numerical damping are plotted for these scheme figure 6. Figure 6 shows that high frequencies



(a) Spectral raidus (b) Damping

Figure 6: Characteristics of some schemes

are considered as spurious and attenuated by these schemes.

The HHT (from Hilber-Hughes-Taylor [10]) and the α-generalized [11] methods are methods closed to the Newmark's one, but a weighting of elastic, viscous and inertial forces over time step is performed in order to control the damping. The general equation of motion to solve is no more (8) but :

$$(1-\alpha_m)M\ddot{u}_{n+1} + \alpha_m M\ddot{u}_n + (1-\alpha_f)C\dot{u}_{n+1} + \alpha_f C\dot{u}_n + (1-\alpha_f)Ku_{n+1} + \alpha_f Ku_n = (1-\alpha_f)F^{ext}_{n+1} + \alpha_f F^{ext}_n \quad (21)$$

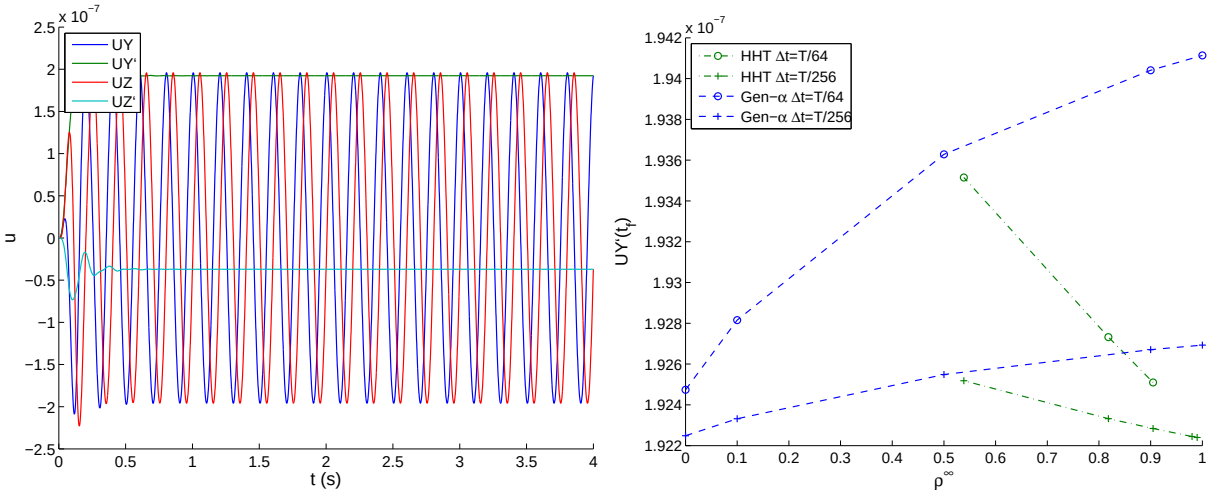
where $\alpha_m = 0$ for the HHT method. The Newmark parameters are adjusted to maintain second order accuracy :

$$\gamma = \frac{1}{2} + \alpha_f - \alpha_m \quad \text{et} \quad \beta = \frac{1}{4}(1+\alpha_f-\alpha_m)^2 \quad (22)$$

For the α-generalized method, the spectral radius ρ_∞ $\omega\Delta t \to \infty$ can be chosen and the coefficients α_m and α_f deduced as :

$$\alpha_m = \frac{2\rho_\infty - 1}{\rho_\infty + 1} \quad \text{et} \quad \alpha_f = \frac{\rho_\infty}{\rho_\infty + 1} \quad (23)$$

Using one of the three aforementioned scheme leads to a slightly damped stable solution as depicted by figure 7a.



(a) Time evolution of displacements obtained with the HHT scheme (α=0.05)

(b) Displacement UY' at th eend of simulation

Figure 7: Results obtained with numerical damping

The stationary value of the UY' displacement as a function of the spectral radius for the HHT and α-generalized methods and for two values of time step is given figure 7b. For this very simple 4-dof system, the analytic solution at steady state is UY'=1.922E-7. Observation of this figure indicates that :

- with the HHT scheme, instability is observed for too small values of α_f and this critical value depends on time step,
- with the HHT scheme, the amplitude of vibration tends to decrease with the spectral radius, which is counter-intuitive !
- with the α-generalized scheme, the system is always stable even if $\rho^\infty = 1$ (no dissipation) !
- with the α-generalized scheme, the finale amplitude increase with the spectral radius but remains a finite value,
- a better solution is found for smaller time step and for respectively large and small radius for HHt and α-generalized schemes.

5.3 Application to 3D rotor-stator assembly

A system very close to the 4-dof previously studied system is considered. The 3D FE mesh of this system is given figure 8.

Average acceleration method is first used with two spatial discretization :

- FE dof : the Finite Element degree of freedom,
- CMS dof : a Component Mode Synthesis method (Craigh Brampton) is used to reduce the number of dof.

Mode shapes used in CMS are plotted figure 9.

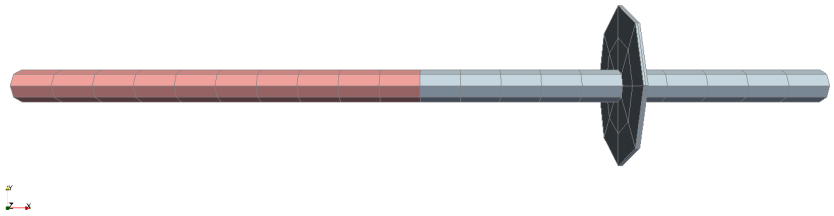


Figure 8: FE mesh : the stator is on the left (pink) and the rotor is on the right (light blue)

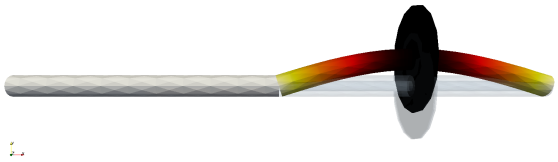
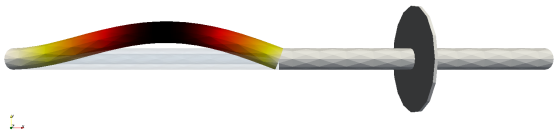
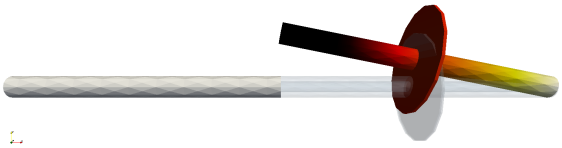


(a) Eigenmode (first flexion of the rotor)



(b) Eigenmode (first flexion of the stator)

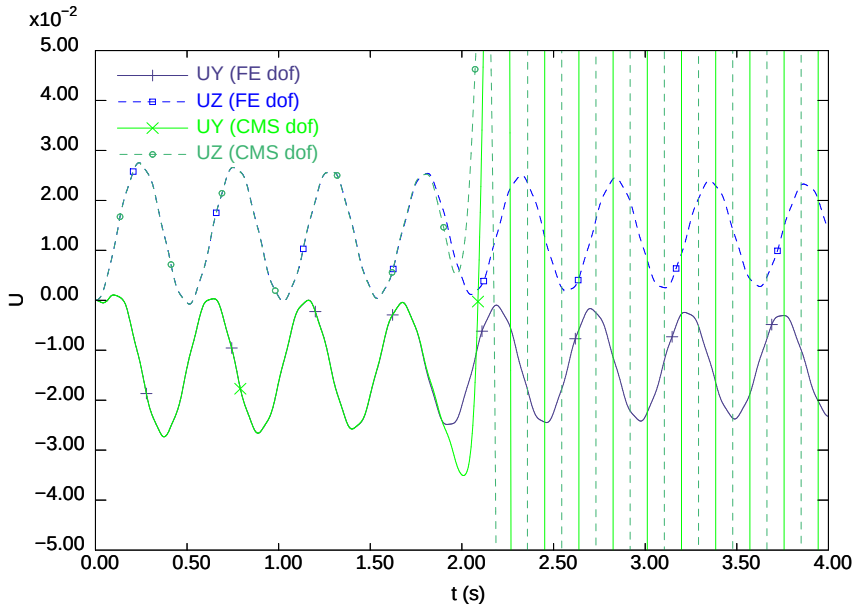
(c) Static solution (lateral displacement imposed to the rotor)



(d) Static solution (lateral displacement imposed to the stator)

Figure 9: Mode shape constituting the CMS base

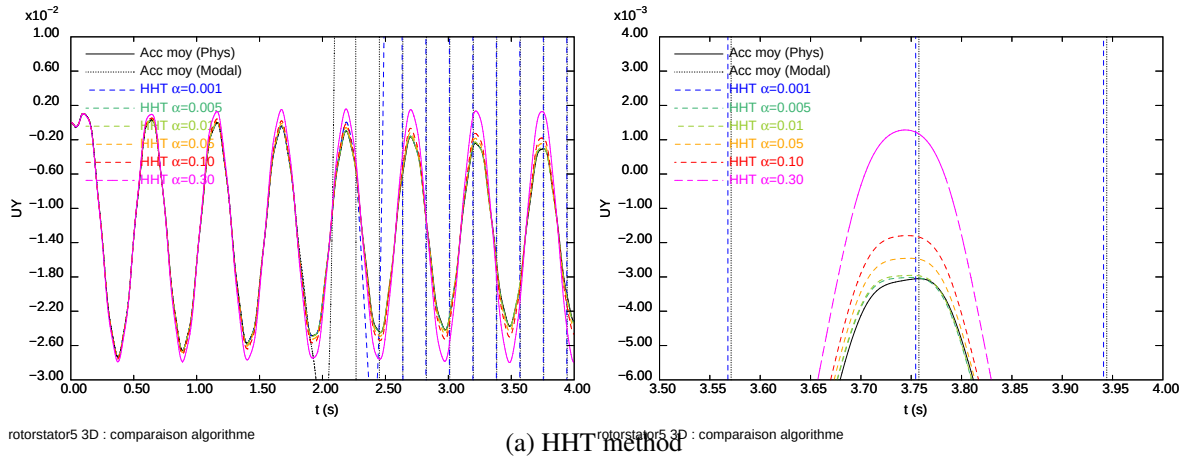
The displacement evolution with time for both spatial discretization is given figure **??**. Whereas FE-dof based response remains stable, it seems that CMS-dof based solution become unstable like the 4-dof system.



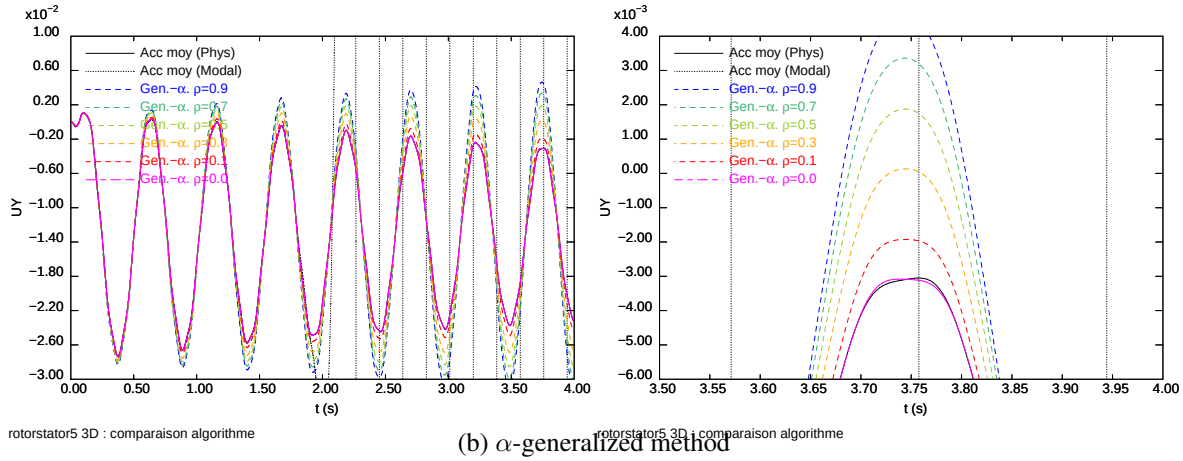
transitoire (Ω=5Hz) − DYNAMOI physique: acc moy. − modal: HHT α_F=0

Application of the numerically damped HHT and α-generalized methods enables to get ride

of this instability as it is shown on figures 10.



(a) HHT method



(b) α-generalized method

Figure 10: Results of time integration applied to 3D rotor-stator assembly

Once again, the HHT method seems efficient for a "just stable" value of parameter $\alpha_f = 0.005$, whereas the α-generalized method is the closest to the reference for an high damping value ($\rho^\infty = 0$).

6 CONCLUSIONS AND PERSPECTIVES

Two kinds of numerical instabilities have been highlighted for both the central difference and the average acceleration method.

The first one concerns the drop of the critical time step when neglecting the gyroscopic term in the operator computing the acceleration at the next time step. A simple remedy is to use the full formulation but it could be expensive if the inversion of a large matrix have to be performed.

For implicit scheme, matrix inversion is naturally done and the time step is expected to be greater. However the kinematic constraints to link the rotating to the non-rotating parts introduce a numerical instability which has to be dissipated. HHT and α-generalized methods have been found to do this task under the condition to choose appropriately the numerical damping.

As this choice may not be obvious in every situations, combination of an explicit integrator with a component mode synthesis method seems to be the most attractive way to model complex 3D rotor-stator assembly.

Future development will concern the integration of nonlinear component (bearing, squeeze-film, rotor-stator contact, ...) in the models.

Keywords: Optimal control, Delayed feedback control, Space-time periodic solution, Viscoelasticity, Steady rolling.

Abstract. *We are interested in fast techniques for calculating a periodic solution to viscoelastic evolution problems with a space-time periodic condition of "rolling" type. Such a solution is usually computed as an asymptotic limit of the initial value problem with arbitrary initial data. We want to invent a control method, accelerating the convergence. The main idea is to modify our problem by introducing a feedback control term, based on a periodicity error, in order to accelerate the convergence to the desired periodic solution of the problem.*

First, an abstract evolution problem has been studied. From the analytic solution of the modified (controlled) problem, an efficient control has been found, optimizing the spectrum of the problem. The proposed control term can be mechanically interpreted, and its efficiency increases with the relaxation time.

In order to confirm numerically the theoretical results, a finite element simulation has been carried out on a full 2D model for a steady rolling of a viscoelastic tyre with periodic sculpture. It has demonstrated that the controlled solution converges indeed faster than the non-controlled one, and that the efficiency of the method increases with the problem's relaxation time, that is when the memory of the underlying problem is large.

1 INTRODUCTION

In industrial applications, in order to avoid the inversion of very large matrices, dynamic periodic state are often computed as the asymptotic limit solution of an initial value evolution problem with arbitrarily chosen initial data. In such cases, one is not really interested in the evolution history, but only in convergence time. Computations can take a lot of time for "viscous" problems, when memory effects are very large. Then the convergence time becomes a significant parameter for industrial implementations, and developing methods accelerating convergence is of current interest.

For such problems, even if the asymptotic limit is periodic, the solution of the initial value evolution problem is not. Thus the periodicity of the desired solution can be considered as an extra information (observation), which makes possible to apply control techniques. In other words, we want to use this information to construct a filter for the evolution problem. This modifies the original evolution problem through a control term based on the observation error. In this framework, the present work is dedicated to the development of acceleration methods for the solution of periodic problems. This kind of problems can be faced, for instance, in the cardiac contractions modeling [2]. Another example is a steady rolling of a viscoelastic tyre [1] with a periodic sculpture. In this case, the steady state satisfies a "rolling" periodicity condition: the state at any point is the same that at the corresponding point of the next sculpture motive but one time period ago. It means the periodicity condition includes shift both in time and space. For such problems, we consider such a space-time periodicity as an observation and we use it for developing an accelerating method. The main idea is to modify the original problem by introducing a feedback control term [2, 3, 4] based on a periodicity error,which accelerates convergence to the stable periodic solution of the problem.

In the following section, we present an analytical analysis of an abstract problem, in order to find out an optimal form of the control. After introducing a delayed feedback control term based on the observation error (in an abstract form), we find the solution to the modified problem, in order study the influence of the control on the convergence rate. Then, we propose the optimal control, optimizing the spectrum of the problem and minimizing the convergence time. The proposed control can be mechanically interpreted. And the efficiency of the method increase with the convergence time of the problem.

The last section applies the technique to a full viscoelastic problem. There we consider the steady rolling of the viscoelastic tyre with a periodic sculpture. The numerical simulation results are presented, comparing both controlled and non-controlled solutions in a simplified 2D framework.

2 ANALYTICAL ANALYSIS

2.1 General problem

Let us consider a general evolution problem with space-time periodic condition:

$$\partial_t u + Au = f \tag{1}$$
$$u(t) = Hu(t-T) \tag{2}$$

defined on a Hilbert space V with scalar product $\langle \cdot, \cdot \rangle$. We make two fundamental assumptions which are usually satisfied for time periodic viscoelastic problems:

- the operator A is V-elliptic, namely there exists a constant $C > 0$ such that $\forall u \in V$ $\langle Au, u \rangle \geq C\|u\|^2$
- the operators A and the space shift H can be diagonalized in the same basis.

In practice, the solution of such problems is usually computed as an asymptotic limit of the solution to the initial value evolution problem (1) with an arbitrary initial condition. Due to the ellipticity condition, this asymptotic limit exists. In the frame of this work, we are going to propose an optimal control method, accelerating the convergence of the initial value problem solution to the solution of (1)-(2).

2.2 Controlled problem

We can consider the condition (2) as an observation and use it to construct a control method. So we modify the initial value problem by introducing a feedback control term [3, 4], based on the observation error, as follows:

$$\partial_t u(t) + Au(t) + \overbrace{G\Big(u(t) - Hu(t-T)\Big)}^{\text{control term}} = f, \tag{3}$$
$$u(t) = \phi(t), \quad t \leq 0. \tag{4}$$

Above $\phi(t)$ represents the initial data, and $u(t) - Hu(t-T)$ is the observation error. Moreover, the gain operator G which acts on this observation error has to be properly identified. It is clear that the solution $u(t,x)$ to the modified problem (3) converges to the solution of the original problem (1). The question is whether there exists a gain operator G, providing the fastest convergence to the time periodic asymptotic limit. This amounts to analyze the influence of the gain operator G on the (vanishing) asymptotic behavior of the homogeneous solution of (3). Thus we have to find the solution of the homogeneous controlled problem as a function of G, which will yield the optimal choice of G by minimizing the real part of the spectrum of the problem. We assume that the gain operator can be expressed as an analytical function $G(A, H)$ of the evolution and shift operators. Then if A and H are diagonalizable in the same base, G is also diagonalizable in this base.

Theorem 1. *Since A, G and H are diagonalizable in the same base $\{v_p(x)\}_{p\in\mathbb{Z}}$, the homogeneous solution to the controlled problem (3) is simply given by*

$$u(t,x) = \sum_{p,k\in\mathbb{Z}} c_{p,k}\, e^{\lambda_{p,k} t} v_p(x) \tag{5}$$

where the coefficients $c_{p,k}$ are defined from the initial data, and the inverse relaxation time $\lambda_{p,k}$ can be expressed in terms of eigenvalues of A, G and H.

Proof. We write the solution $u(t,x)$ in the base $\{v_p(x)\}_{p\in\mathbb{Z}}$, where A, G and H are diagonalizable:

$$u(t,x) = \sum_{p\in\mathbb{Z}} u_p(t) v_p(x) \tag{6}$$

where $u_p(t)$ are the coordinates of $u(t,x)$ in this base. Let α_p, γ_p and σ_p be the eigenvalues of A, G and H respectively, associated to the same eigenfunction $v_p(x)$. Then $u_p(t)$ satisfies

$$\partial_t u_p(t) + (\alpha_p + \gamma_p)\, u_p(t) - (\gamma_p \sigma_p) u_p(t-T) = 0, \qquad \forall p \in \mathbb{Z} \tag{7}$$

This is a simple delay-differential equation [5, 6, 7]. We are looking for its solution in the exponential form $u_p(t) = e^{\lambda_p t}$. The characteristic equation for λ_p is

$$\lambda_p + (\alpha_p + \gamma_p) - (\gamma_p \sigma_p)\, e^{-T\lambda_p} = 0. \tag{8}$$

Multiplying this by $Te^{T(\lambda_p+\alpha_p+\gamma_p)}$, this characteristic equation takes the form:

$$T\,(\lambda_p + \alpha_p + \gamma_p)\, e^{T(\lambda_p+\alpha_p+\gamma_p)} = T\,(\gamma_p\sigma_p)\, e^{T(\alpha_p+\gamma_p)} \tag{9}$$

To represent a solution of this equation, one have to introduce a Lambert W function [8, 10, 11, 7]. It is a complex-valued function denoted by $W\,[z]$ and satisfying $W\,[z]\, e^{W[z]} = z$ $(\forall z \in \mathbb{C})$. The Lambert W function will be described in more details in the next paragraph. For the time being, simply note that the Lambert function W is multivalued and has an infinite number of branches W_k, $k \in \mathbb{Z}$. Then, we can rewrite the equation (9) in terms of W_k as :

$$T\,(\lambda_p + \alpha_p + \gamma_p) = W_k\left[T\,(\gamma_p\sigma_p)\, e^{T(\alpha_p+\gamma_p)}\right], \qquad k \in \mathbb{Z}. \tag{10}$$

So the characteristic equation (8) has an infinite number of roots, corresponding to different branches W_k of the Lambert function :

$$\lambda_{p,k} = -\,(\alpha_p + \gamma_p) + \frac{1}{T} W_k\left[T\,(\gamma_p\sigma_p)\, e^{T(\alpha_p+\gamma_p)}\right], \qquad k \in \mathbb{Z}, \quad p \in \mathbb{Z}. \tag{11}$$

Thus, the general solution to (7) is

$$u_p(t) = \sum_{k\in\mathbb{Z}} c_{p,k} e^{\lambda_{p,k} t}, \qquad \forall p \in \mathbb{Z} \tag{12}$$

Assembling all components of the eigenbase, we then obtain the solution (6) to the controlled problem (3):

$$u(t,x) = \sum_{p\in\mathbb{Z}} \sum_{k\in\mathbb{Z}} e^{\lambda_{p,k} t} c_{p,k} v_p(x) \tag{13}$$

with $\lambda_{p,k}$ as defined by (11). Coefficients $c_{p,k}$ are to be found from the initial data.

□

2.3 A few properties of the Lambert W function

Let us take a brief overview on the Lambert W function [8, 9, 10, 11, 7] with its infinite number of branches $W_k,\ k \in \mathbb{Z}$. For any branch, its first derivative is given by

$$\frac{d}{dz} W_k [z] = \frac{W_k [z]}{z(W_k [z] + 1)}, \qquad k \in \mathbb{Z} \tag{14}$$

Their real values have some order [10, 11]. The rightmost value corresponds to the so called principal branch W_0:

$$\max_{k \in \mathbb{Z}} \Re W_k [z] = \Re W_0 [z], \quad \forall z \in \mathbb{C}. \tag{15}$$

This real value of this principal branch is bounded from below by -1 and reaches the minimum at $z = -\frac{1}{e}$, i.e.

$$\Re W_0 [z] \geq -1, \quad \forall z \in \mathbb{C}, \tag{16}$$

$$W_0 \left[-\tfrac{1}{e}\right] = -1. \tag{17}$$

Inside the circle $|z| < \frac{1}{e}$, the principal branch can be decomposed in power series [9]

$$W_0 [z] = \sum_{n=1}^{\infty} \frac{(-n)^{n-1}}{n!} z^n, \qquad |z| < \frac{1}{e} \tag{18}$$

The real part of the principal branch $\Re W_0$ is plotted on Figure 1 (in this section, all plots are extracted from Mathematica 10.0).

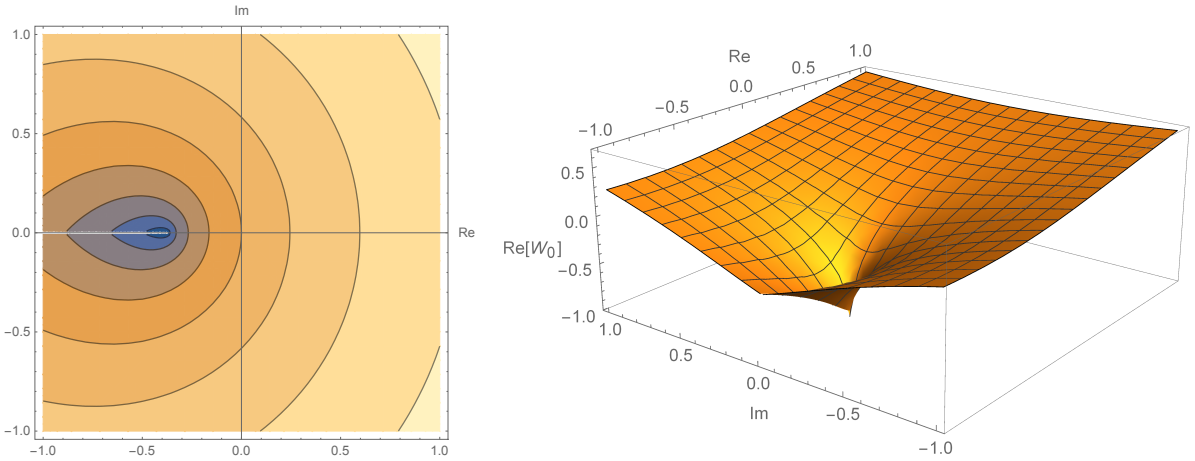

Figure 1: Real part of the principal branch of Lambert W function.

We can also define a Lambert operator W as follows : for any linear operator A, the Lambert W operator function of A is a linear operator $W[A]$, such that $W[A]\, e^{W[A]} = A$. Under minor assumptions on the operator A, one can also prove that this operator has an infinite number of branches W_k, $k \in \mathbb{Z}$, with a principal branch W_0.

2.4 Main result: the optimal control

The next theorem presents the main result of the current paper, namely the characterization of the optimal control for the problem (3).

Theorem 2. *Under the assumptions of paragraph 2.1, the optimal gain operator for the problem (3), providing the fastest convergence to the asymptotic solution, is given by*

$$G = \frac{1}{T} W_0 \left[-\tfrac{1}{e} e^{-TA} H^{-1} \right], \tag{19}$$

where W_0 denotes the operator form of the principal branch of the Lambert W function.

Proof. According to Theorem 1, the solution of the controlled problem takes the exponential form (5) with inverse (complex) relaxation time defined by (11). When all $\lambda_{k,p}$ have negative real part, the solution converges in time to the asymptotic limit, corresponding to the periodic solution of the problem. By properly constructing the eigenvalues of G in (11), we can control the problem's inverse relaxation times $\lambda_{k,p}$. Decreasing their real part, we accelerate the convergence. The optimal control, providing the fastest convergence, moves all eigenvalues $\lambda_{k,p}$ on the left as much as possible. According to (15), for any $p \in \mathbb{Z}$ we have $\Re\lambda_{0,p} = \max_{k\in\mathbb{Z}} \Re\lambda_{k,p}$. Therefore, we need to optimize the principal branches $\lambda_{0,p}$:

$$\lambda_{0,p} = -\alpha_p + \underbrace{\frac{1}{T}\left(W_0 \left[T\sigma_p\gamma_p \, e^{T(\gamma_p+\alpha_p)} \right] - T\gamma_p \right)}_{\text{control term}}, \qquad p \in \mathbb{Z}. \tag{20}$$

The second term in the right part characterizes the convergence rate of the controlled problem. For the non-controlled solution ($\gamma_p = 0, \ \forall p$), this term is equal to zero. Convergence slows down, if it is real value is positive, and accelerates, if it is negative. When its real value is minimal, $\lambda_{0,p}$ is moved to the left as much as possible, and the associated γ_p is optimal. Therefore, for each $p \in \mathbb{Z}$ we need to compute γ_p, which minimizes the control term:

$$\gamma_p = \arg\min_{\gamma} \Re \left(W_0 \left[T\gamma \, e^{T\gamma} \sigma_p e^{T\alpha_p} \right] - T\gamma \right), \qquad p \in \mathbb{Z}. \tag{21}$$

Let us fix p and make the change of variable:

$$\gamma_p = \frac{1}{T} W_0 \left[z \right], \text{ yielding } z = T\gamma_p e^{T\gamma_p}. \tag{22}$$

We therefore have to solve the following minimization problem:

$$\begin{gathered} \text{Find } \ z \in \mathbb{C} \ \text{ minimizing } \ \Re\, J(z), \\ J(z) = W_0 \left[\eta z \right] - W_0 \left[z \right], \end{gathered} \tag{23}$$

where $\eta = \sigma_p e^{T\alpha_p}$ is a given complex number constructed from the eigenvalues of A and H. The minimizers cancel the derivatives of the cost function J, which from formula (14) satisfy :

$$\begin{aligned} \tfrac{d}{dz} J(z) &= \frac{W_0 \left[\eta z \right]}{z(W_0 \left[\eta z \right] + 1)} - \frac{W_0 \left[z \right]}{z(W_0 \left[z \right] + 1)} && (24) \\ &= \frac{J(z)}{z(W_0 \left[\eta z \right] + 1)(W_0 \left[z \right] + 1)} && (25) \end{aligned}$$

There are two candidates, where the derivative takes infinite values:

$$W_0\left[z\right] = -1 \qquad \Leftrightarrow \qquad z = -\tfrac{1}{e} \tag{26}$$

or

$$W_0\left[\eta z\right] = -1 \qquad \Leftrightarrow \qquad z = -\tfrac{1}{\eta e} \tag{27}$$

The point $z = 0$ makes no interest, since it corresponds to the non-controlled case. From (16) we also have

$$\Re J(-\tfrac{1}{e}) = \quad \Re\, W_0\left[-\tfrac{\eta}{e}\right] + 1 \quad \geq 0 \tag{28}$$

$$\Re J(-\tfrac{1}{\eta e}) = \; -\left(1 + \Re\, W_0\left[-\tfrac{1}{\eta e}\right]\right) \; \leq 0 \tag{29}$$

Hence we conclude that the solution of the minimization problem (23) is given by the critical point $z = -\frac{1}{\eta e}$, that is

$$\gamma_p = \frac{1}{T} W_0\left[-\tfrac{1}{e}\,\sigma_p^{-1} e^{-T\alpha}\right] \tag{30}$$

In operator terms, this yields

$$G = \frac{1}{T}\, W_0\left[-\tfrac{1}{e}\, H^{-1} e^{-TA}\right]. \tag{31}$$

□

Corollary 2.1. *If the inverse of the shift H is weakly contracting $\|H^{-1}\| \leq 1$, the optimal control takes the explicit form*

$$G = -\frac{1}{T}\sum_{n=1}^{\infty} c_n \cdot \left(H^{-1} e^{-TA}\right)^n \quad \textit{with} \;\; c_n = \frac{n^{n-1}}{n!\, e^n}. \tag{32}$$

Proof. Since A is elliptic, then $\Re\alpha_p > 0$ and $|e^{-\alpha_p}| \leq 1$. If $\|H^{-1}\| \leq 1$, then $|\sigma_p^{-1}| \leq 1$. Therefore

$$|-\tfrac{1}{e}\,\sigma_p^{-1} e^{-\alpha_p}| < \tfrac{1}{e}, \qquad \forall p \in \mathbb{Z}. \tag{33}$$

So γ_p in (30) can be decomposed in the power series (18):

$$\gamma_p \;=\; \frac{1}{T} W_0\left[-\tfrac{1}{e}\,\sigma_p^{-1} e^{-T\alpha}\right] \tag{34}$$

$$\;=\; \frac{1}{T}\sum_{n=1}^{\infty} \frac{(-n)^{n-1}}{n!}\left(-\tfrac{1}{e}\,\sigma_p^{-1} e^{-T\alpha}\right)^n \tag{35}$$

$$\;=\; -\frac{1}{T}\sum_{n=1}^{\infty} \frac{n^{n-1}}{n!\, e^n}\left(\sigma_p^{-1} e^{-T\alpha}\right)^n \tag{36}$$

yielding the claimed statement. □

Remark 2.1. *In practice, the norm of the shift operator or of its inverse is unity. We can therefore use (32) for calculating G, usually restricting ourselves to the first five terms.*

Remark 2.2. *Note that $e^{-t\mathcal{A}}$ is a fundamental solution of the non-controlled problem, i.e. $u(t,x) = e^{-t\mathcal{A}}u(0,x)$, when $G = 0$. That is e^{-TA} plays role of the T-shift in time for the non-controlled solution. Thus the proposed control can be interpreted as a correction of the present solution by canceling all the future T-shifted periodicity errors :*

$$\mathcal{G}\Delta u(t) \simeq -\frac{1}{T}\sum_{n=1}^{\infty} c_n\, H^{-n}\Delta u(t+nT) \tag{37}$$

where the periodicity error

$$\Delta u(t) = u(t) - Hu(t-T) \tag{38}$$

2.5 Efficiency of the method

We have developed an optimal control for an abstract evolution problem, accelerating convergence to the periodic solution. Now we want to estimate the efficiency of the proposed control, that is how fast does the controlled solution converge in comparison with the non-controlled one. This is based on a direct calculation yielding

$$\begin{aligned}
\lambda_{0,p} &= -\alpha_p + \frac{1}{T}\left(W_0\left[T\gamma_p\sigma_p e^{T(\alpha_p+\gamma_p)}\right] - T\gamma_p \right) && (39)\\
&= -\alpha_p - \frac{1}{T}\left(1 + W_0\left[-\tfrac{1}{e}\sigma_p^{-1}e^{-T\alpha_p}\right] \right) && (40)\\
&= -\alpha_p - \frac{1}{T}\, g\left(\log\sigma_p + T\alpha_p\right) && (41)
\end{aligned}$$

where we define the spectral control term by

$$g(z) = 1 + W_0\left[-\tfrac{1}{e}\, e^{-z}\right] \tag{42}$$

The real part of $g(z)$, $z \in \mathbb{C}$ on the right half-plane $\Re z \geq 0$ is represented on Figure 2, and its restriction on the real axis is detailed on Figure 3.

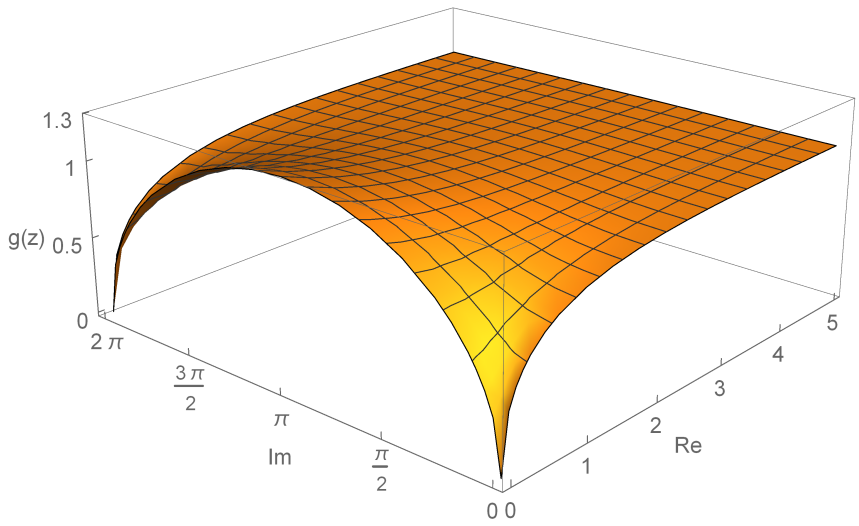

Figure 2: Real part of $g(z)$ on the complex right half-plane $z \in \mathbb{C}$, $\Re z \geq 0$.

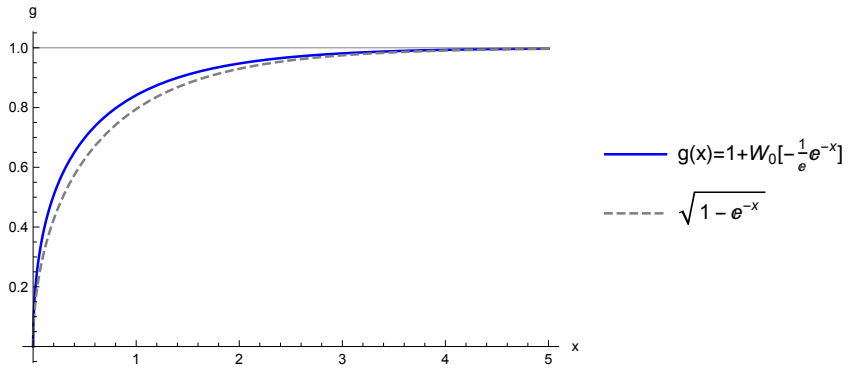

Figure 3: Function $g(x) = 1 + W_0\left[-\frac{1}{e}\, e^{-x}\right]$ on the real half-line $x \geq 0$.

A direct calculation then yields

$$1 + \frac{g(\Re(\log \sigma_p + T\alpha_p))}{T\Re\alpha_p} \leq \left|\frac{\Re\lambda_{0,p}}{\Re\alpha_p}\right| \leq 1 + \frac{g(\Re(\log \sigma_p + T\alpha_p) + i\pi)}{T\Re\alpha_p} \tag{43}$$

For the proposed optimal control, we therefore see that the gain increases when the real part of the spectrum of the operator A goes to zero (see Figure 4). In other words, the method gets more and more efficient when the problem gets more and more viscous, as represented on Figure 4, which computes the approximate minimal gain as the function of the eigenvalues of A, obtained by replacing the control term g by its real approximation $\sqrt{1 - e^{-x}}$.

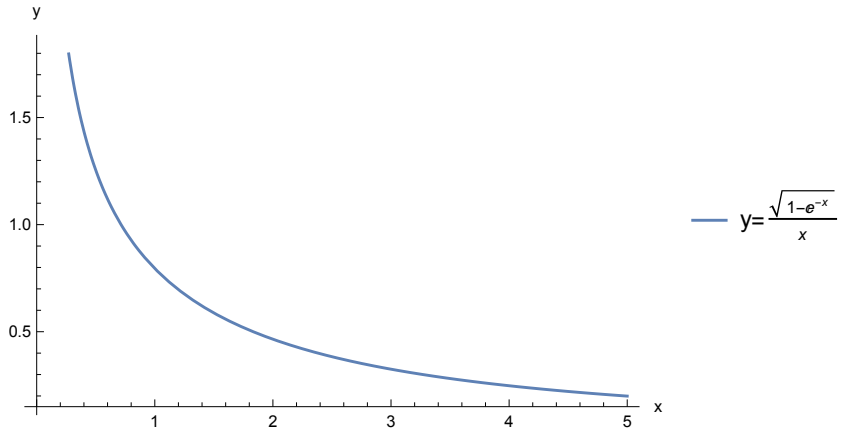

Figure 4: Estimation of the slowest convergence rate: y - gain, x - spectrum of A.

3 APPLICATION: STEADY ROLLING OF A VISCOELASTIC PERIODIC WHEEL

3.1 Model problem

The present section is dedicated to the application of the developed control method to a model problem, in order to justify on practice the theoretical results discussed in the previous section. It considers a steady rolling problem of a 2D viscoelastic tyre [1] presenting a space periodic sculpture. In our approach the periodicity of the sculpture is represented not by a modification of the geometry but by a space periodic modification of the Young's modulus. Thus our model problem considers the steady rolling of a simple viscoelastic ring, with a Young's modulus periodic as a function the angle. We apply a rotating lateral force, representing the contact force applied by the soil. In contrast with the real contact model, we suppose herein that this lateral force is a given function of time and space. Viscoelasticity implies that we deal with an evolution problem in terms of strains. We are interested in the established space-time periodic state, which is the asymptotic limit of the initial value problem with an arbitrary initial state. Applying the optimal control method described in the previous section, we expect to accelerate the convergence to the desired periodic solution.

In more details, let us consider a steady rolling of a wheel (Figure 5, left) with an angular velocity ω. A given force, presenting a ground contact pressure, is applied to the outer border Γ_1 and normal to its surface. In Lagrange (material) configuration, it moves along the exterior boundary with angular velocity $-\omega$. In a Lagrangian frame, its normal component takes the form $f(t, \underline{x}) = f(R_{\omega t}\underline{x})$, with $f(\underline{x})$ quadratic on part of the boundary and zero elsewhere as shown on Figure 5, right. The notation $R_{\omega t}$ represents a rotation of angle ωt around the origin.

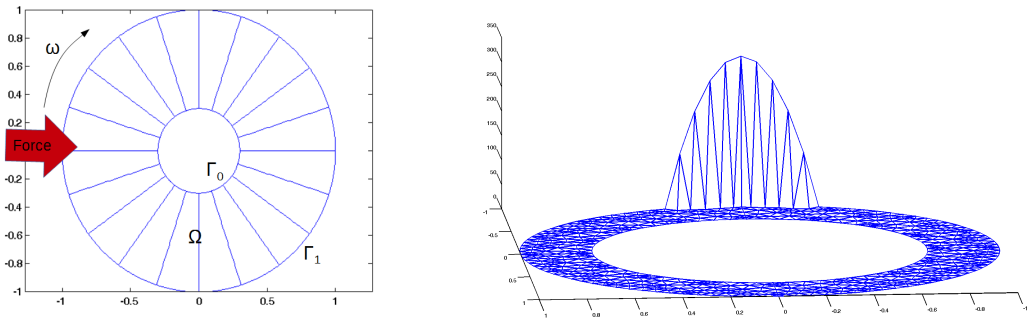

Figure 5: Left: 2D tyre. Right: Normal pressure

On the inner boundary Γ_0, a zero displacement condition is imposed. Thus, in the absence of mass forces, the momentum conservation law writes:

$$\operatorname{div} \underline{\underline{\sigma}} = 0, \qquad \text{in } \Omega \tag{44}$$

$$\underline{\underline{\sigma}}\, \underline{n}\,|_{\Gamma_1} = f\, \underline{n}, \qquad \underline{u}|_{\Gamma_0} = 0, \tag{45}$$

where $\underline{u}$ is the displacement field and $\underline{\underline{\sigma}}$ is a Cauchy stress tensor, $\underline{n}$ denotes a unit normal to the boundary.

The material is considered to be viscoelastic and nearly incompressible. We assume that we are in small strains. The viscoelastic constitutive law is of Kelvin-Voight type :

$$\underline{\underline{\sigma}}\,(t, x) = \eta\, \partial_t \underline{\underline{\varepsilon}}\,(t, \underline{x}) + \underline{\underline{\underline{\underline{K}}}}(\underline{x})\, \underline{\underline{\varepsilon}}\,(t, \underline{x}) \tag{46}$$

where $\underline{\underline{\varepsilon}}$ is the strain tensor

$$\underline{\underline{\varepsilon}} = \frac{1}{2}\left(\nabla \underline{u} + (\nabla \underline{u})^{\top}\right) = \nabla_s \underline{u}, \tag{47}$$

η is a scalar viscosity coefficient; $\underline{\underline{\underline{\underline{K}}}}$ is the fourth-order elasticity tensor:

$$\underline{\underline{\underline{\underline{K}}}}\,\underline{\underline{\varepsilon}} = \lambda \operatorname{tr}\underline{\underline{\varepsilon}}\,\underline{\underline{\mathbb{1}}} + 2\mu\underline{\underline{\varepsilon}}, \tag{48}$$

where Lamé coefficients λ and μ are expressed via Young's modulus E and Poisson's ratio ν:

$$\lambda = \frac{E\nu}{(1+\nu)(1-2\nu)}, \qquad \mu = \frac{E}{2(1+\nu)} \tag{49}$$

Given a nearly incompressible material, the Poisson's ratio is taken close to 0.5. As it was mentioned above, the periodic structure of the wheel is represented by the angular periodicity of the Young's modulus $E(\underline{x})$. Namely, there is an angle $\omega T = 2\pi/M$ (where M is the number of sculpture motives), such that

$$E(\underline{x}) = E(R_{\omega T}\underline{x}). \tag{50}$$

Herein, we have simply taken $E(\underline{x}) = E_0\left(1 + \cos\left[\frac{2\pi}{\omega T}\arg \underline{x}\right]\right)$, where E_0 is the mean of Young's modulus. We are looking for a "rolling" periodic solution, i.e. a solution satisfying the following space-time periodicity condition:

$$\underline{u}(t, \underline{x}) = R_{\omega T}^{-1}\,\underline{u}(t - T, R_{\omega T}\underline{x}). \tag{51}$$

In other words, the state at any point is the same that the one at the corresponding point of the next sculpture motive but one time period ago. Let us therefore define the space shift

$$H = R_{\omega T}^{-1}\,\underline{u}(t - T, R_{\omega T}\underline{x}) \tag{52}$$

Altogether, we are looking for the displacement field $\underline{u}(t, \underline{x})$ which satisfies :

$$\begin{aligned} \operatorname{div}\left[\eta\,\nabla_s \partial_t \underline{u} + \underline{\underline{\underline{\underline{K}}}}\,\nabla_s \underline{u}\right] &= 0, && \text{in } \Omega \\ \left[\eta\,\nabla_s \partial_t \underline{u} + \underline{\underline{\underline{\underline{K}}}}\,\nabla_s \underline{u}\right]\cdot \underline{n} &= f\,\underline{n}, && \text{on } \Gamma_1 \\ \underline{u} &= 0, && \text{on } \Gamma_0 \\ \underline{u}(t) &= H\underline{u}(t - T). \end{aligned} \tag{53}$$

3.2 Controlled problem

Let us introduce the space $V_0 = \{\underline{v} \in H^1(\Omega)^2 \mid \underline{v} = 0 \text{ on } \Gamma_0\}$ and let us define the operators $\mathcal{C}$ and $\mathcal{K}$ as follows: $\forall \underline{v} \in V_0$

$$\int_\Omega \mathcal{C}\underline{u}\cdot\underline{v} = \int_\Omega \eta\,\nabla_s \underline{u} : \nabla_s \underline{v} \tag{54}$$

$$\int_\Omega \mathcal{K}\underline{u}\cdot\underline{v} = \int_\Omega \underline{\underline{\underline{\underline{K}}}}\,\nabla_s \underline{u} : \nabla_s \underline{v} \tag{55}$$

Then the system (53) writes:

$$\int_\Omega (\mathcal{C}\partial_t \underline{u} + \mathcal{K}\underline{u}) \cdot \underline{v} = \int_{\Gamma_1} f\, \underline{n} \cdot \underline{v}, \qquad \forall \underline{v} \in V_0, \tag{56}$$
$$\underline{u}(t) = H\underline{u}(t-T).$$

The associated controlled problem is

$$\int_\Omega \Big(\mathcal{C}\partial_t \underline{u} + \mathcal{K}\underline{u} + \mathcal{G}\left(\underline{u}(t) - H\underline{u}(t-T)\right)\Big) \cdot \underline{v} = \int_{\Gamma_1} f\, \underline{n} \cdot \underline{v}, \qquad \forall \underline{v} \in V_0 \tag{57}$$
$$\underline{u}(t) = \underline{u}_0(t), \qquad t \leq 0$$

with arbitrary initial data $\underline{u}_0$. According to Theorem 2, the optimal gain operator takes the form

$$\mathcal{G} = -\frac{1}{T}\mathcal{C} \sum_{n=1}^{\infty} c_n\, e^{-nT\left(\mathcal{C}^{-1}\mathcal{K}\right)} H^{-n}, \qquad c_n = \frac{n^{n-1}}{n!\, e^n}. \tag{58}$$

If we proceed with the finite element discretization, it can be quite expensive to compute an exponential of the matrix associated to the operator $\mathcal{C}^{-1}\mathcal{K}$. So we need to simplify this expression.

3.3 Simplified controlled problem

Let $\underline{u}_*$ be the periodic solution of the problem (53), that is the true displacement, and $\underline{\underline{\sigma}}_* = \eta\, \nabla_s \partial_t \underline{u}_* + \underline{\underline{\underline{\underline{K}}}}\, \nabla_s \underline{u}_*$ be the true Cauchy stress. Associated to this true stress tensor $\underline{\underline{\sigma}}_*$, the true strain tensor $\underline{\underline{\varepsilon}}_* = \nabla_s \underline{u}_*$ is the solution of the first order differential equation

$$\eta\, \partial_t \underline{\underline{\varepsilon}} + \underline{\underline{\underline{\underline{K}}}}\, \underline{\underline{\varepsilon}} = \underline{\underline{\sigma}}_* \tag{59}$$
$$\underline{\underline{\varepsilon}}\,(t) = H\underline{\underline{\varepsilon}}\,(t-T) \tag{60}$$

If we suppose that we know the true stress tensor $\underline{\underline{\sigma}}_*$, we can apply the optimal feedback control of the previous section to this problem, leading to the associated controlled problem:

$$\eta\, \partial_t \underline{\underline{\varepsilon}} + \underline{\underline{\underline{\underline{K}}}}\, \underline{\underline{\varepsilon}} + \eta\, \underline{\underline{\underline{\underline{G}}}} \left(\underline{\underline{\varepsilon}} - H\underline{\underline{\varepsilon}}(t-T)\right) = \underline{\underline{\sigma}}_* \tag{61}$$
$$\underline{\underline{\varepsilon}}(t) = \nabla_s \underline{u}_0(t), \quad t \leq 0$$

with arbitrary initial data $\underline{u}_0$. According to Theorem 2, the optimal gain operator has the form

$$\underline{\underline{\underline{\underline{G}}}} = -\frac{1}{T} \sum_{n=1}^{\infty} c_n\, e^{-nT\left(\eta^{-1}\underline{\underline{\underline{\underline{K}}}}\right)} H^{-n}, \qquad c_n = \frac{n^{n-1}}{n!\, e^n}, \tag{62}$$

Note that the strain estimator $\underline{\underline{\varepsilon}}$ is not necessarily a displacement symmetric gradient any more and that we do not know the value of the true periodic stress. However, its initial value and its asymptotic limit is a gradient, and we know the divergence of the true stress field. Hence, we decide to decompose the strain estimator into a symmetric gradient and a zero divergence field

$$\underline{\underline{\varepsilon}} = \nabla_s \underline{u} + \underline{\underline{\tilde{\varepsilon}}}, \tag{63}$$

and to take the divergence of the strain controlled problem, omitting all terms in $\underline{\underline{\tilde{\varepsilon}}}$, which leads to the new controlled system

$$\begin{aligned}
\text{div}\,\Big[\eta\,\partial_t\nabla_s\underline{u} + \underline{\underline{\underline{\underline{K}}}}\;\nabla_s\underline{u} + \eta\,\underline{\underline{\underline{\underline{G}}}}\,\Big(\nabla_s\underline{u} - H\nabla_s\underline{u}(t-T)\Big)\Big] &= 0 \\
\Big[\eta\,\partial_t\nabla_s\underline{u} + \underline{\underline{\underline{\underline{K}}}}\;\nabla_s\underline{u} + \eta\,\underline{\underline{\underline{\underline{G}}}}\,\Big(\nabla_s\underline{u} - H\nabla_s\underline{u}(t-T)\Big)\Big]\cdot\underline{n} &= f\,\underline{n}, \qquad \text{on } \Gamma_1 \\
\underline{u} &= 0, \qquad \text{on } \Gamma_0 \\
\underline{u}(t) &= \underline{u}_0(t), \quad t \le 0
\end{aligned} \tag{64}$$

It is seen that $\underline{u}_*$ is the asymptotic limit for this problem, i.e. $\underline{u} \to \underline{u}_*$, and thus (64) is a controlled system associated to the initial model problem (53) with a simplified gain operator, applied to the strain field and computed by the formula

$$\underline{\underline{\underline{\underline{G}}}} = -\frac{1}{T}\sum_n c_n\, e^{-nT\left(\eta^{-1}\underline{\underline{\underline{\underline{K}}}}\right)} H^{-n}, \qquad c_n = \frac{n^{n-1}}{n!\,e^n}. \tag{65}$$

In this way, we have applied the developed optimal control method to the viscoelastic constitutive law. We may have sacrificed a part of the control "optimality" to the simplicity of its form. In practice, for a plane strain problem, introducing the reduced Lamé coefficients $\tilde{\lambda} = -nT\lambda/\eta$ and $\tilde{\mu} = -nT\mu/\eta$, the exponential coefficients in the gain operator (65) are defined by

$$e^{-nT\eta^{-1}\underline{\underline{\underline{\underline{K}}}}}\begin{bmatrix} \varepsilon_{11} & \varepsilon_{12} \\ \varepsilon_{12} & \varepsilon_{22} \end{bmatrix} = e^{\tilde{\lambda}+2\tilde{\mu}}\sinh\tilde{\lambda}(\varepsilon_{11}+\varepsilon_{22})\underline{\underline{\underline{\underline{\mathbb{1}}}}} + e^{2\tilde{\mu}}\begin{bmatrix} \varepsilon_{11} & \varepsilon_{12} \\ \varepsilon_{12} & \varepsilon_{22} \end{bmatrix} \tag{66}$$

3.4 Numerical results

The controlled and non-controlled evolution problems have been solved numerically, in order to compare their rates of convergence and to justify in practice that the controlled one is really faster. The numerical simulation has been carried out in MatLab R2014a by the finite elements method with $P1$ elements on a conforming triangular mesh (Figure 6), ωT-periodic with respect to rotation. It represents a tyre with 15 motives, i.e. $\omega T = 2\pi/15$. The periodic Young's modulus is in the form: $E(\underline{x}) = E_0\,(1 + \cos[15\arg\underline{x}])$, where E_0 is a homogeneous stiffness. An undeformed state is taken as initial data, that is $\underline{u}(0,\underline{x}) = 0$.

We carry out several pairs of simulations (controlled and non-controlled cases) with different values of viscosity coefficient, in order to verify if the efficiency estimation from paragraph 2.5 holds. The gain of the control method is represented by ratio n_0/n_c of the iteration numbers for non-controlled and controlled problem respectively. The gain values corresponding to distinct viscosity coefficients are presented in Table 1. These results are depicted on Figure 7. We can see that the efficiency indeed increases with the viscosity coefficient.

On Figure 8 there are plotted some simulation results: l_2-norm evolution of numerical solution (left column) and periodicity error (right column) with distinct viscosity coefficients ($\eta = E_0, 3E_0, 8E_0$ respectively). The abscissa ticks correspond to the number of ωT-periods. Dashed vertical lines mark the convergence time, that is the moment when the periodicity error becomes less than the specified accuracy. The large visible oscillations of the solution are associated with 2π-periodicity of the tyre, while the oscillations associated with ωT-periodicity are of a much smaller scale and aren't quite visible on the plot.

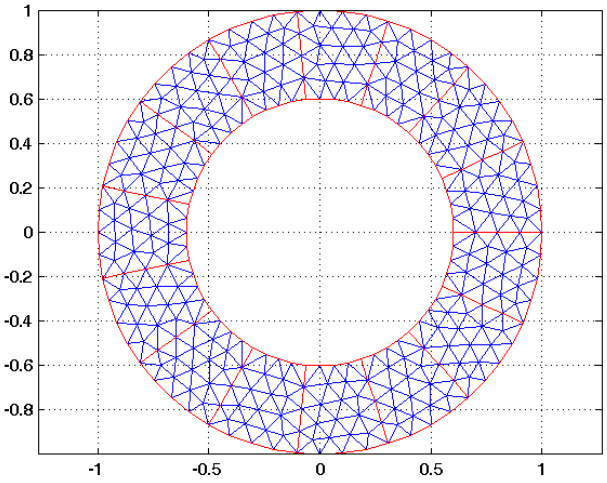

Figure 6: Periodic mesh, representing a tyre with 15 motives

Viscosity η	relax.time^{-1} E_0T/η	Gain n_0/n_c
$0.1E_0$	8.378	1.19
$0.5E_0$	1.676	1.38
E_0	0.838	1.62
$2E_0$	0.419	2.05
$3E_0$	0.279	2.41
$4E_0$	0.209	2.72
$5E_0$	0.168	2.97
$8E_0$	0.105	3.33

4 CONCLUSION

In this paper, we have developed a new control method for calculating viscoelastic evolution problems while accelerating the convergence of its solution to the asymptotic limit, which is time periodic. The method is similar to the feedback control methods, using the eigenvalue assignment technique [3, 4]. From another perspective, it can be interpreted as an observer-controller filtering method, where the space-time periodicity condition plays the role of the observation [2]. It turns out that the proposed control term actually acts like the correction of the present solution by the future periodicity errors (37).

As seen from the construction of the optimal control, its mathematical properties use the Lambert W function. In this way, we have estimated the dependence of the convergence acceleration on the relaxation rate. In fact, the acceleration increases with the memory of the problem. So the developed method might not be efficient for fast converging problems (which is not really of interest) but becomes more and more efficient for the slowly converging problems.

The developed control method has been tested on a full 2D model problem. It has been applied to the steady rolling of a viscoelastic tyre with a periodic sculpture. An approach, when the optimal control is applied to the viscoelastic evolution law, has been formulated. In this case, the control term is quite simple and cheap to compute. The numerical solution of the problem has justified the theoretical results: for a very viscous material, we have indeed obtained a significant acceleration of convergence.

Keywords: gear dynamics, meshing stiffness, 1D modelling, finite element simulation

Abstract. *Although gears have been used in mechanical industry for a long time and first systematic research activities, aimed at understanding gear meshing, started in the '50s, still nowadays a lack of accurate description for several physical phenomena represents a limitation for transmission design. One of the main causes of such limitations is the three-dimensional (3D), local and non-linear nature of contact problems. Given the complexity of these problems, a variety of modelling techniques with different levels of fidelity and required computational effort have been set up. Among the available methodologies, analytical modelling, which has been developed for a vast variety of applications from the early days of gear dynamics research, still attracts the interest of researchers thanks to the low computational requirements and to the capability to efficiently describe specific phenomena.*
Among analytical models, one-dimensional (1D) description aims at studying the torsional gear vibrations around the rotational axes and can be used to simulate either gear whine or gear rattle phenomena.
The aim of this paper is to illustrate a numerical approach, based on 3D (Finite Element) FE simulations, to estimate the mass and inertia properties of a 1D gear pair model. The proposed approach is based on pre-strained modal analyses, carried out on the 3D FE model of a pair of meshing gears, from which the variable meshing stiffness and modal mass values in a given system configuration are derived and used to calibrate the equivalent 1D model. An application example of the proposed method is provided by analyzing a pair of identical spur gears, for which the 1D model is created and used to estimate the dynamic TE at different rotation speeds and under constant external load in steady-state conditions.

1 INTRODUCTION

In the field of mechanical transmissions, simulation tools are acquiring ever more importance in the industrial development process that aims at achieving products of high quality at affordable costs, as to stand the competitive pressure of globalized markets. The dynamic behavior of gears has a direct influence on the performance of the entire system in terms of acoustic emissions and durability. The recent trend for lightweight design stresses even more the necessity to include a proper dynamic behavior as one of the main design targets. The gears themselves bring different challenging problems and difficulties at the design stage [1]. Typical non-linear phenomena [2] due to contact stiffness and clearance has to be well predicted in the initial design phase in order to reduce the development time and increase product quality. Given the complexity of these phenomena, a variety of modelling techniques with different levels of fidelity and required computational effort have been developed in the last decades. Three are the main model categories which can be identified: analytical, Finite Element (FE) and Multibody. Analytical models have been developed for a vast variety of applications[3-6]. They started from the early days of gear dynamics research, with a single gear pair and a single degree of freedom (DoF), and evolved until today's more refined 3D formulations. Ongoing research is still exploring analytical models since they provide low computational requirements, thanks to their lumped parameter formulation, and can be tailored to efficiently describe specific applications.

For these reasons, analytical formulations can be usefully employed, especially for analyses involving long operational time, where the simulation time and cost required by more detailed simulations would be prohibitively high. To achieve an analytical formulation of gear meshing, a one-dimensional (1D) description can be used with the aim of studying the torsional gear vibrations around the rotational. Such a simplified representation can be used to simulate either gear whine or gear rattle phenomena. Rotating masses are lumped into inertia moments and associated to the related rotational DoFs. Connectivity between the DoFs can be set by means of translational spring-damper elements by expressing rotations as equivalent displacements along the line of action, which represents the so called Transmission Error (TE) between the meshing gears. A 1D analytical model, which considers both clearance-type nonlinearity due to backlash and angle-varying mesh stiffness was proposed by Blankenship and Kahraman [3] to address the contact loss phenomenon in steady-state forced response.

When a 1D modeling approach for gear meshing analysis is used, simulation results can be found in a significantly shorter simulation time, as compared to the detailed FE simulations, but a higher approximation level in the description of the dynamic behavior of the engaging gears is paid. This means that, in order to use in a proficient way an analytical model, an a-priori knowledge of the system is required to prevent from neglecting important effects [7] or wasting efforts in modelling irrelevant phenomena.

The dynamic behavior of two engaging gears is strongly related to the variable meshing stiffness of the teeth in contact[8, 9]: a poorly approximated representation of the meshing stiffness in the simulation model causes poor results in terms of accurate prediction of the real behavior. In particular, an inaccurate representation of the meshing stiffness can result in a poor prediction of the dynamic response excited by orders coexisting with the fundamental meshing order in the system.

The purpose of this works is not to develop new analytical models but to present an alternative approach to improve the predictive accuracy of an existing 1D model without increasing its computational cost. From the simulation point of view, FE formulations proved a reliable tool in predicting the static and dynamic behavior of mechanical system

in a detailed manner, at the cost of high computational times. For this reason, the idea behind this work is to combine 3D FE modeling with a one DoF analytical model for dynamic simulation of gear meshing. This way, computationally demanding FE simulations are used in a model preparation phase to derive the gear pair meshing stiffness and resonance frequencies with high accuracy for a discrete number of different positions of the gears along the meshing cycle. A modal mass value is also then derived from the previous estimated quantities for each analyzed position along the meshing cycle. Model data derived from FE simulation is then used to define the parameters (equivalent inertia and instantaneous meshing stiffness) defining the 1D analytical model. The resulting 1D model is then used to simulate the dynamic behavior of a pair of identical gears in different operating conditions.

2 ANALYTICAL MODEL

One of the simplest models that allow predicting the dynamic torsional behavior of a pair of cylindrical gears is proposed in [3] and shown in Figure 1.

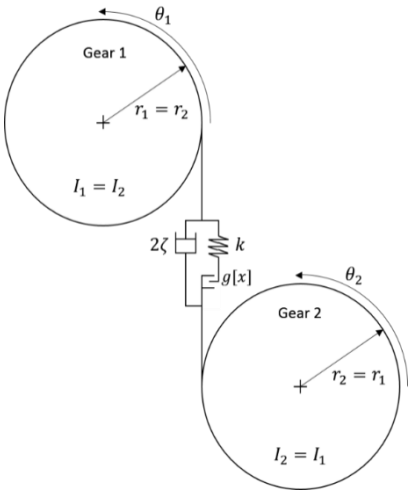

Figure 1: Dynamic representation of the 1D model of meshing cylindrical gears.

The dynamic behavior of this one DoF system, which considers a pair of identical gears, is ruled by the following equation of motion:

$$\ddot{x} + 2\zeta\dot{x} + k[POS(t)]g[x(t)] = F(t) \tag{1}$$

where x is the linear relative displacement of the contact points on the two meshing teeth along the line of action and represents the dynamic Transmission Error (*DTE*) in the system, $\dot{x}$ and $\ddot{x}$ are its first and second time derivatives; ζ is a damping coefficient introduced in the model in order to take into account friction losses between the teeth; the model parameter $k[POS(t)]$ is intended to represent the variable meshing stiffness as function of the instantaneous position of the teeth in the meshing cycle *POS(t)*, which is computed *a priori* with non-linear FE simulations and stored in a mono dimensional look-up table with the corresponding position in the meshing cycle[10, 11].

With this formulation it is also possible to model the backlash b between the gears introducing the restoring function $g[x(t)]$ which is the following function of the relative displacement between the teeth:

$$g[x(t)] = \begin{cases} x(t) - b, & x(t) > b, \\ 0, & |x(t)| \leq b, \\ x(t) + b, & x(t) < -b. \end{cases} \quad (2)$$

The restoring function acts as a switch for the meshing stiffness, by bringing its value to zero when the relative displacement is below the backlash threshold. This situation means that there is no contact between the teeth and consequently no elastic meshing force. When the instantaneous relative displacement assumes a value higher than the imposed backlash, the restoring function allows to consider only the effective penetration between the teeth in contact, subtracting the backlash from the estimated relative displacement.
The external force $F(t)$ in equation (1) represents the loading force in the system. In general, a time-varying load can be considered in the model, but it is considered to be constant in the work presented in this paper, based on the assumption that the imposed value of torque transmitted by the gears is constant.
The instantaneous acceleration value $\ddot{x}$ is computed numerically by using a Runge-Kutta algorithm, implemented in a Simulink model, that solves the following equation:

$$F - (kg + c\dot{x}) = M_{eq}\ddot{x} \quad (2)$$

The relative gear velocity and displacement are obtained by integrating acceleration and velocity respectively. The terms on the left side of equation 2 represent the force contribution due to external excitation, elastic force and damping force. The values of the last two contributions are calculated at each time step by multiplying the relative speed and penetration by the damping coefficient, assumed constant, and by the actual value of meshing stiffness respectively, which instead is dependent on the actual position of the gears along the meshing cycle. The latter is calculated, along with the equivalent mass M_{eq}, through a series of FE dynamic analyses of the two gears in different positions along the meshing cycle, as it will be illustrated in section 3.

3 FE MODEL

In order to enable the use of the analytical model described in section 2 and illustrated in Figure 1, the values of model parameters, such as meshing stiffness, damping coefficient and equivalent mass must be determined before the simulation starts.
The approach proposed in this work to obtain an estimate of these parameters is based on detailed static and dynamic FE simulations[12].
As illustration example, a simple mechanical transmission, consisting of a pair of identical gears already analyzed in [3] and with main geometric properties listed in table 1, is analyzed.

Parameter	Value
Normal module	3 mm
Normal pressure angle	20 deg
Pitch diameter	150 mm
Root diameter	142.5 mm
Facewidth	25.4 mm

Table 1: Gears specifications.

The proposed approach is based on a pre-processing phase in which the variable stiffness, and equivalent mass are computed from FE simulations, for different positions along the meshing stiffness. The 3D gear geometry was generated according to the geometrical parameters listed in table 1 and discretized with hexagonal elements for the FE analyses [13], as shown in figure 2. Data needed for 1D simulation are calculated using the pre-strained modal approach, carried out on a series of models, which represent the gears in discrete angular positions along the meshing cycle. In every position, a two-step FE simulation is carried out, starting from calculating teeth static deflection resulting from the application of a 300 Nm torque on the driving gear and by fixing all the DoFs of the center of rotation of the driven gear. This way, the static deflection of the teeth for different gear pair configurations is obtained, which is later used in combination with the results of a modal analysis, aimed at calculating the fundamental rotational resonant frequency of the system, to estimate the 1D model parameters.

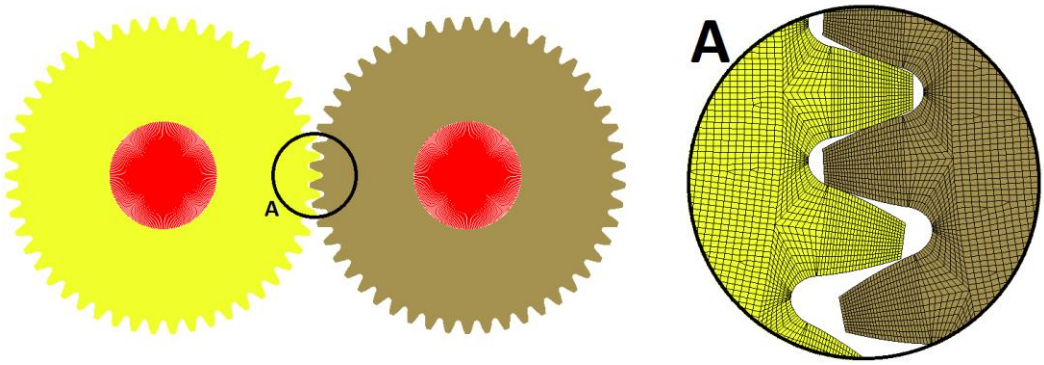

Figure 2: FE model of the analyzed gear pair, used to derive parameter values to be used in the 1D model.

The rotational (torsional) stiffness of the 1D model is calculated according as:

$$k_{\emptyset} = \frac{T}{\emptyset} \tag{3}$$

where T is the applied torque and $\emptyset$ the angular displacement of the statically loaded gear along the rotational axis. Another parameter derived from the simulation results is the equivalent mass, which is calculated as modal mass in the 1D model by using the following equation:

$$M_{eq} = \frac{k_{\emptyset}}{\omega^2} \tag{4}$$

where ω^2 is the square of fundamental torsional frequency estimated for the 3D model. Using this expression, M_{eq} and $k_{\emptyset}$ have been computed, which are used as model parameter data for the 1D model at the later stage. Figure 3 shows the calculated rotational stiffness and first resonant frequency estimated for the gear pair model in different angular positions along the meshing cycle. From these simulation results, it appears clear that the static and dynamic characteristics of a meshing gear pair depend very strongly on the instantaneous configuration. Figure 4 shows the first mode shape of the gears in two different angular positions, in which one and two teeth pairs are in contact. The figure shows also the frequency values of the first resonance in the two configurations, which were identified for these models through a pre-strained modal analysis. It can be seen that the difference is as high as 400 Hz, which is about 20% of the lower value.

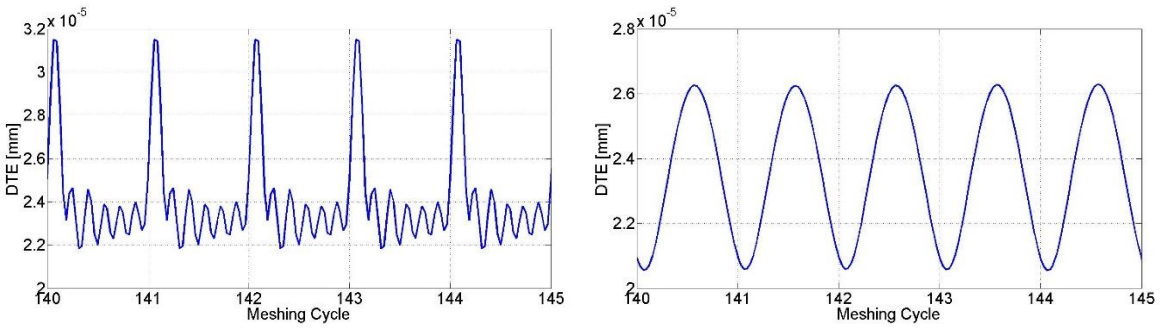
Figure 4. First resonant frequency and mode shape for a gear pair in two different angular configurations

4 RESULTS

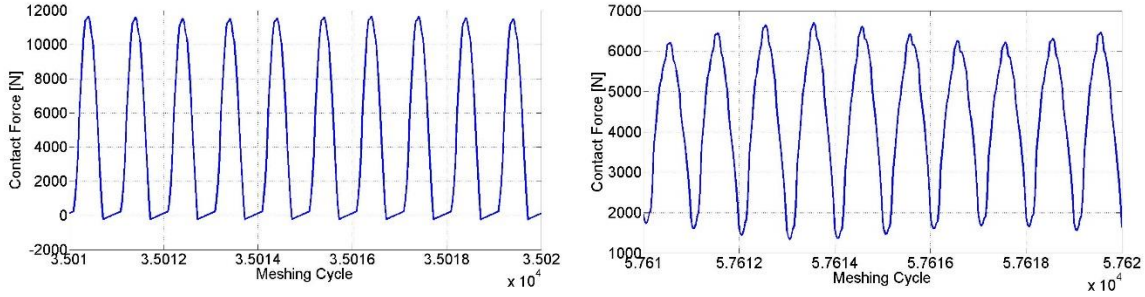
Once the 1D model parameters are calculated, different analyses can be carried out by solving equation 2 and predict the dynamic behavior of the gear pair. In this paper we show the results of analyses that have been performed by operating the input gear with a constant speed until steady state was obtained. This process was repeated for different increasing and decreasing rotational velocities. Figure 5 shows a comparison between the DTE computed for an angular velocity of 600 rpm (a) and of 4200 rpm (b). The different shape of the two curves proves that this model is able to catch dynamic effects of gear meshing on DTE, which are not relevant at low rotational speed. The figure shows also that when the meshing frequency is close to the resonant frequency of the system, as in the case of figure 5-b, the DTE signal is dominated by the meshing order. In this case the first order of the rotational speed corresponds to the natural frequency of the gear pair.



a b

Figure 5. Dynamic transmission error (DTE) for different angular speeds: 600 rpm (a) and 4200 rpm (b)

Effects of system non-linearity due to backlash between the meshing teeth is visible in figure 6, where the contact force along different meshing cycle is plotted. Contact losses between the teeth are shown by values of the meshing force close to 0 in figure 6-a, where elastic force is imposed to be zero by to the restoring function, while the damping force is still acting. Figure 6-b shows the trend of the contact force when no contact loss occurs, and minimum values are far away from zero.



a b

Figure 6: Dynamic meshing force for in case of contact loss a) and without contact loss b)

Other effects that can be analyzed using this proposed simulation approach are the jump phenomena in the RMS value of the computed DTE, due to the clearance type non-linearity (Figure 7).

Due to the backlash between the gear teeth, different branches of RMS curves for the computed DTE are obtained when the rotational velocity changes, corresponding to different states of the system. The lower branch is obtained for slightly increasing speed while the upper branch is obtained for decreasing speed.

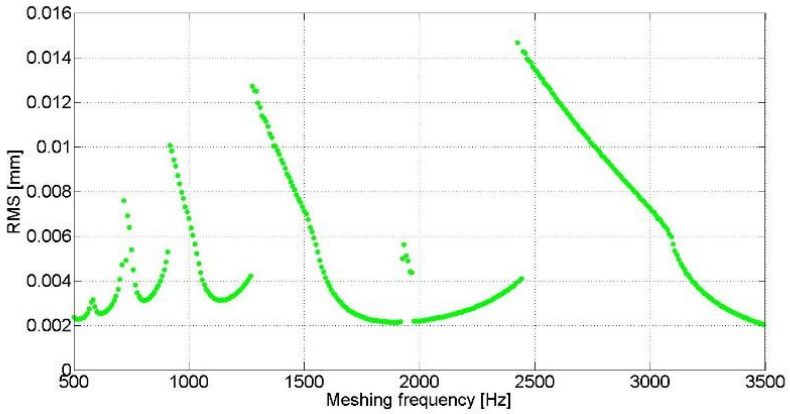


Figure 7: RMS of DTE plotted against meshing frequency

By considering the curves reported in figure 7 it is possible to recognize an almost-linear trend in the regions distant from the jumps frequency. The onset of contact loss causes a knee in the curve, recognizable as a softening effect compared to the almost-linear trend, which is a well-known behavior described in literature [3].

5 CONCLUSIONS

This work shows the possibility to use analytical model to describe complex phenomena related to gear dynamics. In the proposed approach the lack of accuracy of analytical and semi-analytical meshing stiffness formulations is covered by the use of FE

simulations which allow to have a realistic description of the meshing process. A high computational efficiency is reached by limiting the FE simulations in a preparation phase. The simplicity of the analytical formulation makes this model suitable for computationally efficient analyses, in those cases where the numerical complexity of FE-based models requires unaffordable computational time.
Classical jump-up phenomena are predicted by the model and agree with the classical trend shown in literature.
The 1D model described in this work takes into account only the relative rotation between the two gears bodies, under the assumption that the other relative displacements can be neglected during the simulation. The flexibility of the proposed approach for FE-based estimation of model parameters makes it applicable also to more complex analytical models for gear dynamic simulations, which allow taking into account additional relative displacements between the gears.

Abstract. *The present study deals with the effects of contact characteristics on the vibratory response of a beam associated with several rubbing devices. Experimentally different contact configurations are tested by varying the contact area size and roughness of samples. For each tests, the frequency response functions (FRF) are measured and compared. Numerically, temporal calculations are presented and compared to measured data, using Masing's contact model with updated parameter values and averaged estimated values.*

1 INTRODUCTION

The optimization of the vibratory response of structures in presence of rubbing is always very delicate due to the highly nonlinear behavior induced by dry friction occurring at the interfaces. Sticking, macro or micro slipping between interfaces have major effects on both natural frequencies and damping properties.
Due to the diversity of contact configurations, friction models are often very case dependent and cannot be efficiently used without identifying: the type of friction occurring at the interfaces (based on the shape of the hysteresis curve) and contact parameters such as friction coefficient or joint stiffness. Those information may be obtained from specific experimental analyses or from available databases. In [1] for example, the authors propose estimated friction coefficients and contact stiffness values based on a very large experimental campaign they carried.

There is always a need for better understanding of rubbing mechanisms leading to optimal configurations and for more physics-based models than the classical and simple Coulomb or Masing models. A promising way concerns models that take into account material and geometrical properties of contacting surfaces, surface roughness data, and contact loading [2-4]. These models are based on the pioneer work of Greenwood and Williamson on rough contacts [5]. Knowing the behavior of an individual spherical asperity pressed against a flat surface it is possible, thanks to statistical summation, to simulate the global behavior of two rough flat-on-flat rubbing surfaces.

In the present study, a test rig has been developed to measure the dynamic response of a steel beam associated with several friction configurations. The set-up allows punctual or surface to surface contact cases. In the case of surface to surface contact, devices with various area size, shape and roughness were tested in order to assess their influence on the overall response. Numerically, temporal calculations are presented and compared to the measured data using different contact models with updated parameter values and averaged estimated values.

2 THE TEST RIG

The studied structure is a cantilever steel beam with a rectangular cross section of 0.008 m by 0.04 m and a length of 0.50 m. At the free end, the beam may be associated with different rubbing devices (Figure 1).

The experimental set-up allows the measurement of the displacement at 0.35 m of the clamped end of the beam by mean of an accelerometer (measured signal integrated twice). The excitation force provided by a shaker is measured by a force sensor located at the end of the shaker's push rod. The normal and tangential contact forces are also given by a force sensor. Two categories of devices were chosen in order to allow punctual contacts or surface to surface contacts (Figure 2). Sine sweeps (harmonic excitation) were performed at constant excitation force amplitude within the [15-130] Hz frequency range and for various normal contact forces.

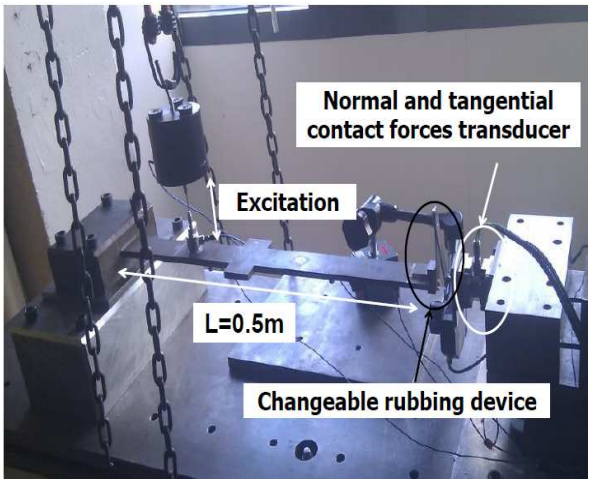

Figure 1: Experimental set up – cantilever steel beam.

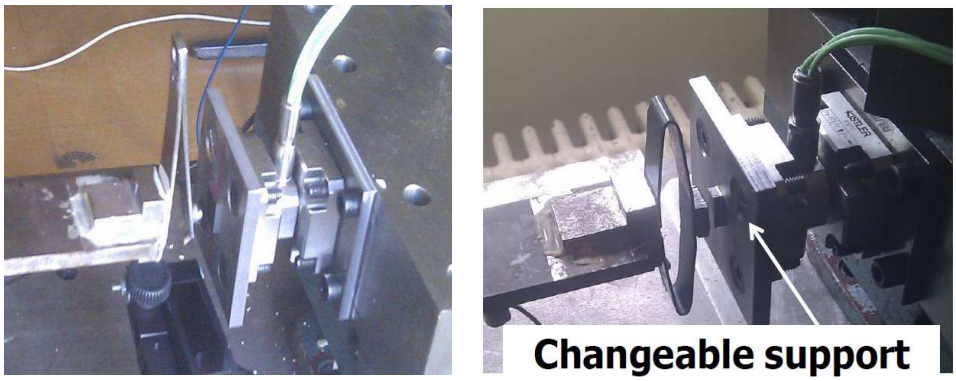

a) Punctual contact b) Surface to surface contact

Figure 2: Rubbing devices.

Figure 3 gives an example of typical measured FRFs for the punctual contact case. The classical influence of normal contact load is exhibited.

For a high normal load (Fn=40N associated to an excitation force of 2 N) contact is stuck. The FRF exhibits a linear behaviour with a peak resonance at 86 Hz. As the normal load is lowered (from 30 N to 0.25 N) relative displacement is allowed at the contact (presence of stick/slip) and vibrational amplitudes around the 86 Hz resonance peak are damped, becoming nearly flat. Finally, for Fn=0.1 N contact is in a slip state and a high resonance peak is again observed at 24Hz (free configuration).

In Figure 4, an example of the measured tangential forces in stick and stick/slip states is shown. When contact is stuck, the tangential force is proportional to displacement (sinusoidal signal). On the other hand, when contact is in a stick/slip state, the tangential force is proportional to displacement in the stuck phase and keep the limit value of $\pm\mu Fn$ (μ friction coefficient) in the slip phase.

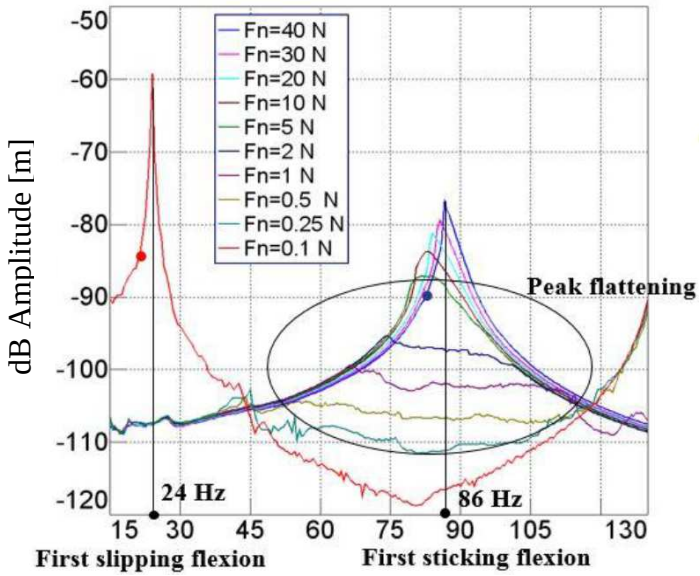

Figure 3: FRF vs normal load.

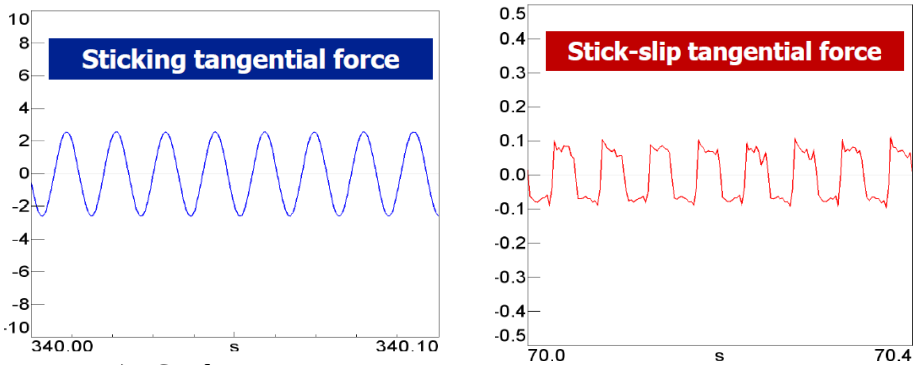

a) Stick contact state b) Stick/slip contact state

Figure 4 : Measured tangential force.

3 DYNAMIC RESPONSE OF THE STRUCTURE

Only the results associated to surface to surface contact configurations are presented here. The different samples considered were made of various contact areas (13x13 mm^2, 9x9 mm^2, 13x5 mm^2, 5x5 mm^2, Figure 5) and two surface finish, one rough and one smooth. Surface finish is described by the average roughness (Ra) defined in [6]:

$$R_a = \frac{1}{L}\int_0^L |z(x)|dx \tag{1}$$

where $z(x)$ represents the height of asperities and L the sampling length.

In Figure 6, the profiles of the 13x13 mm^2 samples are presented. The smooth one has a Ra of 0.714 µm while the rough one has a Ra of 3.76 µm. Regarding the external forces, nor-

mal loads were varied within the range [0.1 – 80] N and the excitation force amplitude remained at 2N.

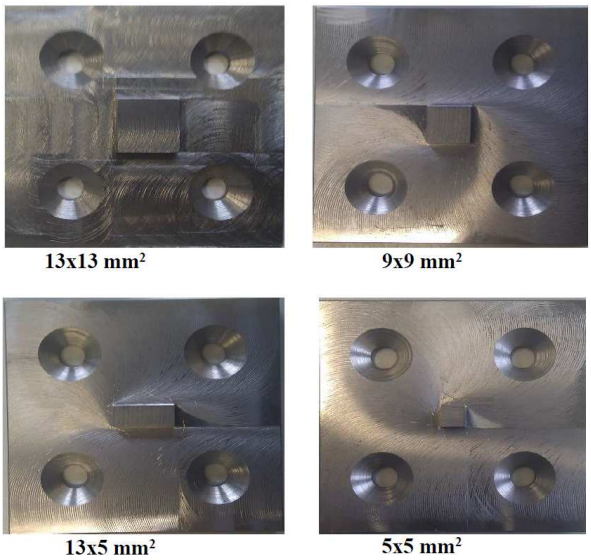

Figure 5: Samples

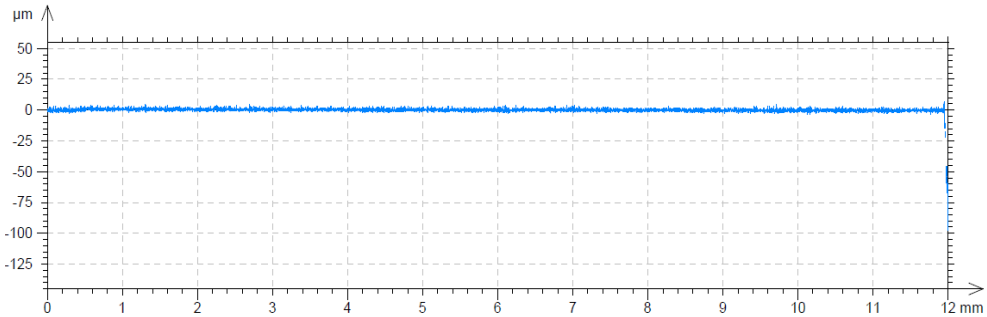
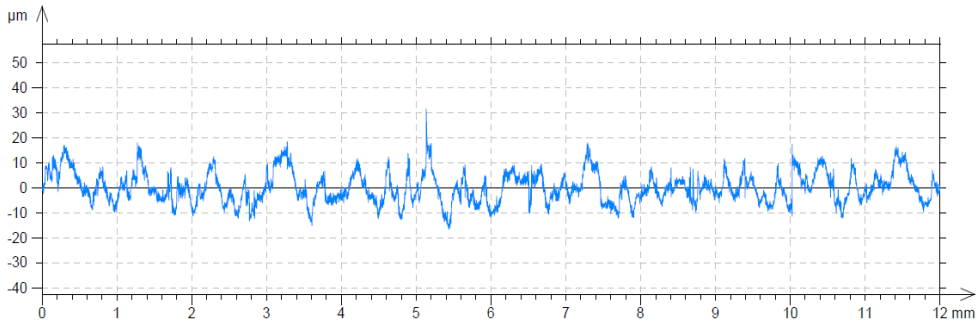


a) Profile of the smooth 13x13 mm^2 sample : Ra=0.714 µm



b) Profile of rough 13x13 mm^2 sample : Ra=3.76 µm

Figure 6: Profiles of the 13x13 mm^2 specimens.

Figure 7 gives the FRFs associated to the four smooth samples for a normal load of 2N. As clearly shown responses are identical and contact area size does not affect significantly the dynamics of the assembly. The same observations were made when assessing the influence of surface roughness.

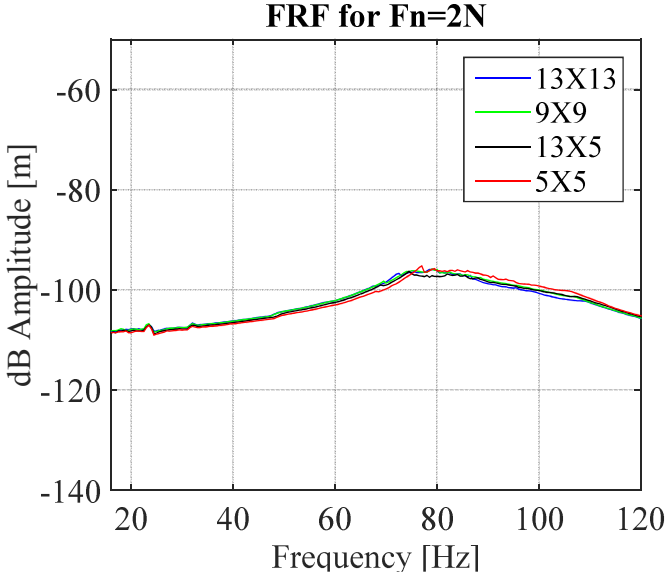


Figure 7: Area size influence on the FRFs for the smooth samples with Fn=2 N.

The overall effect of area size is illustrated in Tables 1 and 2 while the effect of roughness is shown in Tables 3 and 4. Results reported concern surfaces 13x13 mm^2 and 5x5 mm^2. Discrepancies are illustrated via three quantities: maximum displacement amplitudes, frequency at which the maximum amplitudes are obtained and damping ratios.

	Fn=0.1 N	Fn=2 N	Fn=10 N	Fn=80 N
Amplitude differences.	-5.2 %	0.7 %	1.5 %	0.8 %
Frequency at max amplitudes.	0 %	3 %	-1.1 %	0 %
Damping ratio differences.		-0.44 %	0.91 %	0.27 %

Table 1: Effect of area size: 13x13 mm^2 smooth versus 5x5 mm^2 smooth.

	Fn=0.1 N	Fn=2 N	Fn=10 N	Fn=80 N
Amplitude differences.	4 %	1.7 %	1.3 %	3.3 %
Frequency at max amplitudes.	0 %	0 %	0 %	1.6%
Damping ratio differences.		6.9 %	0.59 %	0.81 %

Table 2: Effect of area size: 13x13 mm^2 rough versus 5x5 mm^2 rough.

As shown in Tables 1 and 2, discrepancies between surfaces 13x13 and 5x5 are limited. Variation in maximum displacement amplitudes does not exceed 5.2 % and frequencies of the

maximum amplitudes as well as damping are not affected significantly, with one exception for Fn=2 N with 6.9 % discrepancy on damping.

	Fn=0.1 N	Fn=2 N	Fn=10 N	Fn=80 N
Amplitude differences.	-0.31 %	2.4 %	0.85 %	-0.2 %
Frequency of the maximum amplitudes.	0 %	5.8 %	2.8 %	1.6 %
Damping ratio differences.		-11.3 %	-1 %	0 %

Table 3: Influence of roughness: 13x13 mm^2 smooth versus 13x13 mm^2 rough.

	Fn=0.1 N	Fn=2 N	Fn=10 N	Fn=80 N
Amplitude differences.	8.4 %	-1.5 %	-1 %	2.32 %
Frequency of the maximum amplitudes.	0 %	5.8 %	4 %	1.6 %
Damping ratio differences.		-4.1 %	-1.36 %	0.81 %

Table 4: Influence of roughness: 5x5 mm^2 smooth versus 5x5 mm^2 rough.

The former conclusions remain when considering the effects of roughness on the dynamics of the assembly as shown in Tables 3 and 4.

4 NUMERICAL MODELLING

A finite element model of the structure has been constructed using beam, shell and 8 nodes brick elements. For the contact interface, zero thickness elements are used with Masing's tangential contact model. Masing's model is a combination of a Coulomb's contact model with a spring representing contact stiffness as illustrated in Figure 8 for a single dof mass-spring system. The tangential contact force Ft is given by:

$$\begin{aligned} F_t &= sgn(\dot{x})\mu Fn \quad \text{for slipping contact} \\ F_t &= -sgn(\dot{x})\mu Fn + k_d(x-z) \quad \text{for sticking contact} \end{aligned} \tag{2}$$

where μ is the friction coefficient, F_n the normal contact load, k_d the contact stiffness, x the mass displacement, $\dot{x}$ its velocity and z the internal slipping variable.

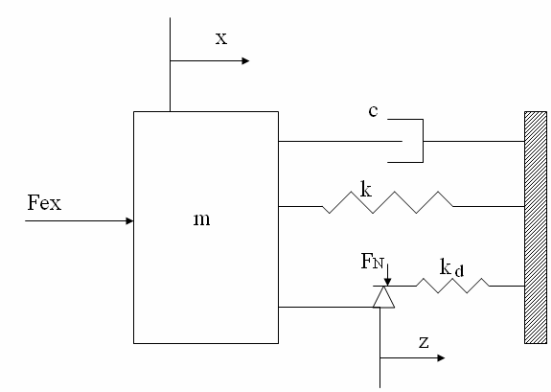

Figure 8: Masing's contact model in case of a 1 dof mass-spring system

Due to nonlinearity, solutions are obtained using a Newmark time integration scheme with Newton-Raphson iterations. Two different set of parameters (μ and k_d) are considered. The first is obtained using model updating from experimental data. The second considers estimated averaged values obtained from [2], as in this reference authors suggest values representing a best compromise when experimental data are not available: friction coefficient of 0.66 and contact stiffness of 3e7 N/m. Table 5 gives the parameters used for the smooth surface with an area of 13x13 mm^2 for models 1 and 2. Parameters suggested in [2] are higher than the identified values.

	Friction coefficient	**Contact stiffness**
Model 1	0.45	3.9e5 N/m
Model 2	0.66	3e7 N/m

Table 5: Parameter for the smooth 13x13 mm^2 surface

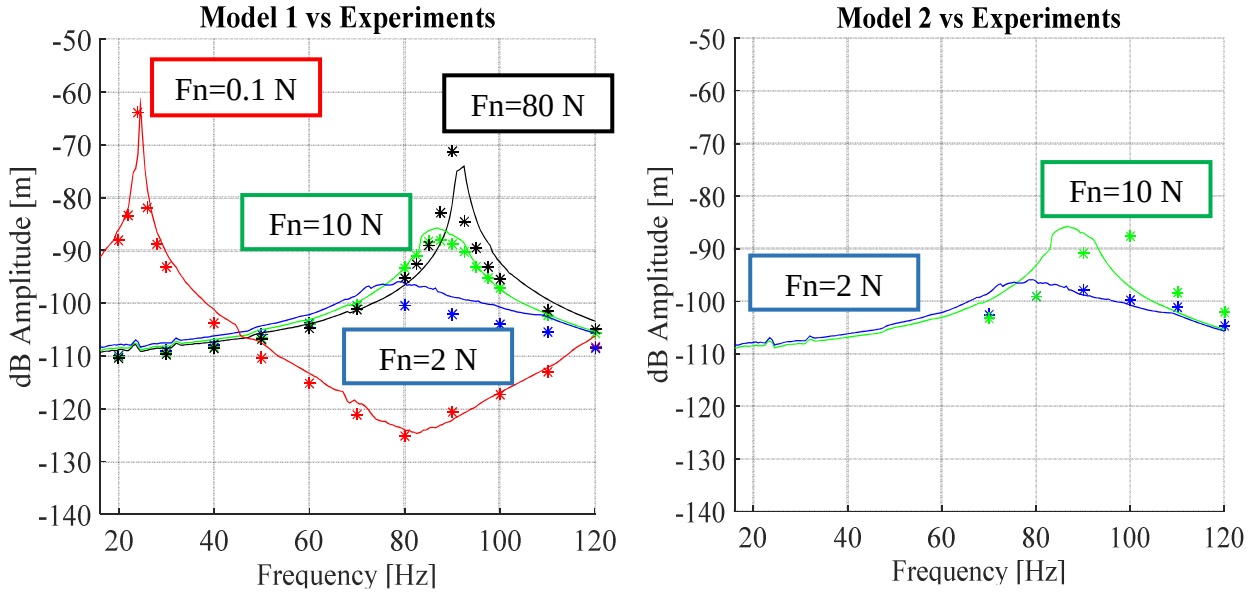

Figure 9: Models 1 and 2 versus experiments

Figure 9 gives numerical and experimental results. In the case of model 2, comparisons are limited to two normal loads, due to calculation time. Results clearly show that model 1 reproduces with good accuracy the experimental FRFs while there is a shift of 10 Hz between model 2 and experiments. Minimal discrepancy is obtained when reaching the maximal displacement amplitudes for both models. A 10 Hz frequency shift is not dramatic considering that no experimental data is available, but illustrates the need for accurate parameter estimation.

Numerical studies were made for the other configurations of contact area size and roughness and confirm little to no influence of these parameters on the dynamic response of the assembly. An example of comparison between surface 13x13 and 5x5 is shown in Table 6.

	Fn=0.1 N	Fn=2 N	Fn=10 N	Fn=80 N
Amplitude differences.	0 %	1.4 %	2.2 %	-3.1 %
Frequency of max amplitudes.	0 %	0 %	0 %	0 %
Damping ratio differences.		1.7 %	1.6 %	0.23 %

Table 6: Contact area size effect on the FRF – smooth 13x13mm^2 versus smooth 5x5 mm^2

In order to examine a broader range of configurations, numerical calculations were performed for higher normal loads (120 – 160 – 200 N) and excitation loads (2 – 20 – 40 - 100 N). In Figure 10, smooth surface 13x13 and rough surface 13x13 are compared for Fn=120 N and Fex=40 N. The maximal amplitude discrepancy is 6.1 % and it appears that the smooth surface dissipates significantly more energy than the rough one. Other calculations show an increase of the influence of contact characteristics for higher external loads (Fn and Fex). However, the observed discrepancies for maximum amplitude remain limited and do not exceed 10% for instance.

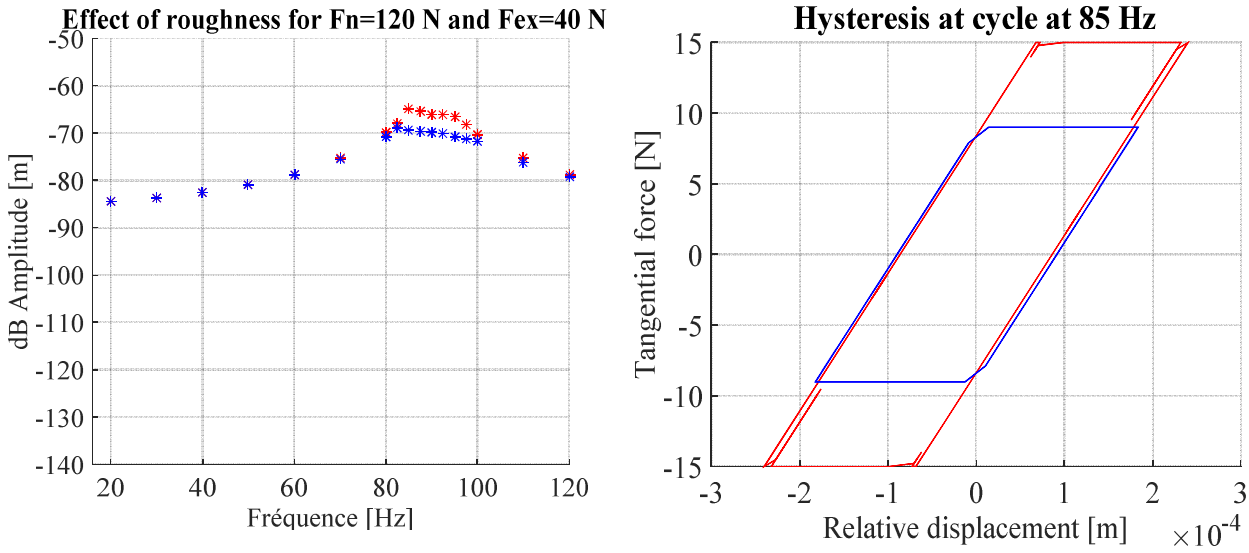

Figure 10: Smooth surfaces (red) versus rough surface (blue)
for 13x13 sample, Fn=120 N and Fex=40 N.

5 CONCLUSIONS

This study focuses on the dynamics of a beam associated with rubbing devices. Both experimental and numerical results are presented. Different configurations were tested in order to assess the effect of contact area size and roughness of the assembly. It was shown that the influence of such characteristics is limited when considering the discrepancies on maximum amplitude of displacements, frequencies of peak displacements and damping ratios. For the configurations considered, the behaviour remain globally in the frame of macro-slip.

Numerically, calculations with Masing's model were done. In the case where experimental data is available, the numerical model and experiments agree very well and confirm the fact that contact area and roughness have limited effects on the FRFs. On the other hand, when measured data are not available, the correlation between the model (using averaged estimated values) and experiments is more delicate as a shift between the peak frequencies is observed. This is due to the fact that the contact stiffness estimation is too high. However a good agreement was noticed for maximum amplitudes. This last results emphasize that work for a better estimation of contact parameters is still needed. A model which does not require prior experimental friction tests such as in [5] is under development.

6 ACKNOWLEDGMENT

This work has been carried out in the context of the FUI 2012-2015 SICODYN Project (pour des Simulations crédibles via la COrrélation calculs-essais et l'estimation d'incertitudes en DYNamique des structures). The authors would like to gratefully acknowledge the support of the FUI (Fonds Unique Interministériel).

Abstract. *In this study, an analytical approach based on the Rayleigh method is adopted to calculate the first resonant frequency of a 46-m-high concrete mobile phone mast system, by considering the geometric stiffness, functions of the concentrated forces, and self-weight of the structure. It is important to bear in mind that actual structures are more complex than simple systems such as beams and columns because the properties of actual structures vary with their length. The mast is done in concrete its nonlinear behavior is linearized reducing the flexural stiffness and the ground is taken into account as distributed springs. Under geometric nonlinearity, the vibration frequency of the fundamental mode is calculated analytically and, for comparison, a finite element method (FEM)-based computer simulation is performed. Finally, the structural stiffness is evaluated. The results of the analytical approach are found to differ slightly from those of the FEM-based model.*

1 INTRODUCTION

Lee [1] relates that because beams are basic structural components, studies on free vibration of linear elastic beams under various conditions have been extensively reported for several decades. Accurate prediction of the natural frequencies of structures or structural components is important, especially in the design of structures subjected to dynamic loads. In various structural engineering fields, including civil, architectural, mechanical, and aeronautical engineering, tapered members, for example, are frequently used in structural designs for economical, aesthetic and geometrical reasons, goes on he.

The dynamic bending of such systems, which mingles with the flexural vibration of beams/columns, was initially investigated by Daniel Bernoulli in the late 18th century. The vibrations of Euler–Bernoulli beams have long been studied, since around 1750, Strutt [2]. As a beam, a column represents a continuous structural member, and its vibrations are governed by nonlinear partial differential equations, relates Norouzi [3], for which exact analytical solutions cannot be found, Awrejcewicz [4].

To investigate of the behavior of a continuous system with infinite degrees of freedom requires discretization techniques in which the structure is transformed into subsystems defined by points called joints. The discretization of differential equations was initialized by Euler through the first order discrete approximation. The Euler method is a one-step discrete method. Eventhough, this method provides a very low computational accuracy, one still used such a method in numerical computations because it is very simple to use, affirm Guo [5]. In fact, the discretization methods lead to the resolution of an algebraic problem for an initial continuous eigenvalue problem. The possibility to solve automatically the algebraic problem using a computer makes the discretization approach advantageous as compared to the initial continuous one, comments Challamel et al [6].

However, continuum systems can be associated with a system having a single degree of freedom, thereby restricting the mode in which the system will deform, and express the properties of such a system as functions of the generalized coordinates. This technique was adopted by Rayleigh [7] in his classic study of elastic system vibration, and his equations were found to be valid in the entire domain of the problem. However, actual structures are more complex than simple beams and columns, because their properties vary with their length and apply that method require a special attention. In order to evaluate the application of the Rayleigh method to an actual structure was selected one piece of concrete with high slenderness, for which the frequency of the first vibration mode was calculated analytically and by a computational model using the finite element method (FEM)**.**

2 CHARACTERISTICS OF THE 46-M-HIGH CONCRETE MAST

The structure is a concrete pole with high slenderness (slenderness of 334) with 46 m high. It has a hollow circular section of external diameter ϕ_{ext} and thickness of the wall of each segment *t*. The geometric details can be seen in shown in Figure 1 and Figure 2. In the structure there is a set of antennas and one platform on top, which totalize a mass of 1097.76 kg. There is even ladder, cables and guardrail, from 6 up to 46 m of height, which gives the structure an additional mass distributed of 40 kg/m. The lateral soil was represented by distributed spring stiffness (K_m) equal to 2668.93 kN/m^3. The density adopted for reinforced concrete foundation was 2500 kg/m^3, while the superstructure is considered to 2600 kg/m^3 concrete to be centrifuged. The foundation is of the kind shaft, relatively deep, with the following characteristics: base diameter 140 cm, shaft diameter 80 cm, length of shaft 580 cm and 20 cm base height. The concrete resistance is 45 MPa for the post, and 20 MPa for the foundation. Because the material has a nonlinear behavior or physical nonlinearity of concrete for is neces-

sary take it into account. What will be done following the recommendations from Brazilian Association for Standardization [8], which preconize um reducer factor of 0.5.

3 SYNTHETIC MATHEMATICAL DESCRIPTION

Below is described synthetically the mathematical bases of the Rayleigh Method. The basic concept underlying that method is the principle of conservation of energy in mechanical systems; therefore, it is applicable to linear and nonlinear structures according to Clough [9]. Temple [10] suggested that the fundamental principles developed by Rayleigh are applicable to both linear and nonlinear continuous systems with finite degrees of freedom. The purpose is to determine the fundamental period of vibration and to analyze the stability of elastic systems with the precision required for engineering problems. Toward this end, the principle of virtual work must be described by adequately chosen generalized coordinates and by a functional form that describes the first mode of vibration. At the end of the calculation, the equation of motion is written in terms of the generalized coordinates, from which one can extract the generalized elastic and geometric properties of the system. However, it is important to have in mind that for actual structure the integrals obtained by the method should be resolved within the limits established for each interval, i.e., the generalized properties calculated for

each segment of the structure, with special attention to the geometric stiffness because each part must consider the normal force distributed in its range as well as forces that operate in the upper segments.

Consider the well-known trigonometric function

$$\phi(x) = 1 - \cos\left(\frac{\pi x}{2L}\right). \tag{1}$$

Applying the principle of virtual work and its adequate derivations, the dynamic properties of interest of the system can be obtained as follows. The conventional stiffness is given by

$$K_0 = \int_0^L EI\left(\frac{d^2\phi(x)}{dx^2}\right)^2 dx, \tag{2}$$

where *E* is the elastic modulus and *I* is the inertia of the section. The geometrical stiffness appears as a function of the axial load, which includes the self-weight, and it is expressed as

$$K_g = \int_0^L N(x)\left(\frac{d\phi(x)}{dx}\right)^2 dx, \tag{3}$$

where *N(x)* is a function of the normal force given by $N(x) = \left[m_0 + \bar{m}\left(L - x\right)\right]g.$

If is necessary to consider the soil participation on the vibration of the system, one way is to associate it as distributed springs along of the height, for that should take the Eq.(4), where *k(x)* is the spring parameter.

$$K_m = \int_0^L k(x)\phi(x)^2 dx. \tag{4}$$

The total generalized mass is given by $M = m_0 + m,$ where m_0 is the tip lumped mass at the element joint and

$$m = \int_0^L \bar{m}\left[\phi(x)\right]^2 dx, \text{ where } \bar{m} \text{ is the mass per unit length} \tag{5}$$

Finally, the natural cyclical frequency should be calculated as

$$\omega = \sqrt{\frac{K}{M}}, \text{since } K = K_0 - K_g + K_m, \tag{6}$$

For further details on the development of this specific analytical procedure, readers may refer to our previous work, Wahrhaftig [11].

4 RESULTS AND DISCUSSION

4.1 Geometric definitions and parameters of the Rayleigh method

The following ordered referring to the heights in the structure are defined: $L_1 = 0.2$ m, $L_2 = 6.0$ m, $L_3 = 12.0$ m, $L_4 = 19.0$ m, $L_5 = 46.0$ m. On the base foundation, one has: $D_1 = 140$ cm, $A_1 = \frac{\pi}{4}D_1^{\,2}$, $I_1 = \frac{\pi}{64}D_1^{\,4}$. On the shaft $D_2 = 80$ cm, $A_2 = \frac{\pi}{4}D_2^{\,2}$, $I_2 = \frac{\pi}{64}D_2^{\,4}$. The variable diameter on the segment between the base and the shaft is obtained by linear interpolation on the variable segment, doing: $D_1(x) = \frac{D_2 - D_1}{L_1}x + D_1$. So, the area and inertia of the section are given by $A_1(x) = \frac{\pi}{4}D_1(x)^2$ and $I_1(x) = \frac{\pi}{64}D_1(x)^4$. Being D_3 and e_3 the ex-

ternal diameter and thickness of the initial section, one has $D_3 = 80$ cm and $t_3 = 13$ cm. Then, the internal diameter, area and inertia of the section are: $d_3 = D_3 - 2t_3$, $A_3 = \frac{\pi}{4}\left(D_3^{\,2} - d_3^{\,2}\right)$ and $I_3 = \frac{\pi}{64}\left(D_3^{\,4} - d_3^{\,4}\right)$. Similarly, D_5, t_5, d_5, A_5 and I_5 are the external diameter, the thickness, area and inertia to the last segment. Between these two segments there is a segment with variable section, of thickness equal to the previous ($t_4 = t_3$), such diameter can be obtained by linear interpolation similarly as done previously, using the expression $D_4(x) = \frac{D_4 - D_3}{L_4 - L_3}\left(x - L_3\right) + D_3$. Therefore, $d_4(x) = D_4(x) - 2t_4$, $A_4(x) = \frac{\pi}{64}\left(D_4(x)^4 - d_4(x)^4\right)$ and $I_4(x) = \frac{\pi}{64}\left(D_4(x)^4 - d_4(x)^4\right)$ are, respectively, the internal diameter , the area and the inertia of the variable section on that correspondent segment.

The parameters of the analytical procedure are listed in Table 1.

Table 1. Parameters of analytical procedure.

Parameter	Value
Elastic modulus of the mast concrete reduced	E = 18782971011 MPa
Elastic modulus of the foundation concrete reduced	E_1 = 12521.98 MPa
Density of structure and foundation concrete	ρ = 2600 kg/m^3, ρ_1 = 2500 kg/m^3
Lumped mass at the top	m_0 = 1097.76 kg
Additional distributed mass per unit height	$\bar{m}_e$ = 40 kg/m
Spring parameter	k_s = 2668.93 kN/m^3
Gravitational acceleration	g = 9.806650 m/s^2

4.2 Calculation of generalized mass of the Rayleigh method

Sub-indices in Roman numerals are introduced from this point on to prevent ambiguity in notation. The generalized mass is calculated using the following integrals.

$$m_1 = \int_0^{L_1} m_I(x)\phi(x)^2\,dx, \text{ where } m_I(x) = \left(\frac{A_2 - A_1}{L_1} + A_1\right)\rho_1;$$

$$m_2 = \int_{L_1}^{L_2} m_{II}\phi(x)^2\,dx, \text{ where } m_{II} = A_2\rho_1;\ m_3 = \int_{L_2}^{L_3} m_{III}\phi(x)^2\,dx, \text{ where } m_{III} = A_3\rho + \bar{m}_e; \tag{7}$$

$$m_4 = \int_{L3}^{L_4} m_{IV}(x)\phi(x)^2\,dx, \text{ where } m_{IV} = A_4(x)\rho + \bar{m}_e \text{ and } A_4(x) = \frac{\pi}{4}\left(D_4(x)^2 - d_4(x)^2\right);$$

$$\text{and } m_5 = \int_{L_4}^{L} m_V\phi(x)^2\,dx, \text{ where } m_V = A_5\rho + \bar{m}_e.$$

The generalized distributed mass is given by $m = \sum_{i=1}^{5} m_i$ and the total generalized mass is given by $M = m_0 + m$. The total generalized mass of the structure is 7848.06 kg.

4.3 Calculation of generalized geometric stiffness by Rayleigh method

To compute the generalized geometric stiffness, it is necessary to determine the normal forces for the parts defined in the geometry. From the top to the bottom of the structure, the axial forces are

$$\begin{gathered} F_0 = m_0 g,\ \ F_5 = \int_{L_4}^{L} m_V g dx,\ F_4 = \int_{L_3}^{L_4} m_{IV}(x) g dx, \\ F_3 = \int_{L_2}^{L_3} m_{III} g dx,\ F_2 = \int_{L1}^{L_2} m_{II} g dx,\ \text{and}\ F_1 = \int_{0}^{L_1} m_I(x) g dx, \end{gathered} \tag{8}$$

where g is the gravitational acceleration. The generalized axial force F is given by $F = \sum_{i=0}^{5} F_i$, and the geometric stiffness is calculated as follows:

$$\begin{gathered} K_{g5} = \int_{L_4}^{L} \left[F_0 + m_V (L-x) g \left(\frac{d}{dx}\phi(x) \right)^2 \right], \\ K_{g4} = \int_{L_3}^{L_4} \left[F_0 + F_5 + m_{IV}(x)(L_4 - x) g \left(\frac{d}{dx}\phi(x) \right)^2 \right], \\ K_{g3} = \int_{L_2}^{L_3} \left[F_0 + F_5 + F_4 + m_{III}(L_3 - x) g \left(\frac{d}{dx}\phi(x) \right)^2 \right], \\ K_{g2} = \int_{L_2}^{L_3} \left[F_0 + F_5 + F_4 + F_3 + m_{II}(L_2 - x) g \left(\frac{d}{dx}\phi(x) \right)^2 \right], \ \text{and} \\ K_{g1} = \int_{L_2}^{L_3} \left[F_0 + F_5 + F_4 + F_3 + F_3 + m_I(x)(L_1 - x) g \left(\frac{d}{dx}\phi(x) \right)^2 \right]. \end{gathered} \tag{9}$$

Thus, the generalized geometric stiffness K_g of the structure is given by $K_g = \sum_{i=1}^{5} K_{gi}$. The generalized geometric stiffness of the structure is 2.630744 kN/m.

4.4 Calculation of generalized conventional stiffness by Rayleigh method

The elastic geometric components are

$$K_{01} = \int_{0}^{L_1} E_1 I_1(x) \left(\frac{d^2}{dx^2}\phi(x) \right)^2 dx,\ K_{02} = \int_{L_1}^{L_2} E_1 I_2 \left(\frac{d^2}{dx^2}\phi(x) \right)^2 dx,$$

$$\begin{gathered} K_{03} = \int_{L_2}^{L_3} EI_3 \left(\frac{d^2}{dx^2}\phi(x) \right)^2 dx,\ K_{04} = \int_{L_3}^{L_4} EI_4(x) \left(\frac{d^2}{dx^2}\phi(x) \right)^2 dx, \\ \text{and}\ K_{05} = \int_{L_4}^{L} EI_5 \left(\frac{d^2}{dx^2}\phi(x) \right)^2 dx. \end{gathered} \tag{10}$$

The generalized elastic stiffness is given by the sum of the above components, as $K_0 = \sum_{i=1}^{5} K_{0i}$ .The generalized conventional stiffness is 8.068271 kN/m.

4.5 Calculation of generalized spring stiffness by Rayleigh method

Once that k_s is the spring factor, such value, for this specific case, is k_s = 2669 kN/m^3, the distributed springs, in the first and second segments are given by $k_1(x) = k_s D_1(x)$ and $k_2(x) = k_s D_2$. The generalized spring stiffness, designed by K_m, is calculated by means of follow equations:

$$K_m = \int_0^{L_1} k_1(x)\phi(x)^2 dx + \int_{L_1}^{L_2} k_2(x)\phi(x)^2 dx. \tag{11}$$

So, the generalized stiffness of the structure can be finally determined by the algebraic sum of the precedents parcels, so that is the total stiffness obtained by: $K = K_0 - K_g + K_m$. The generalized total stiffness is 6.560661 kN/m.

4.6 Calculation of frequency by Rayleigh method

The frequency of the first mode calculated numerically using Eq. (8) is 0.132477 Hz. If the geometric stiffness is not considered, linear analysis, the frequency is 0.172238 Hz.

4.7 Solution from a computational model based on the fem

The formulation corresponding to the finite element method (FEM) in relation to the mathematical procedure is the *geometric nonlinear formulation*. Then, the problem representing the modal analysis is resolved as

$$\det\left[\left[K\right] - \omega^2\left[M\right]\right] = 0 \tag{12}$$

with [*K*] being the stiffness matrix, composed by the conventional and geometric parcels and [*M*] is the mass matrix. In the classical modal analysis, this information is related to the natural frequencies of the system (eigenvalues), clears Shiki [12]. For comparison, a computational model based on the FEM was developed according to SAP2000 (Integrated software for structural analysis and design, Analysis Reference Manual, Computer and Structures, Inc., Berkeley, California, USA), a commercial software packed. The forces and parameters listed in Table 1 were applied to the model with the corresponding masses. The material was assumed to be isotropic, homogeneous, elastically linear, and with the parameters used in the analytical investigation in addition to a Poisson's ratio of 0.2. The spring value also was assigned to the foundation. The structures analyzed were modeled using 40 bar elements with constant and variable cross sections, as appropriate.

The modal analysis was performed over the stiffness came from a nonlinear static preprocessing. The first natural frequency calculated by FEM without geometric nonlinearity is 0.169961 Hz, and with geometric and material nonlinearity is 0.141285 Hz.

5 CONCLUSIONS

- This study employed an analytical procedure based on the Rayleigh method to calculate the initial undamped frequency of a 46-m-high concrete mast under geometric nonlinearity. Computational modeling based on finite element method (FEM) was performed for comparison.
- It was observed that the geometric stiffness represents 32.61% of the conventional stiffness. This implies that the reduction in the stiffness reduces the frequency in 15.51%. The same analysis using the FEM represents a reduction of 30.28%.

- When calculated analytically by the Rayleigh method, under geometric nonlinearity, the vibration frequency of the first natural mode was only 3% greater than that obtained by the FEM using a compatible formulation (0.145517 Hz for the former and 0.141285 Hz for latter). When computed without the geometric stiffness component, this frequency was 0.172238 Hz and 0.184065 Hz for both methods. So, one notes that the analytically solution based on the Rayleigh method has a good approximation with the nonlinear formulation based on the geometric matrix from the FEM. The results showed that there were no absolute differences between both solutions.

Keywords: Maxwell's Equations, Mimetic Methods, Cold Plasma, Exponential Time Differencing, Numerical Dispersion Relation, Yee Scheme.

Abstract. *In this paper we consider the lowest edge-based mimetic finite difference (MFD) discretization in space for Maxwell's equations in cold plasma on rectangular meshes. The method uses a generalized form of mass lumping that, on one hand, eliminates a need for linear solves at every iteration while, on the other hand, retains a set of free parameters of the MFD discretization. We perform an optimization procedure, called m-adaptation, that identified a set of free parameters that lead to the smallest numerical dispersion. The choice of the time stepping proved to be critical for successful optimization. Using exponential time differencing we were able to reduce the numerical dispersion error from second to fourth order of accuracy in mesh size. It was not possible to achieve this order of magnitude reduction in numerical dispersion error using the standard leapfrog time stepping. Numerical simulations independently verify our theoretical findings.*

1 Introduction

A variety of numerical techniques are available in the literature for the simulation of Electromagnetic (EM) wave propagation in linear dispersive media, the gold standard being the Yee Finite difference Time Domain (FDTD) method [6]. EM wave propagation in a medium is modeled by Maxwell's Equations, a vector system of Partial Differential Equations (PDEs), that govern the evolution of the EM field, along with appropriate constitutive equations for the response of the medium to the EM field. The Yee scheme is a FDTD method that simultaneously discretizes Maxwell's equations along with the constitutive laws for the medium to produce a second order accurate discretization in space and time. However, the second order numerical dispersion errors that arise in the discrete solution obtained using the Yee scheme can lead to large errors over long time integration on electrically large domains. Thus, the construction of numerical methods with high order numerical dispersion errors for linear dispersive media, which is the goal of this paper, is crucial to the accurate simulation of EM waves in such media.

In this paper, we consider the simulation of EM waves in a cold isotropic plasma, a type of linear dispersive medium. The model for cold plasma is based on the Auxiliary Differential Equation (ADE) approach in which an Ordinary Differential Equation (ODE) for the evolution of the time derivative of the macroscopic polarization (polarization current density) is appended to Maxwell's equations to produce a hybrid PDE-ODE system. The evolution ODE for the polarization current density models the averaged response of the material to the electromagnetic field. We present the construction of a dispersion minimized numerical method for Maxwell's equations in a cold plasma by performing a novel optimization procedure, called *m-adaptation*, on a family of numerical methods for the cold plasma model based on the Mimetic Finite Difference (MFD) method in space and Exponential Time Differencing (ETD) in time.

MFD methods are a flexible family of methods that are based on general polygonal and polyhedral meshes, see [7] for a comprehensive review. The word mimetic indicates the fact that they mimic/preserve in the discrete settings some properties of the continuous equations. The MFD construction is generally non-unique and leads to a parameterized family of methods with equivalent properties, such as stencil size and base convergence rate among others. Many of the classical discretizations are contained within the MFD family, e.g. Yee scheme on rectangular elements. The number of parameters characterizing the scheme grows rapidly with the dimension, the number of vertices in a polygonal element, and the order of the discretization. The parameterized nature of the family of MFD methods presents an opportunity for optimization for some desired properties. M-adaptation, as introduced in [4, 5], is the process of selecting an optimal member of the family of mimetic schemes for a selected optimization criteria (in this case, minimization of numerical dispersion). In [5] other optimization criteria were analysed.

We have previously considered the problem of optimizing numerical dispersion error in models of electromagnetic wave propagation in free space [1]. In this earlier work, we started with the parameterized family of MFD schemes that all have second (base) order of numerical dispersion error on rectangular meshes. Through m-adaptation we produced a method that has fourth order numerical dispersion error. The present paper extends our prior work to a cold plasma model which, as discussed above, appends an additional evolution equation for the polarization current density to Maxwell's equations. The extension of m-adaptation to the cold plasma model proved to be non-trivial, as illustrated by our first failed attempt presented in the appendix section of this paper. It turns out, that for linear dispersive media, the choice of the time discretization scheme is critical for the m-adaptation technique to produce a high order method. The Leapfrog time differencing method, which we previously employed in [1] for the

case of EM propagation in free space, does not allow m-adaptation to produce a higher order method for the cold plasma model. Instead, replacing the Leapfrog time differencing with ETD allows for successful optimization over the family of fully discrete MFD schemes. The optimal Exponential Time Mimetic Finite Difference (ETMFD) method, produced by m-adaptation, has a fourth order numerical dispersion error as compared to the (base) second order error for the rest of the ETMFD schemes in this family on rectangular meshes.

The ETD method was originally introduced in computational electromagnetism as a scheme for handling stiff problems, such as computing the electric and magnetic fields in a box surrounded by perfectly matched layers [2]. For these problems, explicit time-stepping, for example the Leapfrog time differencing method, requires an extremely small time step in order to be stable. On the other hand implicit schemes that are unconditionally stable can be costly to implement in three dimensions. ETD involves an exact integration of some of the lower order linear terms in the governing equations, and higher order accuracy can be obtained by using a higher order discretization of the resulting integral terms. However, the ETD approach has been shown to offer no major advantages over the time averaging of the lower order linear terms in the Yee scheme, for alleviating stiffness. In some cases, ETD may be less efficient by necessitating smaller step sizes [8].

We would like to emphasize that the reason for the choice of ETD in our work is not for handling stiffness, but rather that it is a good candidate for a time discretization method which allows for successful optimization in the m-adaptation technique. In contrast to other numerical methods for the cold plasma model that use ETD discretization only for the equation of polarization current density [3], our ETMFD method is a discretization of a hyrbrid PDE-ODE system modeling the evolution of the polarization current density and electric field forced by spatial derivatives of field variables.

The outline of the paper is as follows. In Section 2 we present first and second order PDE models for cold plasma, and the corresponding weak formulations. The lowest order edge based MFD discretization for the electric field and current density on rectangular meshes is presented in Section 3, while the exponential time difference discretization for scalar and vector equations is presented in Section 4. In Section 5 we present a fully discrete ETMFD family of discretizations that employs a generalized form of mass-lumping to produce a fully explicit scheme to avoid the need for linear solves at every time step. In Section 5.1 we derive the numerical dispersion relation for this family of discrete schemes and choose the set of MFD parameters that produces a method with the lowest numerical dispersion error. This optimization requires numerical dispersion properties derived in Sections 3 and 4. In Section 6 we present results of numerical simulations that independently validate our theoretical results. In Section 7 we present some concluding remarks. Finally, in Appendix A, we demonstrate that a straightforward extension of our ideas developed in [1] does not allow the m-adaptation process to reduce numerical dispersion error, thus, demonstrating the novelty of the ETMFD method presented in this paper.

2 Maxwell's Equations in a Cold Plasma

The Cold Plasma (CP) model is a special case of the Lorentz model [6] governing the evolution of electromagnetic waves in partially ionized gases without magnetization effects. It consists of Maxwell's equations along with evolution equations for the time derivative of the macroscopic electric polarization field. This time derivative is called the polarization current density. Suppose $\Omega \subset \mathbb{R}^2$ and $T > 0$. Maxwell's equations governing the evolution of wave propagation on $\Omega \times [0, T]$ relate the electric field intensity $\mathbf{E}$, and the magnetic flux density B

as

$$\frac{\partial}{\partial t}\mathbf{E} = c_0^2\ \mathbf{curl}\ B - \frac{1}{\epsilon_0}\mathbf{J}, \tag{2.1a}$$

$$\frac{\partial}{\partial t}B = -\text{curl}\ \mathbf{E}, \tag{2.1b}$$

where c_0, and ϵ_0, are the speed of light, and the electric permittivity of free space, respectively. The vector $\mathbf{J}$ is the polarization current density and is modeled by the evolution equation

$$\frac{\partial}{\partial t}\mathbf{J} + \omega_i \mathbf{J} = \epsilon_0 \omega_P^2 \mathbf{E}. \tag{2.2}$$

Here ω_i is the ion collision frequency and ω_P is the plasma frequency. For a vector field $\mathbf{f} = (\mathbf{f}_x, \mathbf{f}_y)^T$ and for a scalar field f we define the scalar (curl) and vector (**curl**) curl operators as follows,

$$\text{curl}(\mathbf{f}) := \frac{\partial}{\partial x}\mathbf{f}_y - \frac{\partial}{\partial y}\mathbf{f}_x, \qquad \mathbf{curl}(f) := \left(\frac{\partial}{\partial y}f, -\frac{\partial}{\partial x}f\right)^T.$$

All the fields in the system (2.1)-(2.2) are functions of position $\mathbf{x} = (x, y)^T$ and time $t \in [0, T]$. We also assume perfect electrical conductor (PEC) boundary conditions.

$$\mathbf{E} \times \mathbf{n} = 0, \text{ on } \partial\Omega \times [0, T], \tag{2.3}$$

where $\mathbf{n}$ is a unit outward vector to the boundary Ω. The equations (2.1) and (2.2) are subject to appropriate initial conditions.

The first order equations (2.1-2.2) can be written in an equivalent second order formulation, which we call the **Maxwell-CP Model**, by eliminating the magnetic flux density field B as

$$\begin{cases} \dfrac{\partial^2}{\partial t^2}\mathbf{E} = -\dfrac{1}{\epsilon_0}\dfrac{\partial}{\partial t}\mathbf{J} - c_0^2\ \mathbf{curl}\ \text{curl}\ \mathbf{E}, & \text{in} \quad \Omega \times (0, T], \\ \dfrac{\partial}{\partial t}\mathbf{J} = -\omega_i \mathbf{J} + \epsilon_0 \omega_p^2 \mathbf{E}, & \text{in} \quad \Omega \times (0, T], \\ \mathbf{E} \times \mathbf{n} = 0, & \text{on } \partial\Omega \times (0, T], \end{cases} \tag{2.4}$$

along with appropriate initial conditions. We will construct a MFD discretization based on this second order formulation.

2.1 Variational Formulation

The MFD discretization, just like a finite element formulation, will be constructed based on the weak form of (2.4). To this end, we consider the Sobolev spaces

$$\begin{aligned} \mathbf{L}^2(\Omega) &= [L^2(\Omega)]^2, \\ \mathbf{H}(\text{curl}, \Omega) &= \{\mathbf{v} \in \mathbf{L}^2(\Omega) : \text{curl}\ \mathbf{v} \in L^2(\Omega)\}, \\ \mathbf{H}_0(\text{curl}, \Omega) &= \{\mathbf{v} \in \mathbf{H}(\text{curl}, \Omega), \mathbf{v} \times \mathbf{n} = 0, \text{ on } \partial\Omega\}. \end{aligned}$$

The weak formulation of (2.4) is obtained in a standard way. Multiply the first, and the second equation, in (2.4) by test functions, $\boldsymbol{\phi} \in \mathbf{H}_0(\text{curl}, \Omega)$, and $\psi \in \mathbf{L}^2(\Omega)$, respectively, and integrate over the domain Ω. The weak formulation reads

Find $\mathbf{E} \in C^2([0,T];\mathbf{H}_0(\text{curl},\Omega))$, *and* $\mathbf{J} \in C^1([0,T];\mathbf{L}^2(\Omega))$, *subject to appropriate initial conditions, such that for all* $\boldsymbol{\phi} \in \mathbf{H}_0(\text{curl},\Omega)$ and $\psi \in \mathbf{L}^2(\Omega)$ we have

$$[\mathbf{E}_{tt},\boldsymbol{\phi}]_E + c_0^2\,[(\text{curl }\mathbf{E}),(\text{curl }\boldsymbol{\phi})]_F + \frac{1}{\epsilon_0}\,[\mathbf{J}_t,\boldsymbol{\phi}]_E = 0, \tag{2.5}$$

$$[\mathbf{J}_t,\psi]_E + \omega_i\,[\mathbf{J},\psi]_E - \epsilon_0\omega_p^2\,[\mathbf{E},\psi]_E = 0, \tag{2.6}$$

where the bilinear forms are defined as follows:

$$[\mathbf{J},\mathbf{E}]_E := \int_\Omega \mathbf{J}\cdot\mathbf{E}\,d\Omega, \qquad [J,E]_F := \int_\Omega J\,E\,d\Omega. \tag{2.7}$$

Here $(\mathbf{J},\mathbf{E})$ are vector functions, and (J,E) are scalar functions.

2.2 Dispersion Relation

In this paper our aim is to construct a numerical method for the Maxwell-CP model (2.4) that is the optimal method chosen from a family of schemes by minimizing for numerical dispersion error. Thus, in this section, we present a brief overview of continuous and numerical dispersion relations and their connections to symbols of differential operators.

Given a plane wave

$$\mathbf{u}(t,\mathbf{x}) := \mathrm{e}^{\mathrm{i}(\mathbf{k}\cdot\mathbf{x}-\omega t)}\mathbf{u}_0, \tag{2.8}$$

a continuous or discrete *dispersion relation* is a relation between the frequency ω and the wave vector $\mathbf{k}$, under which $\mathbf{u}$, or its restriction to a discrete grid, is a solution of a continuum PDE, or its discrete approximation, respectively.

Consider an abstract linear equation

$$\mathcal{L}_t\{\mathbf{u}\} = \mathcal{L}_\mathbf{x}\{\mathbf{u}\}, \tag{2.9}$$

where $\mathcal{L}_t$ and $\mathcal{L}_x$ are linear operators corresponding to time and space, respectively, and $\mathbf{u}$ is either a continuous plane wave (2.8) or its discrete representation. For example, $\mathcal{L}_t$ and $\mathcal{L}_\mathbf{x}$ could be the continuous differential operators $\mathcal{L}_t\{\mathbf{u}\} = \frac{\partial^2}{\partial t^2}\mathbf{u}$ and $\mathcal{L}_\mathbf{x}\{\mathbf{u}\} = \triangle\mathbf{u}$ or their discrete approximations.

As it turns out, for all linear operators $\mathcal{L}_t$ and $\mathcal{L}_x$ (continuous or discrete) considered in this paper the plane wave (2.8) is a generalized eigenfunction, i.e.

$$\mathcal{L}_t\{\mathbf{u}\} = \mathcal{T}(\omega)\mathbf{u} \qquad \text{and} \qquad \mathcal{L}_x\{\mathbf{u}\} = \mathcal{S}(\mathbf{k})\mathbf{u}, \tag{2.10}$$

where $\mathcal{T}(\omega)$ and $\mathcal{S}(\mathbf{k})$ are square matrices acting on $\mathbf{u}_0$, i.e.

$$\mathcal{T}(\omega)\mathbf{u} = \mathrm{e}^{\mathrm{i}(\mathbf{k}\cdot\mathbf{x}-\omega t)}\,\mathcal{T}(\omega)\mathbf{u}_0 \qquad \text{and} \qquad \mathcal{S}(\mathbf{k})\mathbf{u} = \mathrm{e}^{\mathrm{i}(\mathbf{k}\cdot\mathbf{x}-\omega t)}\,\mathcal{S}(\mathbf{k})\mathbf{u}_0.$$

If $\mathcal{T}(\omega)$ and $\mathcal{S}(\mathbf{k})$ were scalars, they would be eigenvalues and $\mathbf{u}$ would be the eigenfunction of $\mathcal{L}_t$ and $\mathcal{L}_x$. Since, in general, they are not scalars we refer to $\mathbf{u}$ as a generalized eigenfunction and call $\mathcal{T}(\omega)$ and $\mathcal{S}(\mathbf{k})$ - symbols of linear operators $\mathcal{L}_t$ and $\mathcal{L}_x$, respectively.

Substituting (2.10) into (2.9) and cancelling the exponential terms $\mathrm{e}^{\mathrm{i}(\mathbf{k}\cdot\mathbf{x}-\omega t)}$ on both sides we obtain a dispersion relation written in terms of symbols of linear operators

$$\mathcal{T}(\omega)\mathbf{u}_0 = \mathcal{S}(\mathbf{k})\mathbf{u}_0. \tag{2.11}$$

In this work we are primarily concerned with *dispersion error*, which can be defined as the absolute value of the difference between the frequency $\omega(\mathbf{k})$, solution to the continuous dispersion relation, and its discrete counterpart, $\omega_{\Delta t,h}(\mathbf{k})$, solution to the discrete dispersion relation. There are other ways in which the dispersion error can be defined as discussed in Section 6. Dispersion error is the result of frequency dependent speed of propagation of plane waves in the discretized grid regardless of whether the continuum solution has such frequency dependent propagation or not. In particular, the speed of propagation of waves in the discrete grid always differs from that in the continuum case and is commonly observed as non-physical oscillations in discrete solutions. Thus, if $\mathcal{T}_{\Delta t}$ is a discrete approximation of $\mathcal{T}$, and $\mathcal{S}_h$ is a discrete approximation of $\mathcal{S}$ then we have

$$\mathcal{T}_{\Delta t} - \mathcal{S}_h = \mathcal{T} - \mathcal{S} + \mathcal{O}(h^\alpha). \tag{2.12}$$

Where $\Delta t > 0, h > 0$ are mesh resolution parameters. It will be our goal to find $\mathcal{T}_{\Delta t}$ and $\mathcal{S}_h$ so that α is as large as possible reducing the discrepancy in wave speed.

3 Mimetic Finite Difference Discretization in Space

A mimetic finite difference discretization of the continuous variational formulation (2.5-2.6) has the form

$$[(\mathbf{E}_h)_{tt}, \boldsymbol{\phi}_h]_{\mathscr{E}} + c_0^2 \left[(\text{curl}_h\ \mathbf{E}_h), (\text{curl}_h\ \boldsymbol{\phi}_h)\right]_{\mathscr{F}} + \frac{1}{\epsilon_0}\left[(\mathbf{J}_h)_t, \boldsymbol{\phi}_h\right]_{\mathscr{E}} = 0, \tag{3.1}$$

$$[(\mathbf{J}_h)_t, \psi_h]_{\mathscr{E}} + \omega_i \left[\mathbf{J}_h, \psi_h\right]_{\mathscr{E}} - \epsilon_0 \omega_p^2 \left[\mathbf{E}_h, \psi_h\right]_{\mathscr{E}} = 0. \tag{3.2}$$

Here $\mathbf{E}_h$, and $\mathbf{J}_h$, are discrete approximations of the solutions $\mathbf{E}$, and $\mathbf{J}$, respectively; $\boldsymbol{\phi}_h$ and ψ_h are discrete test functions; curl_h is a discrete linear operator approximating its continuous counterpart curl. The bilinear forms $[\cdot,\cdot]_{\mathscr{E}}$ and $[\cdot,\cdot]_{\mathscr{F}}$ are discrete approximations of the continuous bilinear forms $[\cdot,\cdot]_E$ and $[\cdot,\cdot]_F$ defined in (2.7). We will now make all of the above precise.

3.1 Discrete Spaces and Interpolation

Let $\mathscr{T}$ be a polygonal partitioning (mesh) of the domain Ω. Let $\mathscr{E}$, and $\mathscr{F}$, be the set of all edges e, and faces (cells) f, respectively, of the mesh $\mathscr{T}$. In the discrete form every function will be represented in terms of a finite number of values called degrees of freedom (DoF) assembled into a vector (e.g. $\mathbf{E}_h$, $\mathbf{J}_h$) assuming some ordering of these DoF. Each DoF will be associated either to an edge or to a face/element. The DoF of scalar functions (e.g. $\text{curl}\,\mathbf{E}$) will be associated with faces only (one DoF per face) and can be interpreted as an average value of the function over the face/cell. The DoF of vector functions (e.g. $\mathbf{E}$ and $\mathbf{J}$) will be associated with edges only (one DoF per edge) and can be interpreted as an average value of the tangential component of the vector function along the edge. See Figure 1 for illustration.

We will denote the discrete space corresponding to vector functions as $\mathscr{E}_h$ and the discrete space corresponding to scalar functions as $\mathscr{F}_h$. We define interpolation operators $\mathcal{I}^{\mathscr{E}_h}$, and $\mathcal{I}^{\mathscr{F}_h}$, as linear operators that for each function in $\mathbf{H}(\text{curl}, \Omega)$, and L^2, assigns a vector of DoF in $\mathscr{E}_h$, and $\mathscr{F}_h$, respectively.

The interpolation operator $\mathcal{I}^{\mathscr{E}_h}$, and the vector of DoF for vector functions are defined as

$$\mathcal{I}^{\mathscr{E}_h} : \mathbf{H}(\text{curl}, \Omega) \to \mathscr{E}_h, \qquad \mathbf{E}_e := \frac{1}{|e|}\int_e \mathbf{E}\cdot\boldsymbol{\tau}_e\, de, \tag{3.3}$$

$$\mathcal{I}^{\mathscr{E}_h}(\mathbf{E}) = \mathbf{E}_h := \left(\mathbf{E}_e\right)_{e\in\mathscr{E}}, \tag{3.4}$$

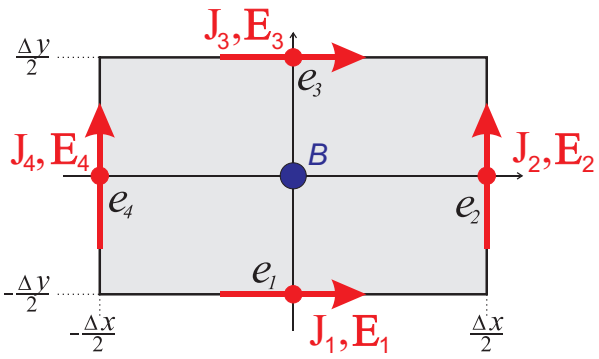

Figure 1: Illustration of DoF for vector functions, marked as $\mathbf{E}$, and scalar functions, marked as B on a rectangular element centered at the origin.

where $\boldsymbol{\tau}_e$ is a counter-clockwise tangent to the edge e. The interpolation operator $\mathcal{I}^{\mathscr{F}_h}$ for scalar functions, and the vector of DoF for scalar functions are defined as

$$\mathcal{I}^{\mathscr{F}_h} : L^2 \to \mathscr{F}_h, \qquad B_f := \frac{1}{|f|}\int_f B\, df, \tag{3.5}$$

$$\mathcal{I}^{\mathscr{F}_h}(B) = B_h := \big(B_f\big)_{f\in\mathscr{F}}. \tag{3.6}$$

3.2 Discrete Inner Products and the Adjoint Curl

Discrete bilinear forms $[\cdot,\cdot]_{\mathscr{E}}$ and $[\cdot,\cdot]_{\mathscr{F}}$ can be represented by square matrices and are defined through a standard assembly process

$$(\mathbf{E}_h)^T\mathbb{M}_{\mathscr{E}}\mathbf{D}_h = [\mathbf{E}_h,\mathbf{D}_h]_{\mathscr{E}} := \sum_{f\in\mathscr{F}}[\mathbf{E}_h,\mathbf{D}_h]_{\mathscr{E},f} = \sum_{f\in\mathscr{F}}(\mathbf{E}_{h,f})^T\mathbb{M}_{\mathscr{E},f}\mathbf{D}_{h,f}, \tag{3.7}$$

$$(B_h)^T\mathbb{M}_{\mathscr{F}}M_h = [B_h,M_h]_{\mathscr{F}} := \sum_{f\in\mathscr{F}}[B_h,M_h]_{\mathscr{F},f} = \sum_{f\in\mathscr{F}}(B_{h,f})^T\mathbb{M}_{\mathscr{F},f}M_{h,f}, \tag{3.8}$$

where $[\mathbf{E}_h,\mathbf{D}_h]_{\mathscr{E},f}$ and $[B_h,M_h]_{\mathscr{F},f}$ are to be defined locally on each face f.

For scalar functions the definition for the local bilinear form is the simplest

$$[B_h,M_h]_{\mathscr{F},f} := |f|B^T_{h,f}M_{h,f}, \qquad \text{i.e.} \quad \mathbb{M}_{\mathscr{F},f} = |f|, \tag{3.9}$$

where $|f|$ is the area of the face f.

Next, we define the discrete curl_h operator as a mapping from the discrete space $\mathscr{E}_h$, approximating vector functions, to the discrete space $\mathscr{F}_h$, approximating scalar functions. The definition will be made locally on each face f through the identity

$$[\psi_h,\mathrm{curl}_h\mathbf{E}_h]_{\mathscr{F},f} = \int_f \psi\,\mathrm{curl}(\mathbf{E})\, df, \tag{3.10}$$

which must hold for any constant ψ and any vector function $\mathbf{E}$ whose local discrete representation on the face f is $\mathbf{E}_{h,f}$. Identity (3.10) defines curl_h uniquely since the RHS of (3.10) can be expressed in terms of the vector of DoF $\mathbf{E}_{h,f}$ of $\mathbf{E}$ on the face f only using integration by parts

$$\int_f \psi\,\mathrm{curl}(\mathbf{E})\, df = \psi\sum_{e\in\partial f}\int_e \mathbf{E}\cdot\boldsymbol{\tau}_e\, de, \tag{3.11}$$

where $\boldsymbol{\tau}_e$ is a counter-clockwise tangent to the edge e of the face f. The edge integrals in (3.11) are exactly the DoF of $\mathbf{E}$, defined in (3.3), up to orientation of the edges. On a rectangular element the local matrix curl_h is a column vector of length four given by

$$\text{curl}_{h,f} = \frac{1}{\Delta x \Delta y}(\Delta x, \Delta y, -\Delta x, -\Delta y)^T. \tag{3.12}$$

The construction of the mass matrix $\mathbb{M}_{\mathscr{E}}$ contains many details that are not necessary for performing dispersion reduction analysis that is the center point of this paper. Therefore, we limit ourselves to presenting the final form of the matrix on a rectangular mesh and refer interested readers to [1] for all details.

In fact, instead of computing $\mathbb{M}_{\mathscr{E},f}$ we compute an approximation to its inverse

$$\mathbb{W}_{\mathscr{E},f} \approx \mathbb{M}^{-1}_{\mathscr{E},f}, \qquad \mathbb{W}_{\mathscr{E},f} = \frac{1}{4\Delta x \Delta y}\begin{pmatrix} 1+4w_1 & 4w_2 & 1-4w_1 & -4w_2 \\ 4w_2 & 1+4w_3 & -4w_2 & 1-4w_3 \\ 1-4w_1 & -4w_2 & 1+4w_1 & 4w_2 \\ -4w_2 & 1-4w_3 & 4w_2 & 1+4w_3 \end{pmatrix}. \tag{3.13}$$

Here w_1, w_2 and w_3 are free parameters. Different values of these parameters give rise to different numerical schemes, as discussed in [1]. In particular, this family of matrices $\mathbb{W}_{\mathscr{E},f}$ contains the Yee-scheme as one of its members. In order to recover the famous Yee-FDTD stencil, $\mathbb{W}_{\mathscr{E}} = \frac{1}{2\Delta x \Delta y}\mathbb{I}$, one has to take $w_1 = w_3 = \frac{1}{4}$ and $w_2 = 0$.

Our global matrices are then assembled in the usual way for every face f. As we are considering a second order formulation we introduce the following discrete curl-curl operator,

$$\mathbb{A}_h = (\text{curl}_h)^T \mathbb{M}_{\mathscr{F}} \text{curl}_h. \tag{3.14}$$

This matrix can be assembled from local matrices $(\text{curl}_{h,f})^T \Delta x \Delta y \, \text{curl}_{h,f}$.

3.3 Discrete in Space Continuous in Time Formulation on Rectangular Meshes

A discrete in space continuous in time formulation of the second order Maxwell-CP system is as follows:
Find $\mathbf{E}_h \in C^2([0,T], \mathscr{E}_h \cap \mathbf{H}_0(\text{curl}, \Omega))$ *and* $\mathbf{J}_h \in C^1([0,T], \mathscr{E}_h)$ *such that:*

$$\begin{cases} \dfrac{\partial^2}{\partial t^2}\mathbf{E}_h + \dfrac{1}{\epsilon_0}\dfrac{\partial}{\partial t}\mathbf{J}_h = -c_0^2 \mathbb{W}_{\mathscr{E}} \mathbb{A}_h \mathbf{E}_h, \\ \dfrac{\partial}{\partial t}\mathbf{J}_h = -\omega_i \mathbf{J}_h + \epsilon_0 \omega_P^2 \mathbf{E}_h. \end{cases} \tag{3.15}$$

3.4 Dispersion Analysis for Discrete in Space Continuous in Time Formulation

To obtain dispersion relations we assume plane wave solutions for the electric field and the polarization current density. Thus, in the discrete in space and continuous in time formulation (3.15), we represent the spatially discrete electric field, $\mathbf{E}_h(t)$, and polarization current density, $\mathbf{J}_h(t)$, as

$$\begin{aligned} \mathbf{E}_h(t) &= \mathcal{I}^{\mathscr{E}_h}\left(\mathbf{E}_0 e^{\mathrm{i}(\mathbf{k}\cdot\mathbf{x})}\right) E(t), \\ \mathbf{J}_h(t) &= \mathcal{I}^{\mathscr{E}_h}\left(\mathbf{J}_0 e^{\mathrm{i}(\mathbf{k}\cdot\mathbf{x})}\right) J(t). \end{aligned} \tag{3.16}$$

Here $\mathbf{E}_0$ and $\mathbf{J}_0$ are two-dimensional vectors that specify the initial intensity and the orientation of the corresponding vector fields. The continuous plane wave vector fields are characterized

by the wave vector $\mathbf{k}$ (whose magnitude we refer to as the wave number k) and the vectors $\mathbf{E}_0$ and $\mathbf{J}_0$. In the spatially discrete setting a similar characterization is made. We use U_i to denote a DoF for either the electric field or polarization current density. The role of the vectors $\mathbf{E}_0$ and $\mathbf{J}_0$ is assumed by two DoF associated with two adjacent orthogonal edges, as depicted in Figure 2. The DoF U_1 is associated to a horizontal edge, while the DoF U_2 is associated to a vertical edge. Other DoF, U_i, for the waves of the form (3.16) can be written in terms of U_1, U_2, and the exponent $e^{\mathrm{i}(\mathbf{k}\cdot\boldsymbol{\Delta}\mathbf{x_i})}$ as

$$\begin{aligned} U_i &= U_1 e^{\mathrm{i}(\mathbf{k}\cdot\boldsymbol{\Delta}\mathbf{x_i})} \qquad \text{for a horizontal edge } e_i, \\ U_i &= U_2 e^{\mathrm{i}(\mathbf{k}\cdot\boldsymbol{\Delta}\mathbf{x_i})} \qquad \text{for a vertical edge } e_i, \end{aligned} \tag{3.17}$$

where $\boldsymbol{\Delta}\mathbf{x_i}$ is the "shift"-vector from the center of the edge e_1 or e_2 to the center of the edge e_i, respectively. In particular, the vector of four DoF $(U_1, U_2, U_3, U_4)^T$, corresponding to the element f, can be written in terms of the vector of the first two DoF $(U_1, U_2)^T$ and $\mathbf{k} = (k_x, k_y)^T$ as follows:

$$\begin{pmatrix} U_1 \\ U_2 \\ U_3 \\ U_4 \end{pmatrix} = \mathbb{S} \begin{pmatrix} U_1 \\ U_2 \end{pmatrix}, \qquad \text{where} \quad \mathbb{S} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \\ \mathrm{e}^{\mathrm{i}k_y\Delta y} & 0 \\ 0 & e^{-\mathrm{i}k_x\Delta x} \end{pmatrix}. \tag{3.18}$$

In the semi-discrete formulation (3.15), we perform several multiplications of waves of the form (3.16) by global matrices $\mathbb{A}$ and $\mathbb{W}$ assembled from identical local matrices $\mathbb{A}^f$ and $\mathbb{W}^f$. The following result presents a simple way of performing such a multiplication.

Lemma 1. *Consider the result of multiplication*

$$\mathbf{V} = \mathbb{Z}\mathbf{U}, \tag{3.19}$$

where the global matrix $\mathbb{Z}$ is assembled from identical local matrices $\mathbb{Z}^f$ and the vector of DoF $\mathbf{U}$ *has the form* (3.17) *Then the vector of DoF* $\mathbf{V}$ *also has the form* (3.17) *The vector of two DoF $(V_1, V_2)^T$ characterizing the vector* $\mathbf{V}$ *depends linearly on the vector of two DoF $(U_1, U_2)^T$ characterizing the vector* $\mathbf{U}$*; the two-by-two matrix corresponding to the linear mapping has the form $(\mathbb{S}^*\mathbb{Z}^f\mathbb{S})$:*

$$\begin{pmatrix} V_1 \\ V_2 \end{pmatrix} = (\mathbb{S}^*\mathbb{Z}^f\mathbb{S}) \begin{pmatrix} U_1 \\ U_2 \end{pmatrix}, \tag{3.20}$$

where $\mathbb{S}$ was defined in (3.18) *and $\mathbb{S}^*$ is a conjugate transpose of $\mathbb{S}$.*

Proof. The fact that $\mathbf{V}$ satisfies (3.17) follows immediately from the fact that $\mathbf{U}$ satisfies (3.17). The linear relation between $(V_1, V_2)^T$ and $(U_1, U_2)^T$ is a direct consequence of the linear relation (3.19). The main point of the lemma is to show that the linear relation (3.20) is given by the two-by-two matrix $(\mathbb{S}^*\mathbb{Z}^f\mathbb{S})$.

Consider the two elements f_1 and f_2 that determine the value of V_1 and the two elements f_1 and f_3 that determine the values of V_2, as shown in Figure. 2. The value of V_1 is a sum of the contributions from the elements f_1 and f_2

$$\begin{aligned} V_1 &= \begin{bmatrix} 1 & 0 & 0 & 0 \end{bmatrix} \mathbb{Z}^f\mathbb{S} \begin{bmatrix} U_1 \\ U_2 \end{bmatrix} + \begin{bmatrix} 0 & 0 & 1 & 0 \end{bmatrix} \mathbb{Z}^f\mathbb{S} \begin{bmatrix} e^{-\mathrm{i}k_2\Delta y}U_1 \\ e^{-\mathrm{i}k_2\Delta y}U_2 \end{bmatrix} = \\ &= \begin{bmatrix} 1 & 0 & e^{-\mathrm{i}k_2\Delta y} & 0 \end{bmatrix} \mathbb{Z}^f\mathbb{S} \begin{bmatrix} U_1 \\ U_2 \end{bmatrix}. \end{aligned} \tag{3.21}$$

Here the product $\mathbb{Z}^f\mathbb{S}(U_1,U_2)^T$ is a size four vector of contributions from the element to the four DoF of $\mathbf{V}$, while multiplication on the left by $(1,0,0,0)$ extracts the first component of this vector.

Similarly, to (3.21) we get the expression for V_2

$$\begin{aligned} V_2 &= \begin{bmatrix} 0 & 1 & 0 & 0 \end{bmatrix} \mathbb{Z}^f\mathbb{S} \begin{bmatrix} U_1 \\ U_2 \end{bmatrix} + \begin{bmatrix} 0 & 0 & 0 & 1 \end{bmatrix} \mathbb{Z}^f\mathbb{S} \begin{bmatrix} e^{-\mathrm{i}k_1\Delta x}U_1 \\ e^{-\mathrm{i}k_1\Delta x}U_2 \end{bmatrix} = \\ &= \begin{bmatrix} 0 & 1 & 0 & e^{-\mathrm{i}k_1\Delta x} \end{bmatrix} \mathbb{Z}^f\mathbb{S} \begin{bmatrix} U_1 \\ U_2 \end{bmatrix}. \end{aligned} \tag{3.22}$$

Combining (3.21) and (3.22) and recalling the definition (3.18) of the transformation matrix $\mathbb{S}$ we obtain the final result (3.20). □

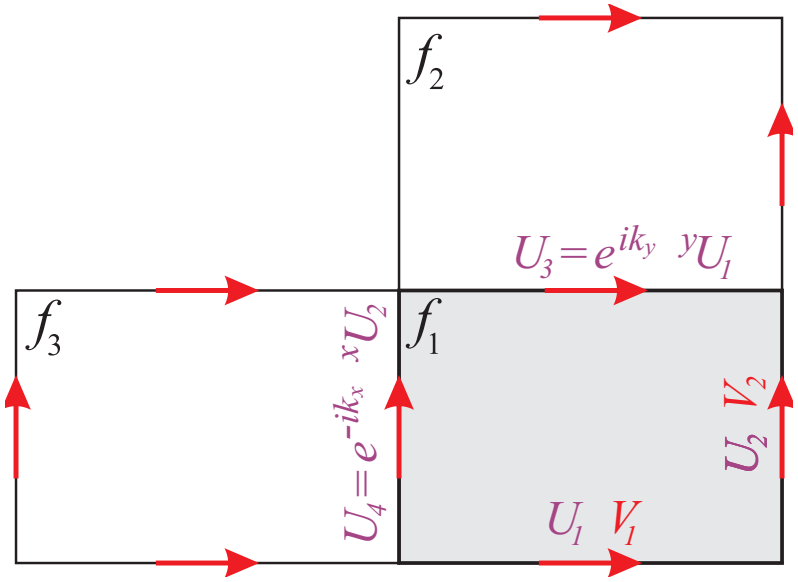

Figure 2: Three cells used to assemble the contributions after multiplication by a uniform matrix.

For a rectangular mesh the two discretization parameters are $h = \Delta x$, which without loss of generality we assume to be the smallest of Δx and Δy, and the aspect ratio of the elements

$$\gamma = \frac{\Delta y}{\Delta x}. \tag{3.23}$$

The characterization of waves by two DoF (3.17) and the wave vector $\mathbf{k}$ together with Lemma 1 suggests rewriting the first equation in (3.15), only in terms of two DoF associated to two orthogonal edges e_1 and e_2, as

$$\frac{\partial^2}{\partial t^2}\mathbf{E}_{(e_1,e_2)} + \frac{1}{\epsilon_0}\frac{\partial}{\partial t}\mathbf{J}_{(e_1,e_2)} = -c_0^2\overline{\mathbb{W}}_{\mathscr{E}}\overline{\mathbb{A}}_h\mathbf{E}_{(e_1,e_2)}. \tag{3.24}$$

In the above we use the DoF notation introduced in (3.3), with $\mathbf{U}_{(e_1,e_2)} := (U_{e_1},U_{e_2})^T$, for $\mathbf{U} = \mathbf{E}$ or $\mathbf{U} = \mathbf{J}$. Here $\overline{\mathbb{W}}_{\mathscr{E}}$ and $\overline{\mathbb{A}}_h$ are 2×2 matrices defined as

$$\overline{\mathbb{W}}_{\mathscr{E}} = \mathbb{S}^\star\mathbb{W}_{\mathscr{E},f}\mathbb{S} \qquad \text{and} \qquad \overline{\mathbb{A}}_h = \mathbb{S}^\star\mathbb{A}_{h,f}\mathbb{S}. \tag{3.25}$$

Performing dispersion analysis on the semi-discrete system (3.24) yields a 2×2 eigenvalue problem. The matrix $\mathbb{A}_h$ has rank one, thus the product $\overline{\mathbb{W}}_{\mathscr{E}}\overline{\mathbb{A}}_h$ is at most rank one. This implies

that one of two eigenvalues is zero. This eigenvalue corresponds to evanescent waves, which are not of interest as they do not propagate in space. We focus on the non-zero eigenvalue of the matrix $\overline{\mathbb{W}}_{\mathscr{E}}\overline{\mathbb{A}}_h$. The non-zero eigenvalue corresponds to transient waves. Since one of the eigenvalues of this matrix is zero, the symbol is given by the trace of the matrix as

$$\begin{aligned}\mathcal{S}_h(\mathbf{k}) &= -c_0^2\mathrm{Tr}(\overline{\mathbb{W}}_{\mathscr{E}}\overline{\mathbb{A}}_h)\\ &= -\frac{4c_0^2}{h^2}\sin^2\frac{k_x h}{2}\left(1+(1-4w_3)\sin^2\frac{k_x h}{2}\right)\\ &- \frac{32c_0^2}{\gamma h^2}w_2\sin^2\frac{k_x h}{2}\sin^2\frac{k_y\gamma h}{2}\\ &- \frac{4c_0^2}{\gamma^2 h^2}\sin^2\frac{k_y\gamma h}{2}\left(1+(1-4w_1)\sin^2\frac{k_y\gamma h}{2}\right).\end{aligned} \tag{3.26}$$

The difference between the continuous and the discrete symbols, in the case of exact time integration, defines the order of numerical dispersion. Therefore, we are interested in making this difference, $\mathcal{S}(\mathbf{k})-\mathcal{S}_h(\mathbf{k})$, as small as possible. For a general member of the MFD family this difference is second order in h. This can be seen by taking $\mathbf{k} = k(\cos\theta, \sin\theta)^T$ and expanding $\mathcal{S}_h(\mathbf{k})$ in a Taylor series in h as

$$\begin{aligned}\mathcal{S}_h(\mathbf{k}) = -(c_0k)^2\Big\{1+\Big(&\tfrac{(3w_3-1)}{3}\cos^4\theta + 2\gamma w_2\cos^2\theta\sin^2\theta+\\ &+\tfrac{\gamma^2(3w_1-1)}{3}\sin^4\theta\Big)k^2h^2+\mathcal{O}(h^4)\Big\}.\end{aligned} \tag{3.27}$$

We observe that we can eliminate the angular (θ) dependence of the h^2 term in (3.27) through the following choice of free parameters in the MFD scheme

$$\tfrac{\gamma^2(3w_1-1)}{3} = \gamma w_2 = \tfrac{(3w_3-1)}{3}, \quad \text{e.g. by taking} \quad \begin{cases} w_1 = \frac{3w_2\gamma^{-1}+1}{3},\\ w_3 = \frac{3w_2\gamma+1}{3}.\end{cases} \tag{3.28}$$

This yields the following discrete symbol

$$\mathcal{S}_h(\mathbf{k}) = -(c_0k)^2\left\{1+\gamma w_2k^2h^2+\mathcal{O}(h^4)\right\}. \tag{3.29}$$

Taking $w_2 = 0$ we can eliminate the second order difference between the continuous and discrete symbols, thus making the numerical dispersion fourth order accurate. Then by using a fourth order discretization in time, we could arrive at a method with fourth order dispersion error. This approach has its advantages especially at low spatial resolution. Unfortunately, the storage necessary for these schemes may be prohibitive for large problems. We will instead focus on choosing a second order time integrator so that w_2 can eliminate all second order dispersion errors.

4 Exponential Time Differencing

Exponential differencing is a time integration technique commonly used for lossy dielectrics. The idea is as follows. Consider a time dependent ODE of the form

$$\dot{u} = cu + F(u,t). \tag{4.1}$$

To create the exact solution of (4.1) one exploits the fact that

$$\frac{d}{dt}\left(e^{-ct}u\right) = e^{-ct}\left(\dot{u}-cu\right). \tag{4.2}$$

Multiply (4.1) by e^{-ct}, integrate from t_n to t_{n+1} and divide by $e^{-ct_{n+1}}$

$$u(t_{n+1}) - \mathrm{e}^{c\Delta t}u(t_n) = \int_{t_n}^{t_{n+1}} F(u(s),s)\mathrm{e}^{c(\Delta t - s)}\, ds. \tag{4.3}$$

Formula (4.3) is exact. Thus, in principle, higher order accuracy can be obtained by using higher order discretization of the integral term, c.f. [2]. In practice, due to specifics of definitions of $F(u(s),s)$, it could be convenient to use the following approximation to the integral in (4.3)

$$\int_{t_n}^{t_{n+1}} F(u(s),s)\mathrm{e}^{c(\Delta t - s)}\, ds \approx F^{n+1/2}\int_{t_n}^{t_{n+1}} \mathrm{e}^{c(\Delta t - s)}\, ds = c^{-1}(\mathrm{e}^{c\Delta t}-1)F^{n+1/2}, \tag{4.4}$$

where $F^{n+1/2}$ is an approximation of $F(u(t_{n+1/2}), t_{n+1/2})$. When F depends on u then this approach may be implicit. However, in our case F depends only on t as we employ a staggering technique so this quantity is computed explicitly. This approach can be generalized to vector valued ODE in time

$$\dot{\mathbf{u}} = \mathbb{X}\mathbf{u} + \mathbf{F}(\mathbf{u}, t) \tag{4.5}$$

to produce the following discretization when $\mathbb{X}$ is invertible

$$\mathbf{u}^{n+1} - \mathrm{e}^{\mathbb{X}\Delta t}\mathbf{u}^n = \mathbb{X}^{-1}(\mathrm{e}^{\mathbb{X}\Delta t} - \mathbb{I})\mathbf{F}^{n+1/2}. \tag{4.6}$$

4.1 Continuous in Space Discrete in Time Formulation

Rewrite the first order PDEs (2.1-(2.2)) as

$$\begin{cases} \dot{\mathbf{u}} = \mathbb{X}\mathbf{u} + \mathbf{F}, \\ \dot{B} = -\mathrm{curl}\mathbf{E}, \end{cases} \tag{4.7}$$

where

$$\mathbf{u} = \begin{pmatrix} \mathbf{E} \\ \mathbf{J} \end{pmatrix}, \qquad \mathbb{X} = \begin{pmatrix} 0 & -\dfrac{1}{\epsilon_0} \\ \epsilon_0\omega_P^2 & -\omega_i \end{pmatrix}, \qquad \mathbf{F} = \begin{pmatrix} c_0^2\, \mathbf{curl} B \\ 0 \end{pmatrix}. \tag{4.8}$$

We will consider a time discretization $\mathbf{E}^n$ and $\mathbf{J}^n$ of $\mathbf{E}$ and $\mathbf{J}$ on integer time steps $t_n := n\Delta t$ and $B^{n+1/2}$ of B on staggered half-integer time steps $t_{n+1/2} := (n+1/2)\Delta t$.

For the first equation in (4.8) we use the ETD scheme (4.6), where we define the matrix

$$\mathbb{Y} := \mathbb{X}^{-1}(\mathrm{e}^{\mathbb{X}\Delta t} - \mathbb{I}). \tag{4.9}$$

For the second equation we use the standard time-staggered leap-frog. Thus, the semi-discrete scheme for (4.8) reads

$$\begin{cases} \begin{pmatrix} \mathbf{E}^{n+1} \\ \mathbf{J}^{n+1} \end{pmatrix} = \mathrm{e}^{\mathbb{X}\Delta t}\begin{pmatrix} \mathbf{E}^{n} \\ \mathbf{J}^{n} \end{pmatrix} + \mathbb{Y}\begin{pmatrix} c_0^2\, \mathbf{curl}\, B^{n+1/2} \\ 0 \end{pmatrix}, \\ B^{n+1/2} = B^{n-1/2} - \Delta t\ \mathrm{curl}\ \mathbf{E}^n. \end{cases} \tag{4.10}$$

In order to obtain from (4.10) an appropriate second order formulation we proceed similarly to how we obtained (2.4) from (2.1-(2.2)) by eliminating the magnetic induction B from the evolution equation. We do this by applying a leap-frog step to both sides of the first equation in (4.10). This yields a continuous in space discrete in time discretization

$$\begin{pmatrix} \mathbf{E}^{n+1} \\ \mathbf{J}^{n+1} \end{pmatrix} = (\mathbb{I} + e^{\mathbb{X}\Delta t})\begin{pmatrix} \mathbf{E}^{n} \\ \mathbf{J}^{n} \end{pmatrix} - \mathrm{e}^{\mathbb{X}\Delta t}\begin{pmatrix} \mathbf{E}^{n-1} \\ \mathbf{J}^{n-1} \end{pmatrix} - c_0^2\Delta t\mathbb{Y}\begin{pmatrix} \mathbf{curl}\ \mathrm{curl}\ \mathbf{E}^n \\ 0 \end{pmatrix}. \tag{4.11}$$

4.2 Dispersion Analysis for Continuous in Space Discrete in Time Formulation

To obtain a discrete in time dispersion relation we divide both sides of (4.11) by the exponential integrator $\mathbb{Y}$ to get

$$\frac{1}{\Delta t}\mathbb{Y}^{-1}\left[\begin{pmatrix}\mathbf{E}^{n+1}\\ \mathbf{J}^{n+1}\end{pmatrix} - (\mathbb{I}+e^{\mathbb{X}\Delta t})\begin{pmatrix}\mathbf{E}^{n}\\ \mathbf{J}^{n}\end{pmatrix} + \mathrm{e}^{\mathbb{X}\Delta t}\begin{pmatrix}\mathbf{E}^{n-1}\\ \mathbf{J}^{n-1}\end{pmatrix}\right] = \begin{pmatrix}-c_0^2\,\mathbf{curl}\,\mathrm{curl} & 0\\ 0 & 0\end{pmatrix}\begin{pmatrix}\mathbf{E}^{n}\\ \mathbf{J}^{n}\end{pmatrix}. \tag{4.12}$$

Assuming time-harmonic solutions in the above equation we produce the system

$$\mathbb{Y}^{-1}\frac{\mathrm{e}^{-\mathrm{i}\omega\Delta t}\mathbb{I} - (\mathbb{I}+\mathrm{e}^{\mathbb{X}\Delta t}) + \mathrm{e}^{\mathrm{i}\omega\Delta t}\mathrm{e}^{\mathbb{X}\Delta t}}{\Delta t} = \begin{pmatrix}-c_0^2\,\mathbf{curl}\,\mathrm{curl} & 0\\ 0 & 0\end{pmatrix}. \tag{4.13}$$

Defining the discrete symbol in time to be

$$\mathcal{T}_{\Delta t}(\omega) = \mathbb{Y}^{-1}\frac{\mathrm{e}^{-\mathrm{i}\omega\Delta t}\mathbb{I} - (\mathbb{I}+\mathrm{e}^{\mathbb{X}\Delta t}) + \mathrm{e}^{\mathrm{i}\omega\Delta t}\mathrm{e}^{\mathbb{X}\Delta t}}{\Delta t}, \tag{4.14}$$

and expanding $\mathcal{T}_{\Delta t}$ in a Taylor Series in the variable Δt we obtain

$$\mathcal{T}_{\Delta t}(\omega) = (-\omega^2\mathbb{I} + \mathrm{i}\omega\mathbb{X}) + \frac{\Delta t^2}{12}(-\omega^2\mathbb{I} + \mathrm{i}\omega\mathbb{X})^2 + \mathcal{O}(\Delta t^4). \tag{4.15}$$

We will make use of this expansion in our method optimization proceedure.

5 Exponential Time Mimetic Finite Difference Method (ETMFD) for Cold Plasma

We now present the fully discrete **Exponential Time Mimetic Finte Difference (ETMFD)** method for the Maxwell-CP model, based on MFD in space and ETD in time. Our fully discrete problem is:
Given $\mathbf{E}_h^\ell, \mathbf{J}_h^\ell \in \mathscr{E}_h$ for $\ell \in \{0,1\}$, find $\mathbf{E}_h^n, \mathbf{J}_h^n \in \mathscr{E}_h \quad \forall n \geq 0$ such that

$$\begin{pmatrix}\mathbf{E}_h^{n+1}\\ \mathbf{J}_h^{n+1}\end{pmatrix} = (\mathbb{I}+\mathrm{e}^{\mathbb{X}\Delta t})\begin{pmatrix}\mathbf{E}_h^{n}\\ \mathbf{J}_h^{n}\end{pmatrix} - \mathrm{e}^{\mathbb{X}\Delta t}\begin{pmatrix}\mathbf{E}_h^{n-1}\\ \mathbf{J}_h^{n-1}\end{pmatrix} - c_0^2\Delta t\mathbb{Y}\begin{pmatrix}\mathbb{W}_{\mathscr{E}}\mathrm{curl}_h^T\mathbb{A}_h\mathbf{E}^n\\ 0\end{pmatrix}. \tag{5.1}$$

5.1 M-Adaptation of the ETMFD

To perform m-adaptation for the ETMFD we must first find its discrete dispersion relation. Intuitively the dispersion relation for (5.1) would be determined by equality between the space discrete symbol $\mathcal{S}_h$ and the time discrete symbol $\mathcal{T}_{\Delta t}$. However, the temporal symbol as defined is matrix valued while the spatial symbol is scalar. Consider our space discretization of the first row of (2.4) assumuing $\mathbf{E}_h$ and $\mathbf{J}_h$ are appropriate transient plane waves as discussed in (3.26)

$$\frac{\partial^2}{\partial t^2}\mathbf{E}_{(e_1,e_2)} + \frac{1}{\epsilon_0}\frac{\partial}{\partial t}\mathbf{J}_{(e_1,e_2)} = \mathcal{S}_h(\mathbf{k}_h)\mathbf{E}_{(e_1,e_2)}, \tag{5.2}$$

This evolution equation implies that $\mathbf{E}_{(e_1,e_2)}$ and $\mathbf{J}_{(e_1,e_2)}$ must be colinear as $\mathcal{S}_h$ is scalar. We therefore define the quantities

$$E_0 = |\mathbf{E}_{(e_1,e_2)}|, \qquad J_0 = |\mathbf{E}_{(e_1,e_2)}|. \tag{5.3}$$

Thus, the spatial symbol of the ETMFD must be some 2x2 matrix multiplied by $\mathcal{S}_h(\mathbf{k})$ acting on the vector $(E_0, J_0)^T$. However as $\mathcal{S}_h(\mathbf{k})$ does not depend on J_0 and has no influence on the second row of the system (4.13) so this matrix must be

$$\mathbb{P}_1 = \begin{pmatrix}1 & 0\\ 0 & 0\end{pmatrix}. \tag{5.4}$$

Given that $\mathcal{S}_h\mathbb{P}_1$ is matrix valued we can now pose the discrete dispersion relation as a 2×2 eigenvalue problem on the initial orientations of the fields $\mathbf{E}_0$ and $\mathbf{J}_0$, which must be non-zero eigenvectors of the matrix $\overline{\mathbb{W}}_{\mathscr{E}}\,\overline{\mathbb{A}}_h$. The discrete dispersion relation for (5.1) is then given by

$$\mathcal{T}_{\Delta t}(\omega)\begin{pmatrix}E_0\\J_0\end{pmatrix} = \mathcal{S}_h(\mathbf{k})\mathbb{P}_1\begin{pmatrix}E_0\\J_0\end{pmatrix}. \tag{5.5}$$

To perform m-adaptation we begin by choosing w_1, w_3 as defined in (3.28) which eliminates dependence on angle of propagation and leaves us with one free parameter w_2, i.e.

$$w_1 = \frac{3w_2\gamma^{-1}+1}{3}, \qquad w_3 = \frac{3w_2\gamma+1}{3}. \tag{5.6}$$

In order to relate time and space discretization sizes we introduce the Courant number

$$\nu = \frac{c_0\Delta t}{h}. \tag{5.7}$$

By moving both terms in (5.5) to the left side and expanding in a Taylor series in h we get

$$\begin{aligned} 0 &= \Big(\mathcal{T}_\Delta t(\omega) - \mathcal{S}_h(\mathbf{k})\mathbb{P}_1\Big)\begin{pmatrix}E_0\\J_0\end{pmatrix} = \\ &= \left(\big(-\omega^2\mathbb{I} + \mathrm{i}\omega\mathbb{X} + c_0^2k^2\mathbb{P}_1\big) + \frac{h^2}{12c_0^2}\Big(\nu^2(-\omega^2\mathbb{I}+\mathrm{i}\omega\mathbb{X})^2 + 12\gamma w_2 c_0^4k^4\mathbb{P}_1^2\Big)\right)\begin{pmatrix}E_0\\J_0\end{pmatrix} + \\ &\quad + \mathcal{O}(h^4)\begin{pmatrix}E_0\\J_0\end{pmatrix}. \end{aligned} \tag{5.8}$$

As $(\omega, \mathbf{k})$ is a solution of the discrete dispersion relation we have

$$c_0^2k^2\mathbb{P}_1\begin{pmatrix}E_0\\J_0\end{pmatrix} = \big(\omega^2\mathbb{I} - \mathrm{i}\omega\mathbb{X} + \mathcal{O}(h^2)\big)\begin{pmatrix}E_0\\J_0\end{pmatrix}. \tag{5.9}$$

Substituting this into the order h^2 term in (5.8) we have

$$\frac{h^2}{12c_0}\left(\nu^2 + 12\gamma w_2\right)c_0^4k^4\mathbb{P}^2 + \mathcal{O}(h^4). \tag{5.10}$$

We can eliminate order h^2 term entirely by a proper choice of the parameter w_2

$$\left(\nu^2 + 12\gamma w_2\right) = 0 \qquad \Rightarrow \qquad w_2 = -\frac{\nu^2}{12\gamma}. \tag{5.11}$$

Under the choice (5.11) the dispersion error is

$$\Big(\mathcal{T}_{\Delta t}(\omega) - \mathcal{S}_h(\mathbf{k})\mathbb{P}_1\Big)\begin{pmatrix}E_0\\J_0\end{pmatrix} = \big(-\omega^2\mathbb{I} + \mathrm{i}\omega\mathbb{X} + c_0^2k^2\mathbb{P}_1 + \mathcal{O}(h^4)\big)\begin{pmatrix}E_0\\J_0\end{pmatrix}. \tag{5.12}$$

For convenience we explicitly write out the the choice of the optimal matrix $\mathbb{W}_{\mathscr{E},f}$

$$\mathbb{W}_{\mathscr{E},f} = \frac{1}{12\Delta x\Delta y}\begin{pmatrix} 7-\nu_y^2 & -\nu_x\nu_y & \nu_y^2-1 & \nu_x\nu_y \\ -\nu_x\nu_y & 7-\nu_x^2 & \nu_x\nu_y & \nu_x^2-1 \\ \nu_y^2-1 & \nu_x\nu_y & 7-\nu_y^2 & -\nu_x\nu_y \\ \nu_x\nu_y & \nu_x^2-1 & -\nu_x\nu_y & 7-\nu_x^2 \end{pmatrix}, \qquad \begin{aligned}\nu_x &= \frac{c_0\Delta t}{\Delta x},\\ \nu_y &= \frac{c_0\Delta t}{\Delta y}.\end{aligned} \tag{5.13}$$

6 Numerical Simulations for Specific Media

For our experiments we introduce a change of variables for $\mathbb{X}$ which allows for an easier formulation of the matrix exponential.

$$\mathbb{X} = \begin{pmatrix} 0 & -\epsilon_0^{-1} \\ \epsilon_0(\alpha^2+\beta^2) & 2\alpha \end{pmatrix}, \quad \alpha = -\frac{\omega_i}{2},\ \beta = \frac{\sqrt{4\omega_P^2 - \omega_i^2}}{2}. \tag{6.1}$$

The ODE system governing the cold plasma model is a classical damped, driven oscillator. For different values of the parameters the character of the system changes. We present results for the case when the system is under damped ($\omega_i^2 < 4\omega_p^2$). The matrix exponential for $\mathbb{X}\Delta t$ is given by

$$\mathrm{e}^{\mathbb{X}\Delta t} = \mathrm{e}^{\alpha\Delta t}\begin{pmatrix} \cos(\beta\Delta t) - \alpha\dfrac{\sin(\beta\Delta t)}{\beta} & -\dfrac{\sin(\beta\Delta t)}{\epsilon_0\beta} \\ \epsilon_0(\alpha^2+\beta^2)\dfrac{\sin(\beta\Delta t)}{\beta} & \cos(\beta\Delta t) + \alpha\dfrac{\sin(\beta\Delta t)}{\beta} \end{pmatrix} := \begin{pmatrix} \alpha_1 & \alpha_2 \\ \beta_2 & \beta_1 \end{pmatrix}. \tag{6.2}$$

The integral of this matrix is given by

$$\int_0^{\Delta t} \mathrm{e}^{\mathbb{X}s}\, ds = \begin{pmatrix} \alpha_3 & \alpha_4 \\ \beta_3 & \beta_4 \end{pmatrix}, \tag{6.3}$$

where the coefficients in the matrix above are defined as

$$\alpha_3 := \frac{1}{\beta}\left(\frac{\mathrm{e}^{\alpha\Delta t}(2\alpha\beta\cos(\beta\Delta t) + (\beta^2-\alpha^2)\sin(\beta\Delta t)) - 2\alpha\beta}{\alpha^2+\beta^2}\right), \tag{6.4}$$

$$\alpha_4 := \frac{1}{\beta}\left(-\frac{\beta - \mathrm{e}^{\alpha\Delta t}(\alpha\sin(\beta\Delta t) - \beta\cos(\beta\Delta t))}{\epsilon_0(\alpha^2+\beta^2)}\right), \tag{6.5}$$

$$\beta_3 := \frac{1}{\beta}\left(\epsilon_0(\beta + \mathrm{e}^{\alpha\Delta t}(\alpha\sin(\beta\Delta t) - \beta\cos(\beta\Delta t)))\right), \tag{6.6}$$

$$\beta_4 := \frac{1}{\beta}\left(\mathrm{e}^{\alpha\Delta t}\sin(\beta\Delta t)\right). \tag{6.7}$$

The second order formulation for the discrete electric field $\mathbf{E}$ and polarization current density $\mathbf{J}$, as introduced in Section 5.1, was a convenient formulation of the discrete ETMFD method for the analysis of numerical dispersion. However, in our numerical experiments we have found that L^2 errors in the second order system for $\mathbf{E}$ and $\mathbf{J}$ are very sensitive to the choice of initial conditions. Thus, for our numerical simulations we will use a different formulation of the discrete ETMFD method, with an equivalent numerical dispersion relation, that retains the second order discrete evolution equation for the electric field, but uses a first order discrete evolution equation for the polarization current density $\mathbf{J}$. Since the focus of this paper is on numerical dispersion optimized methods, we do not investigate the appropriate initialization of the discrete ETMFD scheme here. We defer this investigation to future work.

The hybrid second order evolution equation for the discrete electric field $\mathbf{E}$ and first order evolution equation for the polarization density $\mathbf{J}$ is given as

$$\mathbf{E}_h^{n+1} = (1+\alpha_1)\mathbf{E}_h^n + \alpha_2\mathbf{J}_h^n - \alpha_1\mathbf{E}_h^{n-1} - \alpha_2\mathbf{J}_h^{n-1} - c_0^2\Delta t\alpha_3\mathbb{W}_{\mathscr{E}}\mathbb{A}_h\mathbf{E}_h^n \qquad n \geq 2, \tag{6.8}$$

$$\mathbf{J}_h^{n+1} = \beta_1\mathbf{J}_h^n + \beta_2\mathbf{E}_h^n + \frac{\beta_3}{\alpha_3}(\mathbf{E}_h^{n+1} - \alpha_1\mathbf{E}_h^n - \alpha_2\mathbf{J}_h^n) \qquad n \geq 1. \tag{6.9}$$

This formulation is explicit when we compute $\mathbf{E}^{n+1}$ before $\mathbf{J}^{n+1}$. It requires three initial conditions given by

$$\mathbf{E}_h^0 = \mathcal{I}^{\mathscr{E}_h}(\mathbf{E}(0)), \qquad \mathbf{E}_h^1 = \mathcal{I}^{\mathscr{E}_h}(\mathbf{E}(\Delta t)), \qquad \mathbf{J}_h^0 = \mathcal{I}^{\mathscr{E}_h}(\mathbf{J}(0)). \tag{6.10}$$

In our numerical simulations we used a midpoint quadrature on every edge for $\mathbf{E}_h$ and computed $\mathbf{J}_h$ exactly; i.e.,

$$\mathbf{E}_{h|e}^j = \boldsymbol{\tau}_e \cdot \mathbf{E}(x_c, y_c, j\Delta t), \;\; j = \{0, 1\}, \qquad \mathbf{J}_{h|e}^0 = \frac{1}{|e|}\int_e \mathbf{J}(x, y, 0) \cdot \boldsymbol{\tau}_e ds. \tag{6.11}$$

Experiment 1. In our first experiment we investigate the numerical anisotropy of our method. If $(\omega_n, \mathbf{k}_n)$ are solutions of the numerical dispersion relation, then as eigenvalue pairs they satisfy the relation

$$\det\left(\mathcal{T}_{\Delta t}(\omega_n) - \mathcal{S}_h(\mathbf{k}_n)\mathbb{P}_1\right) = 0. \tag{6.12}$$

The continuous dispersion relation between ω and $\mathbf{k}$ can be written as

$$-\mathrm{i}\omega^3 + \omega_i\omega^2 - \mathrm{i}(\omega_p^2 + c_0^2k^2)\omega - \omega_i c_0^2 k^2 = 0. \tag{6.13}$$

Assume that $\mathbf{k}$ is fixed and real valued. Let $(\omega, \mathbf{k})$ be a solution to (6.13). We define the relative dispersion error as

$$\mathcal{E}(\omega) = \frac{1}{|\omega|}\det\left(\mathcal{T}_{\Delta t}(\omega) - \mathcal{S}_h(\mathbf{k})\mathbb{P}_1\right) \tag{6.14}$$

which is analogous to a local truncation error, i.e., we measure how close the true root ω of the continuous dispersion relation (6.13) is to being a root of the numerical dispersion relation (6.12). We parameterize the wave vector as $\mathbf{k} = 4(\cos\theta, \sin\theta)$. For this experiment we will also choose $\omega_i = 1$ and $\omega_p = 1$. In Figure 3 we plot $\mathcal{E}(\omega)$ as a polar function of θ on a log scale. A perfect circe in this diagram indicates isotropic error, otherwise the error shows the directional dependence of dispersion. For the purpose of comparison we also include the relative dispersion error of ETD in time and Yee like staggering in space, which we refer to as the ET-Yee scheme.

Figure 3 illustrates that while the dispersion error of our method is anisotropic it is significantly reduced compared to that of the ET-Yee scheme. By varying the aspect ratio we find that we can reduce dispersion error in the direction of increased refinement at the expense of increased dispersion error in the less refined direction.

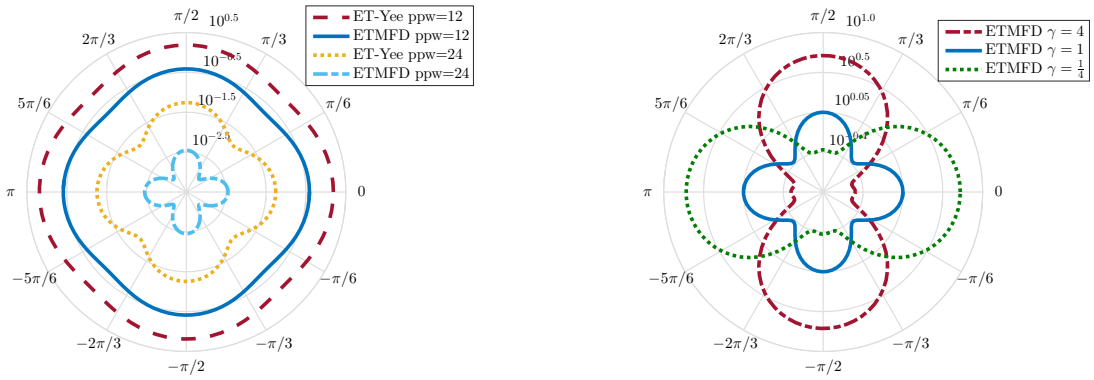
Experiment 2. In our second experiment we will investigate the accuracy of our ETMFD method for discretizing problems with a known exact solution. For $\mathbf{k} = (k_x, k_y)^T$ with $k_x, k_y \in \pi\mathbb{Z}$, let $a + \mathrm{i}b = \omega$ be a (complex) root of the dispersion relation (6.13). We consider the exact solution for the Maxwell-CP model given by

$$\mathbf{E}(x, y, t) = \mathrm{e}^{at}\cos(bt)\begin{pmatrix} -k_y\cos(k_x x)\sin(k_y y) \\ k_x\sin(k_x x)\cos(k_y y)\end{pmatrix}, \tag{6.15}$$

$$\mathbf{J}(x, y, t) = \epsilon_0\omega_p^2\mathrm{e}^{at}\frac{(a+\omega_i)\cos(bt) + b\sin(bt)}{b^2 + (a+\omega_i)^2}\begin{pmatrix} -k_y\cos(k_x x)\sin(k_y y) \\ k_x\sin(k_x x)\cos(k_y y)\end{pmatrix}. \tag{6.16}$$

For our experiments we consider $\omega_P = \omega_i = \epsilon_0 = c = 1$ and $k_x = k_y = \pi$. For this we have $a \approx 0.023$ and $b \approx 4.55$. We choose the final time to be $T = 4$. To calculate relative L^2 errors we use an appropriate inner product, based on our mimetic discretization, which is defined as

$$\mathcal{E}_{L^2}^h(\mathbf{F}_h^n) := \frac{\sqrt{(\mathbf{F}_h^n - \mathcal{I}^{\mathscr{E}_h}(\mathbf{F}(n\Delta t))^T\mathbb{M}_{\mathscr{E}}(\mathbf{F}_h^n - \mathcal{I}^{\mathscr{E}_h}(\mathbf{F}(n\Delta t))}}{\sqrt{\mathcal{I}^{\mathscr{E}_h}(\mathbf{F}(n\Delta t))^T\mathbb{M}_{\mathscr{E}}\mathcal{I}^{\mathscr{E}_h}(\mathbf{F}(n\Delta t))}}, \tag{6.17}$$



(a) (b)

Figure 3: We consider a cold isotropic plasma with $\omega_P = 1$ and $\omega_i = 1$. Figure (a) plots relative dispersion error for a wave with $k = 4$ and resolved at 12 and 24 points per wavelength on a mesh with an aspect ratio $\gamma = 1$ for both the ET-Yee and ETMFD schemes. We choose the Courant number to be $\nu = \frac{1}{2}$. Figure (b) plots the relative dispersion error for a cell with $\Delta x \Delta y = 12^{-2}$ for the aspect ratios $\gamma = 4, 1, \frac{1}{4}$. In this case we choose the Courant number to be $\nu = \frac{1}{2}\min\{\gamma^3, 1\}$.

where $\mathbf{F}_h^n = (\mathbf{E}_h^n, \mathbf{J}_h^n)^T$ and the interpolation $\mathcal{I}^{\mathscr{E}_h}$ operator is defined in (3.3).

To define the dispersion error we fit an appropriate temporal function, $F(t : \omega_h)$, to temporal grid data $\{\mathbf{E}_{h,e_i}^n\}_{n=0}^N$ at some edge e_i to find the best discrete frequency w_h. To calculate the relative dispersion errors, we perform the following procedure. If (a_h, b_h) is the result of the non-linear least squares fitting of time tracking data $\{\mathbf{F}_{h|e}^n\}_{n=1}^N$ to the appropriate function $(\exp(a_h t)\cos(b_h t)$ for the electric field and $\epsilon_0\omega_p^2 \mathrm{e}^{a_h t}\frac{(a_h+\omega_i)\cos(b_h t)+b_h \sin(b_h t)}{b_h^2+(a_h+\omega_i)^2}$ for the current density) then we define the relative dispersion error by

$$\mathcal{E}_d^h(\mathbf{F}_h) := \sqrt{\frac{(a-a_h)^2 + (b-b_h)^2}{a^2+b^2}}, \tag{6.18}$$

where a, b are the true data. For comparison, we have also performed our simulations with the corresponding ET-Yee scheme (i.e., Yee spatial staggering with ETD), which is second order accurate in space and time. In Table 1 we present relative L^2 errors in the electric field and polarization density, while in Table 2 we present relative dispersion errors for the electric field and polarization density, respectively. Figures 4, and 5 plot the results of Tables 1-2. Our results indicate fourth order dispersion and L^2 error convergence for the ETMFD as compared to the corresponding (well known) second order convergence for the ET-Yee scheme.

7 Conclusions

We have constructed a new successful m-adaptation of Mimetic Finite Difference (MFD) method for Maxwell's equations in a cold plasma. We started from a second order edge based family of MFD discretizations in space. We used a generalized form of mass lumping. This was done, on one hand, to obtain a fully explicit scheme, thus avoiding linear solves at every time step. As a result the new scheme is highly efficient. On the other hand, the generalized form of mass lumping preserves free parameters in the MFD discretization. This allows for further optimization within the family.

We demonstrated that using the standard leapfrog time stepping does not allow reduce the numerical dispersion within the MFD family. Fortunately, using exponential time differencing

allows for a successful m-adaptation of the MFD family. For the optimal choice of parameters in the exponential time MFD (ETMFD) discretization the numerical dispersion errors were shown to be fourth order as opposed to second order for a general member of the ETMFD family. Numerical simulations independently verified our theoretical results showing fourth order numerical dispersion and L^2-errors for some special solutions.

One of the advantages of our m-adapted ETMFD method over other fourth order methods, that have been constructed in the literature using the modified equation approach (see e.g. [9]), is smaller stencil size as compared to those of other fourth order methods. This is due to the low order base discredization. Higher order approximation is a result m-adaptation procedure, which is possible due to mesh regularity and symmetry.

The use of ETD offers a number of advantages in complex dispersive media. First, it allows for an explicit staggering of the electric field and current density from the magnetic field. This is in contrast to time averaging schemes which are semi-implicit with spatial staggering. Though ETD may require smaller time steps than a semi-implicit approach, linear dispersive media such as a cold isotropic plasma are stiff media requiring very small time steps in numerical discretizations in order to capture the fast decaying transients in the media. Thus a cheaper explicit scheme is preferable to a more expensive implicit scheme when run with comparable time steps.

Finally, our approach can be interpreted as a generalization (though non-trivial) of m-adaptation in vacuum. It inherits a similar structure for its discrete symbol in time and allows for successful optimization over numerical dispersion errors. As a consequence, the optimal choice of free MFD parameters and the corresponding local mass matrices turn out to be the same in the case of vacuum and Maxwell-CP model. In the future we will investigate the sensitivity of errors to initial conditions and extend the ideas and techniques considered here to other types of linear and nonlinear dispersive materials.

Maxwell's equations include divergence constraints on the electric and magnetic flux densities. It is well known that if solutions satisfy these divergence constraints initially then the curl equations guarantee that these conditions are satisfied at later times. Thus, the divergence constraints are redundant in the continuum equations as long as they are satisfied by initial conditions. This property may or may not hold for solutions to discrete approximations of Maxwell's equations. We are currently working on understanding the divergence properties of our ETMFD method along with a stability analysis of our schemes. These and related issues will be part of a future paper that will address the construction of ETMFD schemes for a large class of linear dispersive models.

A M-Adaptation for leapfrog time stepping

We demonstrate the need for exponential time differencing in the spatially discretized cold plasma model to produce a fully discrete method with high order numerical dispersion by first considering the case of a simple conductive medium. A conductive medium is a special case of CP where we take $\omega_i \to \infty$ and assume the ratio $\epsilon\omega_P^2/\omega_i \to \sigma$ as $\omega_i \to \infty$. A conductive medium is modeled by the second order PDE

$$\frac{\partial^2}{\partial t^2}\mathbf{E} + \frac{\sigma}{\epsilon_0}\frac{\partial}{\partial t}\mathbf{E} = -c_0^2\mathbf{curl}\ \mathrm{curl}\mathbf{E}, \tag{A.1}$$

in which σ is the electrical conductivity. Let $\tau = \frac{\epsilon_0}{\sigma}$. The standard Leapfrog discretization in time with semi-implicit time averaging of the low order term gives us the scheme

$$\frac{\mathbf{E}^{n+1} - 2\mathbf{E}^n + \mathbf{E}^{n-1}}{\Delta t^2} + \frac{\mathbf{E}^{n+1} - \mathbf{E}^{n-1}}{2\tau\Delta t} = -c_0^2\mathbf{curl}\ \mathrm{curl}\mathbf{E}^n. \tag{A.2}$$

The symbol of the time discretization and its expansion in ω is given by

$$\frac{-4\sin^2\frac{\omega\Delta t}{2}}{\Delta t^2} - \frac{\mathrm{i}}{\tau}\frac{\sin\omega\Delta t}{\Delta t} = -\omega^2 - \frac{\mathrm{i}}{\tau}\omega + \frac{\Delta t^2}{12}\omega^2\left(\omega^2 + \frac{2\mathrm{i}}{\tau}\omega\right) + \mathcal{O}(\Delta t^4). \tag{A.3}$$

Defining the Courant number to be $\nu = \frac{c\Delta x}{\Delta t}$, and discretizing in space using the MFD for a rectangular mesh gives us a discrete dispersion relation of the form

$$0 = \frac{-4\sin^2\frac{\omega\Delta t}{2}}{\Delta t^2} - \frac{\mathrm{i}}{\tau}\frac{\sin\omega\Delta t}{\Delta t} - \mathcal{S}_h(\mathbf{k}) \tag{A.4}$$

$$= -\omega^2 - \frac{\mathrm{i}}{\tau}\omega + c_0^2k^2 + \frac{h^2}{12c_0^2}\left(\nu^2\omega^2\left(\omega^2 + \frac{2\mathrm{i}}{\tau}\omega\right) + 12\gamma w_2 c_0^4 k^4\right) + \mathcal{O}(h^4). \tag{A.5}$$

As the whole series must be equal to zero, we have that

$$c_0^2 k^2 = \omega^2 + \frac{\mathrm{i}}{\tau}\omega + \mathcal{O}(h^2). \tag{A.6}$$

Substituting this into the Δx^2 term of the Taylor series we arrive at

$$0 = \frac{h^2}{12c_0^2}\left(\nu^2\omega^2\left(\omega^2 + \frac{2\mathrm{i}}{\tau}\omega\right) - 12\gamma w_2\left(\omega^2 + \frac{\mathrm{i}}{\tau}\omega\right)^2\right) + \mathcal{O}(h^4). \tag{A.7}$$

As

$$\omega^2\left(\omega^2 + \frac{2\mathrm{i}}{\tau}\omega\right) \neq \left(\omega^2 + \frac{\mathrm{i}}{\tau}\omega\right)^2, \forall\omega, \tag{A.8}$$

we cannot choose w_2 independent of ω to eliminate this term in the dispersion error. We consider this a failure as we are interested in time domain schemes that have higher order numerical dispersion error rather than schemes that reduce or eliminate numerical dispersion at a design frequency (though such schemes are of interest in their own right).

Keywords: computational fluid dynamics, multirate time advancing, explicit scheme, volume agglomeration, unstructured grid, hybrid turbulence model.

Abstract. *A frequent configuration in computational fluid mechanics combines an explicit time advancing scheme for accuracy purposes and a computational grid with a very small portion of much smaller elements than in the remaining mesh. Examples of such situations are the traveling of a discontinuity followed by a moving mesh, and the large eddy simulation of high Reynolds number flows around bluff bodies where together very thin boundary layers and vortices of much more important size need to be captured. For such configurations, explicit time advancing schemes with global time stepping are very costly. In order to overcome this problem, the multirate time stepping approach represents an interesting improvement. The objective of such schemes, which allow to use different time steps in the computational domain, is to avoid penalizing the computational cost of the time advancement of unsteady solutions which can become large due to the use of small global time steps imposed by the smallest elements such as those constituting the boundary layers. In the present work, a new multirate scheme based on control volume agglomeration is proposed for the solution of the compressible Navier-Stokes equations possibly equipped with turbulence models. The method relies on a prediction step where large time steps are performed with an evaluation of the fluxes on macro-cells for the smaller elements for stability purpose, and on a correction step in which small time steps are employed only for the smaller elements. The efficiency of the proposed method is evaluated on several benchmarks flows: the problem of a moving contact discontinuity (inviscid flow), the computation with hybrid turbulence model of flows around bluff bodies like a tandem cylinders at Reynolds number* 1.66×10^5 *, a circular cylinder at Reynolds number* 8.4×10^6*, and a flow around a space probe model at Reynolds number* 1×10^6.

1 INTRODUCTION

A frequent configuration in CFD calculations combines an explicit time advancing scheme for accuracy purpose and a computational grid with a very small portion of much smaller elements than in the remaining mesh. Examples of such situations are isolated traveling shock and large eddy simulation of high Reynolds number flows around bluff bodies where very thin boundary layers and vortices of much more important size need to be captured.

For such configurations, explicit time advancing schemes with global time stepping are very costly. In order to overcome this problem, the multirate time stepping approach represents an interesting alternative. By using several different timestep sizes on different subdomains, multirate timestepping avoids to apply too small timesteps in regions where the mesh is rather coarser. Then it avoids to use the small timesteps of boundary layer on the whole domain and thus penalize the global computational cost of the advancement in time of unsteady solutions. Many works have been published on multirate methods in the field of ODE, see for example [1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12], but only few works were conducted on multirate time advancing schemes for the solution of PDE and hyperbolic conservation laws [13, 14, 15, 16, 18, 17], and rare applications were performed in Computational Fluid Dynamics (CFD), for shock propagation in [17] and for shallow water computations in [18, 19]. Therefore, there is still much work to do to provide a viable multirate method for CFD applications. In this work, we propose a new multirate scheme based on control volume agglomeration which is well suited to our numerical framework using a mixed finite volume/finite element formulation. The method relies on a prediction step where large time steps are used with an evaluation of the fluxes performed on the macro-cells for the smaller elements, and on a correction step in which small time steps are employed only for the smaller elements. Target applications are three-dimensional unsteady flows modeled by the compressible Navier-Stokes equations equipped with turbulence models and discretized on unstructured possibly deformable meshes.

2 Multirate time advancing by volume agglomeration

In this section, we present a multirate time advancing scheme based on volume agglomeration which is currently being developed for the solution of the three-dimensional compressible Navier-Stokes equations. The finite-volume spatial discretization combined with an explicit forward-Euler time-advancing is written:

$$vol_i \; w_i^{n+1} = vol_i \; w_i^n \; + \; \Psi_i, \quad \forall \, i = 1, ..., ncell,$$

where vol_i is the volume of $cell_i$, $w_i^n = (\rho_i^n, (\rho u)_i^n, (\rho v)_i^n, (\rho w)_i^n, E_i^n, (\rho k)_i^n, (\rho \varepsilon)_i^n)$ are as usually the density, moments, total energy, turbulent energy and turbulent dissipation at $cell_i$ and time level t^n, and $ncell$ the total number of cells in the mesh.

We assume that we can define a maximal stable time step (*local timestep*) $\Delta t_i, i = 1, ..., ncell$ on each node. This can be based on a stability analysis which in practice takes into account advective terms (condition of Courant-Friedrichs-Lewy or CFL) and diffusive terms of the discrete PDE under study, together with the type of explicit time advancing scheme. In short, using Δt_i is advancing at $CFL = 1$. A consistent time advancing should use for stability a *global time step* $\Delta t = \min_{1,ncell} \; \Delta t_i$. The user is supposed to choose a (integer) *timestep factor* $K \; > \; 1$.

We first define the inner zone and the outer zone, the coarse grid, and the construction of the fluxes on the coarse grid, ingredients on which our multirate time advancing scheme is based.

- **Definition of the Inner and Outer zones** :
  - We define the **outer zone** as the set of cells i for which the explicit scheme is stable for a time step $K\Delta t$
$$\Delta t_i \ \geq \ K\Delta t,$$
  - the **inner zone** is the set of cells for which
$$\Delta t_i \ < \ K\Delta t.$$

- **Definition of the coarse grid** :
  - **Objective** :
    - Advancement in time is performed with time step $K\Delta t$
    - Advancement in time preserves accuracy in the outer zone (space order of 3, Runge-Kutta 4)
    - Advancement in time is consistent in the inner zone
  - A **coarse grid** is defined on the inner zone by applying cell agglomeration in such a way that on each macro-cell, the maximal local time step is at least $K\Delta t$. Agglomeration consists in considering each cell and aggregating to it neigboring cells which are not yet aggregated to an other one (Figure 1). Agglomeration into macro cell is re-iterated until macro-cells with maximal timestep smaller then $K\Delta t$ have disappeared.
  - **Time-advancing on the macro-cells** :
    - We advance in time the chosen explicit scheme (Runge-Kutta 4 in our examples) on the coarse grid with $K\Delta t$ as time step
    - A flux smoothing can be performed on the macro cells for stability purpose.

- **Construction of the flux on the coarse grid**
  - The nodal fluxes Ψ_i are assembled on the fine cells (as usual)
  - Fluxes are summed on the macro-cells I (inner zone) :
$$\Psi^I = \sum_{k \in I} \Psi_k \tag{1}$$
  - Possibly smoothing of the coarse flux (inner zone) :
$$\Psi^I = (\sum_{K \in \mathcal{V}(I)} \Psi^K vol^K)/(\sum_{K \in \mathcal{V}(I)} vol^K) \tag{2}$$

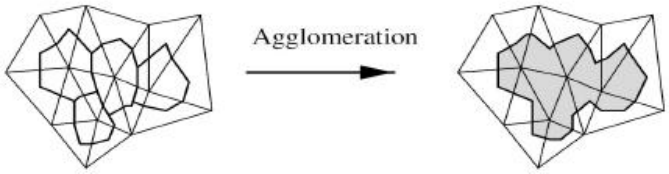

Figure 1: Sketch (in 2D) of the agglomeration of 4 cells into a macro-cell. Cells are dual cells of triangles, bounded by sections of triangle medians.

The multirate algorithm is then based on a **prediction step** and a **correction step** as defined hereafter :

Step 1 (prediction step) :
The solution is advanced in time with time step $K\Delta t$, on the macro cells in the inner zone and on the fine cells in the outer zone :

For $\alpha = 1, RKstep$

$$\text{outer zone :} \quad vol_i w_i^{(\alpha)} = vol_i w_i^{(0)} + b_\alpha K\Delta t \; \Psi_i^{(\alpha-1)} \tag{3}$$

$$\text{inner zone :} \quad vol^I w^{I,(\alpha)} = vol^I w^{I,(0)} + b_\alpha K\Delta t \; \Psi^{I,(\alpha-1)} \tag{4}$$

$$w_i^{(\alpha)} = w^{I,(\alpha)} \quad \text{for } i \in I \tag{5}$$

EndFor α.

Step 2 (correction step) :

- The unknowns are frozen in the outer zone at level $t^n + K\Delta t$.
- The outer unknowns near the boundary of the outer zone which are necessary for advancing the inner zone are interpolated in time.
- In the inner zone, using these interpolated values, the solution is advanced in time with the chosen explicit scheme and time step Δt.

Remark: The complexity, proportional to the number of points in the inner zone, is therefore mastered.

3 Applications

The multirate algorithm introduced in the previous section was implemented in the parallel CFD code AIRONUM shared by INRIA Sophia-Antipolis, LEMMA company and University of Montpellier. The parallelism relies on mesh partitioning and MPI. A description of this tool, which solves with a mixed element/volume method on unstructured meshes the compressible Euler and Navier-Stokes equations possibly equipped with a turbulence model, can be found in [20] and [21]. When computing hybrid RANS-LES flows, an important part of the mesh is dedicated to the boundary layer and involved possibly very small cells. Another important part of the mesh is dedicated to the capture of vortices with many cells of medium size (possibly 10-100 larger than smaller cells of the boundary layers). In introducing the multirate algorithm, attention was paid to several issues related to parallelism, and in particular a macro-cell belongs to only one subdomain of the partition, and we have optimized the evaluation of the fluxes on the macro-cells located at the boundary between neighboring subdomains. However, in the present phase of the study, no optimization of the MPI partitions for balancing the load in the inner zone has been done.

3.1 Contact discontinuity

In this first example, we consider the case of a moving contact discontinuity. For this purpose, the compressible Euler equations are solved in a rectangular parallelepiped as computational domain where the density is initially discontinuous at its middle (see Figure 2) while moments and pressure are uniform.

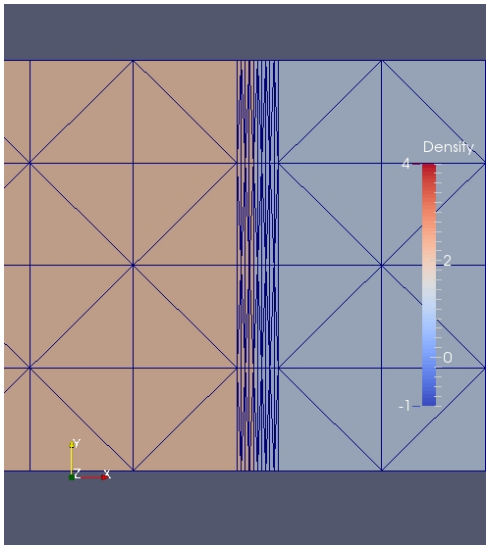

Figure 2: ALE calculation of a traveling contact discontinuity. Instantaneous mesh with mesh concentration in the middle of zoom and corresponding advected discontinuous fluid density.

The uniform velocity is a purely horizontal one. As can be seen in Figure 2, small cells are present on either side of the disconstinuity. The mesh moves during the computation in such a way that the nodes located at the discontinuity are still the same, and that the number of small cells are equally balanced on either side of the discontinuity. An Arbitrary Lagrangian-Eulerian formulation is then used to solve the Euler equations on the resulting deforming mesh. Our long term objective is to combine the multirate time advancing with a mesh adaptation algorithm in such a way that the small time steps imposed by the necessary good resolution of

the discontinuity remain of weak impact on the global computational time.

The mesh used in this simulation contains 25000 nodes and 96000 tetrahedra. The computational domain is decomposed into 2 subdomains. When integer K, used for the definition of the inner and outer zones, is set to 5, 10 and 15, the percentage of nodes located in the inner zone is always 1.3%, which corresponds to the vertices of the small cells located on either side of the discontinuity.

The multirate scheme with the aforementioned values of K, as well as a 4-stage Runge-Kutta method, are used for the computation. Each simulation was run over an elapsed time of 10 minutes, and 2 cores were used on a Bullx B720 cluster. This elapsed time corresponds to 2390 time steps for the explicit scheme, and 268, 365 and 536 times steps for K equals 15, 10 and 5, respectively. An improvement in the efficiency of about 1.75, 1.58 and 1.15 is observed when K is set to 15, 10 and 5, respectively.

3.2 Tandem cylinders

Our main study concerning the application of multirate is the calculation of a flow around a tandem cylinders at Reynolds number 1.66×10^5. This was a test case of an AIAA workshop, see [22]. It is a challenging computation since several complex flow features need to be captured around multiple bodies (stagnation zones, boundary layers, shear layers, separations, laminar-turbulent transition, recirculations, vortex sheddings, wakes). Furthermore, small cells are necessary for a proper prediction of the very thin boundary layers, which implies very small global time steps so that classical explicit calculations become very costly. The application of our multirate scheme to the tandem cylinders benchmark is also made more difficult by the fact that we use a hybrid turbulence model based on RANS and VMS-LES approaches, so that additional equations associated with turbulent variables need to be advanced in time.

In order to illustrate the quality of resolution, the Q-criterion isosurfaces are shown in Figure 3. It shows the complex flow features and the very small structures that need to be captured by the numerical model and the turbulence model, which renders this simulation particularly challenging. Further information concerning the comparison between computation and experiments are available in [21].

Two meshes were used for this study : a coarse mesh which contains 2.6 million nodes and 15 million tetrahedra, and a fine mesh with 16 million nodes and 96 million tetraedra. For both the smallest cell thickness is $1.2.10^{-4}$.

- **Coarse mesh**

  The computational domain is decomposed into 192 subdomains. When integer K, used for the definition of the inner and outer zones, is set to 2, 5 and 10, the percentage of nodes located in the inner zone is 4%, 16% and 25%, respectively.

  The lift curve obtained by the multirate scheme with $K = 10$ and the explicit scheme corresponding to half of a period of vortex shedding for the first cylinder is given in Figure 4. The underlying explicit scheme is the 4-stage Runge-Kutta method and the CFL number was set to 1. Each simulation was left running over an elapsed time of 40 hours. A number of 192 cores on a Bullx B720 cluster was used to perform these computations. One can check that the responses given by the two schemes are close to each other, except for the oscillations at the top of the lift curve for the multirate method that are an unproperly controlled restart in the simulation. The number of time steps is 15284 for the multirate

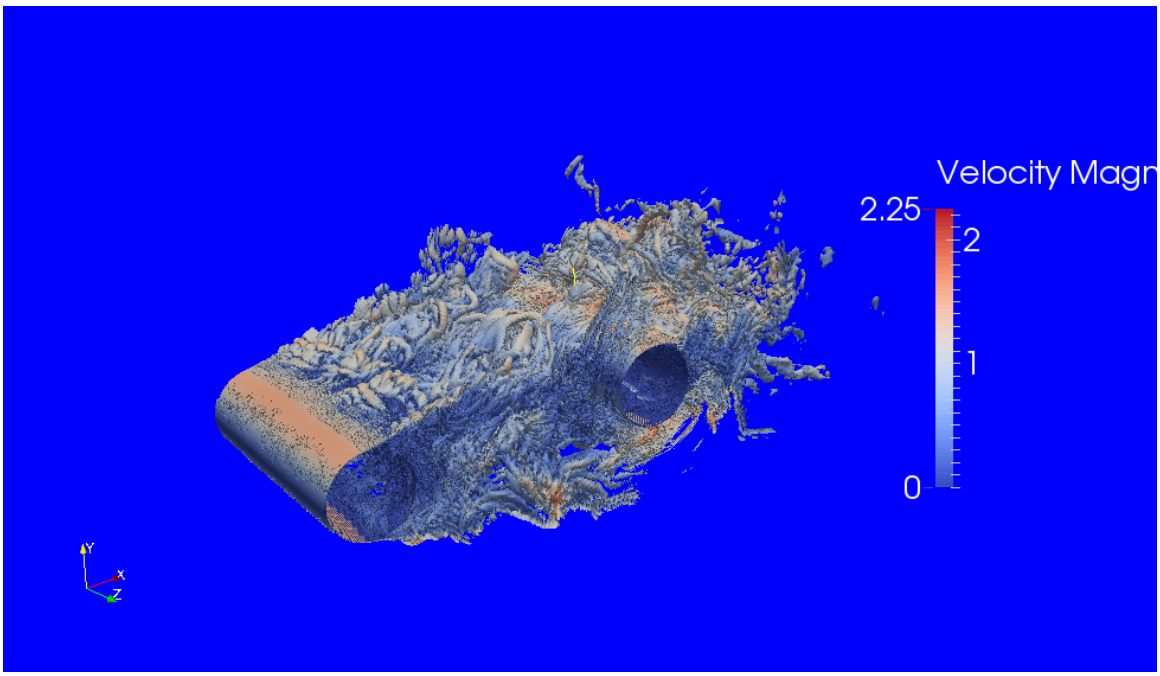

Figure 3: Tandem cylinders at Reynolds number 1.66×10^5: instantaneous Q-criterion isosurfaces (coloured with velocity modulus).

scheme and 132531 for the classical explicit scheme. From Figure 4, an improvement in the efficiency of about 1.14 is observed when the multirate scheme is used in our parallel solver. This rather slight improvement in efficiency can be explained by the fact that some of the subdomains almost contain only inner nodes so that workload is not equally shared by each computer core when the proposed multirate approach is used. Indeed, in our parallel strategy which is based on a decomposition of the computational domain in subdomains, designed to minimize the inter-core communications, and on a message passing parallel programming (MPI) model, each subdomain is assigned to a computer core. It is clear that in order to further increase the efficiency of the multirate approach in our parallel computing framework, the domain decomposition needs to be adapted.

Based on the fact that the cost per node in these explicit simulations is essentially due to the computation of the convective and diffusive fluxes, we can deduce that, for the multirate simulation that was performed and which involves $K = 10$ and 25% of the nodes located in the inner zone, the benefit-cost ratio between the multirate scheme and the classical 4-stage Runge-Kutta method would be 3 from a sequential computation.

In a second step, the multirate simulation is carried out with $K = 5$ for the same benchmark, which means that the RK4 scheme is now performed with time steps $5\Delta t$ and Δt for the nodes located in the outer zone and the nodes located in the inner zone, respectively. The lift curve obtained by the multirate scheme with $K = 5$ and $K = 10$ for the first cylinder is depicted in Figure 5. Both simulations were left running over an elapsed time of 20 hours, which allows to simulate a quarter of a period of vortex shedding with a CFL number set to 1. One can notice that the response is similar, as expected, for both values of K, and that the efficiency is improved by a factor 1.09 when the multirate scheme is used with $K = 10$ in our parallel solver. From a sequential point of view, we can also deduce that the cost of the multirate scheme with $K = 5$ and $K = 10$ would be

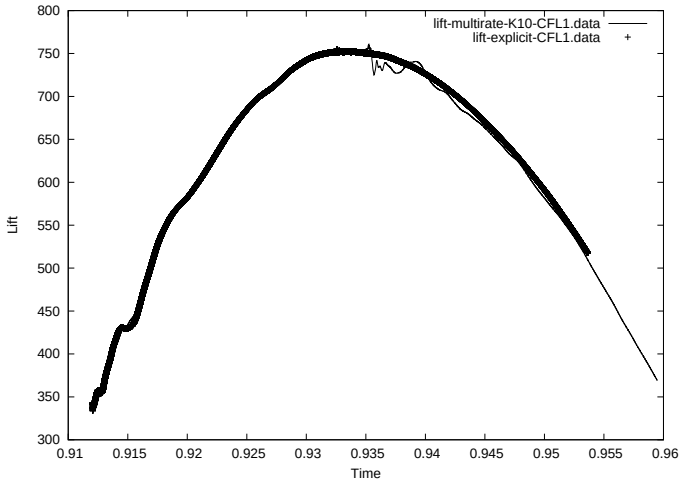

Figure 4: Coarse mesh - Tandem cylinders at Reynolds number 1.66×10^5 : lift curve for the first cylinder, multirate scheme (K=10) and explicit RK4 scheme, corresponding to an elapsed time of 40 hours.

of the same order.

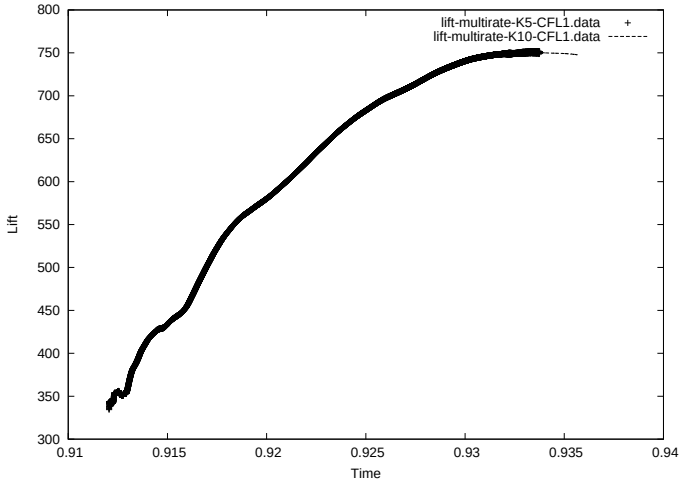

Figure 5: Coarse mesh - Tandem cylinders at Reynolds number 1.66×10^5 : lift curve for the first cylinder, multirate scheme with K=5 and K=10, corresponding to an elapsed time of 20 hours.

- **Fine mesh:**

The computational domain is decomposed into 768 subdomains. When integer K, used for the definition of the inner and outer zones, is set to 5, 10 and 20, the percentage of nodes located in the inner zone is 18%, 24% and 35%, respectively.

The lift curve obtained by the multirate scheme with $K = 5$, $K = 10$, and $K = 20$, and by the explicit scheme, is shown in Figure 6. The underlying explicit scheme is the 4-stage

Runge-Kutta method and the CFL number was set to 1. Each simulation was left running over an elapsed time of 1 hour. A number of 768 cores on the Bullx cluster was used to perform these computations.

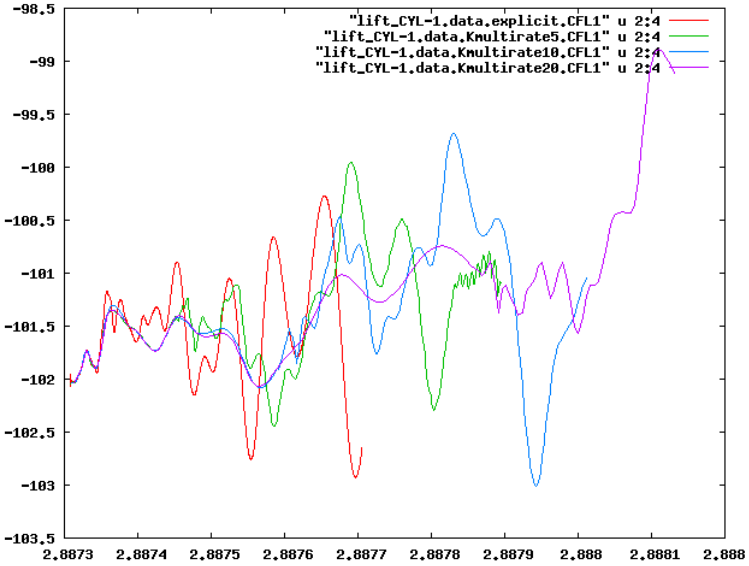

Figure 6: Fine mesh - Tandem cylinders at Reynolds number 1.66×10^5 : lift curve for the first cylinder, multirate scheme ($K = 5$, $K = 10$, $K = 20$) and explicit RK4 scheme, corresponding to an elapsed time of 1 hour.

One can observe that the lift curves quickly become different between the various options because of differences in the time step size and the rapidly fluctuating small scales that can be captured by this fine mesh. These differences affect the instantaneous solution but do not notably affect the flow statistics. From this Figure, an improvement in the efficiency of a factor slightly greater than 2 is observed when the multirate option is used with $K = 20$ compared to the classical 4-stage Runge-Kutta explicit scheme. For $K = 5$ and $K = 10$ this improvement becomes 1.5 and 1.8, respectively (see Figure 7). The better efficiency observed with the fine mesh compared to the coarse mesh is certainly due to a better distribution of the workload among the cores when the multirate approach is used.

As for the coarse mesh, the benefit-cost ratio between the multirate scheme and the classical 4-stage Runge-Kutta method would be 3 from a sequential point of view.

3.3 Circular cylinder

The third application concerns the simulation of the flow around a circular cylinder at Reynolds number 8.4×10^6. As for the previous benchmark, the computational domain is made of small cells around the body in order to allow a proper representation of the very thin boundary layer that occurs at such a high Reynolds number. On the other hand, the same hybrid RANS/VMS-LES model as that of the previous benchmark is used to compute this flow, which implies again that both the fluid and turbulent variables need to be advanced by the time integration scheme, and therefore also the multirate method.

Figure 8 depicts the Q-criterion isosurfaces and shows the very small and complex structures that need to be captured by the numerical and the turbulence models, which renders this simulation very challenging.

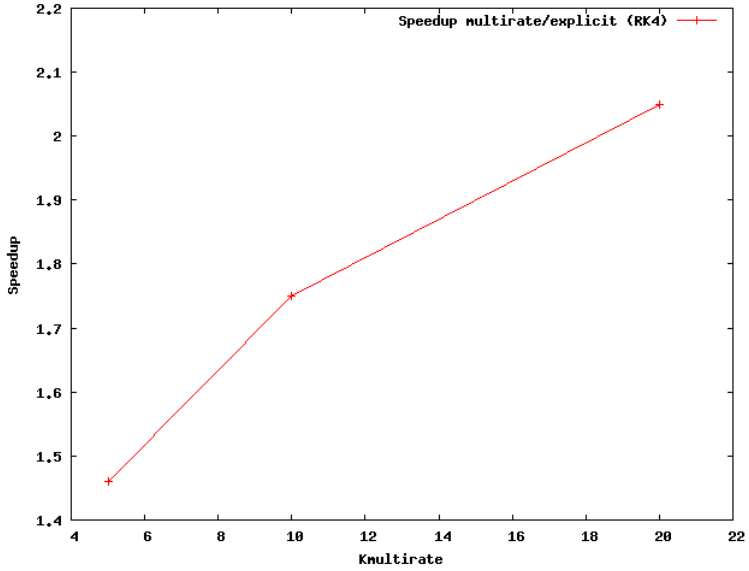

Figure 7: Fine mesh - Tandem cylinders at Reynolds number 1.66×10^5 : speedup multirate/explicit (RK4).

The mesh used in this simulation contains 4.3 million nodes and 25 million tetrahedra. The smallest cell thickness is $2.5.10^{-6}$. The computational domain is decomposed into 768 subdomains. When integer K, used for the definition of the inner and outer zones, is set to 5, 10 and 20, the percentage of nodes located in the inner zone is 15%, 19% and 24%, respectively.

The lift curve corresponding to the explicit scheme and the multirate option with $K = 20$ is shown in Figure 9. The explicit scheme is the 4-stage Runge-Kutta method. Each simulation was left running over an elapsed time of 20 minutes, and 768 cores were used on a Bullx B720 cluster. The number of time steps is 175 for the multirate scheme and 2153 for the explicit method. From Figure 9, we deduce an improvement in the efficiency of about 1.62 when the multirate scheme is used with $K = 20$, as compared with 3 which would be, from a sequential point of view, the ideal benefit-cost ratio between the multirate scheme, with $K = 20$ and 24% of the nodes located in the inner zone, and the explicit scheme. This result in efficiency is pretty good, considering the fact that the domain decomposition does not equally share the number of inner nodes between the subdomains, as noticed in the previous section.

The multirate simulation was also carried out for $K = 5$ and $K = 10$, which means that the time step ratio between the outer zone and the inner zone is 5 and 10, respectively. The efficiency is then improved by a factor 1.25 ($K = 5$), 1.46 ($K = 10$) and 1.62 for $K = 20$.

3.4 Spatial probe

The last case is the supersonic flow around a probe model for Exomars (see for example [23]). We choose a Reynolds number of 1 million. Delicate features in this simulation are a separation arising on a highly curved wall and relatively large recirculation zone at afterbody. Hybrid RANS-LES calculation brings more information than pure RANS does. The mesh involves $4,380000$ cells and the smallest mesh thickness is 2.10^{-5}. A sketch of this flow is presented in Figure 10. The impact of multirate on accuracy is very low (Figure 11). The gain in efficiency varies from 2.18 with $K = 10$ and 56 cells in the inner zone to a maximum of 2.89 with $K = 40$ and 151 cells in the inner zone. For $K = 40$, only 15 subdomains have inner cells (mean number 15 inner cells).

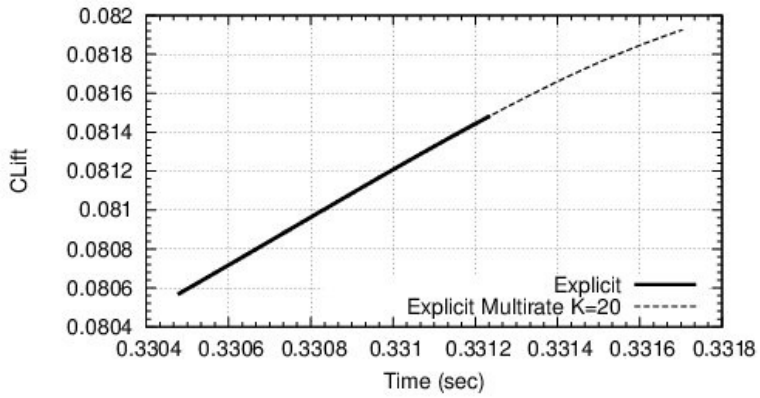

Figure 9: Circular cylinder at Reynolds number 8.4×10^6 : comparison of lift coefficient curves for explicit (bold line) and multirate (dashes) .

4 Conclusion

A new multirate strategy is proposed in this work. The method is based on control volume agglomeration, and relies on a prediction step where large time steps are used and where the fluxes for the smaller elements are evaluated on macro cells for stability purpose. A correction step follows in which only the smaller elements are advanced in time with a small time step. Preliminary results are given. They show that the proposed multirate strategy can be applied in complex CFD problems such as the prediction of three-dimensional flows around bluff bodies with complex hybrid turbulence models. Nevertheless, there is still work to do to obtain an

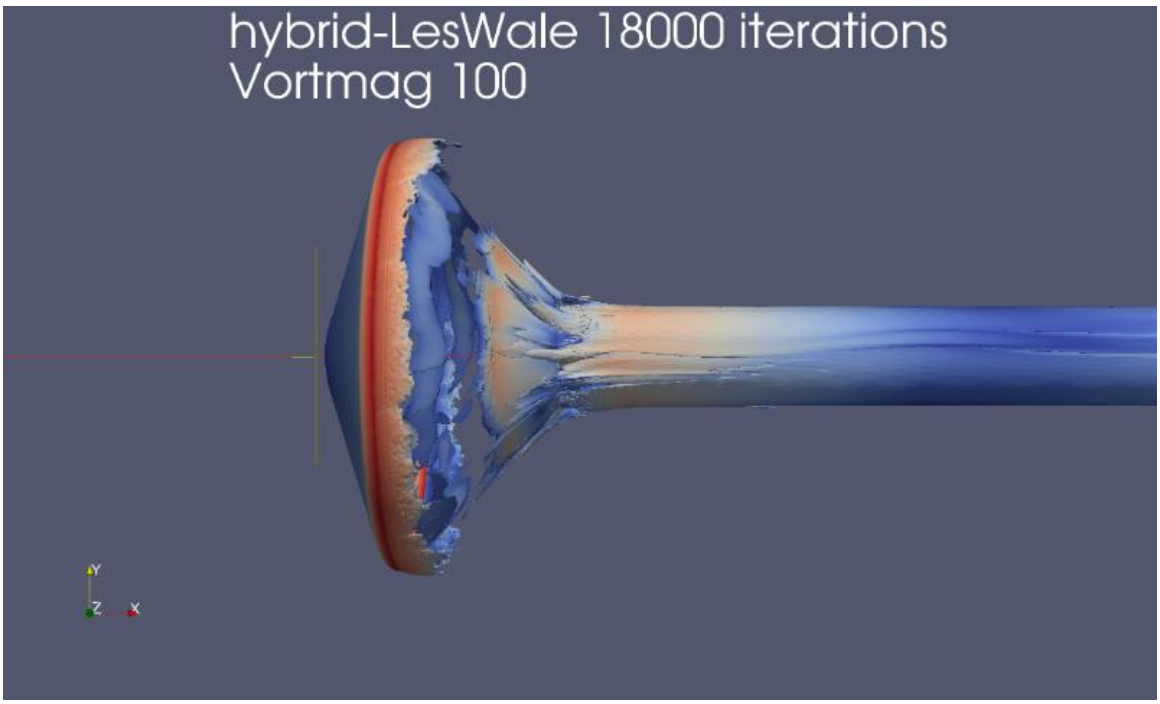

Figure 10: Flow around a probe model at Reynolds number 1 million. Q criterion.

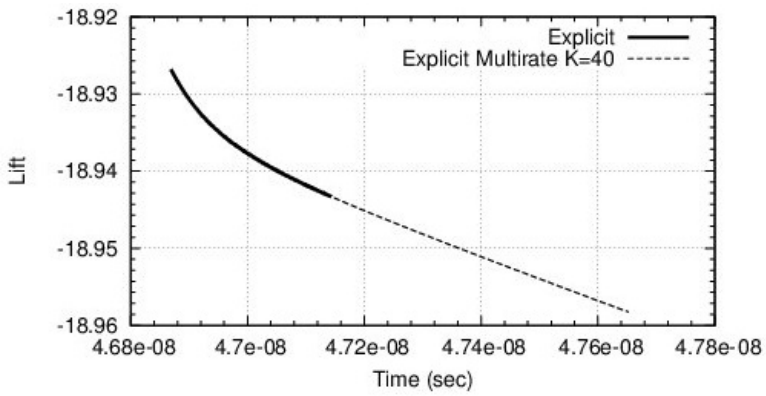

Figure 11: Flow around a probe model at Reynolds number 1 million. Impact of multirate on instantaneous lift accuracy.

efficient multirate method in a parallel numerical framework. Indeed, at the present time, the domain decomposition into subdomains is designed to minimize the inter-core communications. We need to adapt the domain decomposition in such a way that the workload becomes shared equally for both Step1 and Step2 of the multirate.

Keywords: Thermomechanics, Finite volume method, Impacts, Thermo-elastic-plastic solids.

Abstract. *We present in this work two implementation schemes of the finite volume method for the numerical simulation of impacts on thermo-elastic-plastic solids within the small strain framework for one dimension (bar) solid media, based on the Lax-Wendroff and high (second) order TVD methods. A strong thermomechanical coupling and adiabatic conditions are assumed. Comparison is performed with results obtained with the classical finite element method and an analytical solution on a test case involving a discontinuous solution. The finite volume methods (mainly the high order TVD one) improve both the track of the shock wave path, even after many reflexions of waves, and the computation of plastic strains and temperature.*

1 INTRODUCTION

The modelling and numerical simulation of hyperbolic initial boundary value problems including extreme loading conditions such as impacts require the ability to accurately capture and track the wave front of shock waves induced in the medium. Indeed, this permits to both understand correctly the path of waves and assess accurately the field of plastic strains and hence that of residual stresses within a structure. These problems require therefore numerical schemes able to meet high orders of accuracy and a high resolution of discontinuity without any spurious oscillations.

The numerical simulation of impacts on dissipative solids has been and is again mainly performed with the classical finite element method implemented in many industrial codes. However, finite elements do not use any feature of the characteristic structure of the set of hyperbolic equations, and the amount of artificial viscosity added to numerical time integrators is hard to assess properly in order to remove the sole spurious oscillations. Hence, a poor resolution of discontinuity and track of the wave path is generally achieved.

The finite volume method, initially developed for the simulation of gas dynamics [1], has gained recently more and more interest for problems involving impacts on solid media. The characteristic structure of the set of hyperbolic equations can be accounted for by the solution of a Riemann problem at interfaces between cells, and the same order of convergence is achieved for both the displacement and stress fields [2]. Several authors [3, 4, 5, 6, 7] have proposed many ways to simulate impacts on dissipative solid media such that elastic-plastic solids.

In this work, we use the finite volume method for the numerical simulation of impacts on thermo-elastic-plastic solids within the small strain framework in one dimension (actually bars here), and compare it to results obtained with the classical finite element method. First, the set of equations considered are presented in section 2. Since the material is deformed at high strain rate, adiabatic conditions are assumed to compute the rise of temperature, and the thermal softening is accounted for. Next, two implementations schemes of the finite volume method for this kind of material are presented in section 3: the Lax-Wendroff method and a high-order TVD method using the Superbee limiter. Then, the finite volumes numerical solutions are compared to the results of the finite element method and to an analytical solution of a test case involving a discontinuous solution in section 4.

2 INITIAL BOUNDARY VALUE PROBLEM FOR A THERMO-ELASTIC-PLASTIC MATERIAL IN ONE DIMENSION

We consider in this work a unidimensional initial boundary value problem written for a thermo-elastic-plastic material within the linearized small strain framework. The set of conservation laws reads:

$$\frac{\partial \mathbf{u}}{\partial t} + \frac{\partial \mathbf{f}(\mathbf{u})}{\partial x} = \mathbf{0} \quad \forall x \in]0, L[\tag{1}$$

within a domain of length L, the unknown vector $\mathbf{u}$ and the flux $\mathbf{f}(\mathbf{u})$ are defined as

$$\mathbf{u} = \begin{bmatrix} \sigma \\ v \end{bmatrix} \; ; \quad \mathbf{f} = \begin{bmatrix} -Hv \\ -\sigma/\rho \end{bmatrix} \tag{2}$$

where ρ is the mass density, and σ and v denote the axial stress and velocity components respectively. The conservations laws (1) should be supplemented with appropriate boundary and initial conditions. For a purely elastic material, the modulus H is equal to the Young's modulus

E. For an elastic-plastic material, the modulus H stands for the tangent modulus:

$$\frac{d\sigma}{d\varepsilon} = \frac{EQ}{E+Q} \tag{3}$$

In this work, an elastic-plastic material with a linear isotropic material is considered. Moreover, the influence of the thermal part on the mechanical part is accounted for through thermal softening via a linear decrease of the tensile yield stress with the temperature. The constitutive set of equations are listed below:

$$\dot{\varepsilon} = \dot{\varepsilon}^e + \dot{\varepsilon}^p \tag{4}$$

$$\dot{\sigma} = E\dot{\varepsilon}^e \tag{5}$$

$$\dot{\varepsilon}^p = \dot{p}\ \text{sign}(\sigma) \tag{6}$$

$$f = |\sigma| - (\sigma_0 + Qp)\left(1 - A\frac{(T-T_0)}{T_0}\right) \leq 0 \tag{7}$$

$$\dot{p} \geq 0;\ f \leq 0; f\dot{p} = 0 \tag{8}$$

where the equations (4), (5), (6), (7) and (8) refer to the additive partition of the total strain rate ($\dot{\varepsilon}$) into elastic ($\dot{\varepsilon}^e$) and plastic ($\dot{\varepsilon}^p$) parts, the elastic law, the plastic flow rule, the criterion and the Kuhn-Tucker complementary conditions. In (6), $\dot{p}$ denotes the rate of cumulated plastic strain. The tensile yield stress in (7) involve the initial tensile yield stress σ_0, a strain hardening modulus Q, a decrease coefficient A and the reference temperature T_0. The temperature is solution of the heat equation, assuming adiabatic conditions, written with the sole mechanical dissipation on the right hand side:

$$\rho C\dot{T} = \sigma\dot{\varepsilon}^p - Qp\dot{p} \tag{9}$$

where C is the thermal heat capacity.

3 FINITE VOLUME METHODS

The finite volume methods are based on subdividing the spatial domain into grid cells [1] of length Δx, and defining the approximation $\mathbf{U}_i$ of $\mathbf{u}$ within the i^{th} grid cell by integral averaging. These are then updated using the conservation laws (2) written in integral form on one cell, generally coupled with an explicit time integration scheme. We present here the application of the Lax-Wendroff method and a high-order Total Variation Diminishing (TVD) method using the Superbee limiter, to a thermo-elastic-plastic material.

3.1 LAX-WENDROFF

The Lax-Wendroff method is a second order accurate method, presented here in its Richtmyer two-steps version. The first step amounts to approximate $\mathbf{u}$ at the midpoint in time $t_{n+1/2} = t_n + \Delta t/2$ (n referring to the time step number) by:

$$\mathbf{U}_{i+\frac{1}{2}}^{n+\frac{1}{2}} = \frac{\mathbf{U}_i^n + \mathbf{U}_{i+1}^n}{2} + \frac{\Delta t}{2\Delta x}(\mathbf{F}_i^n - \mathbf{F}_{i+1}^n) \tag{10}$$

The second step requires to evaluate the flux at this point

$$\mathbf{F}_{i+\frac{1}{2}}^n = \mathbf{f}\left(\mathbf{U}_{i+\frac{1}{2}}^{n+\frac{1}{2}}\right) \tag{11}$$

in order to update the unknowns at time t_{n+1} with the following conservative scheme:

$$\mathbf{U}_i^{n+1} = \mathbf{U}_i^n - \frac{\Delta t}{\Delta x}\left(\mathbf{F}_{i+\frac{1}{2}}^n - \mathbf{F}_{i-\frac{1}{2}}^n\right) \tag{12}$$

For implementing a thermo-elastic-plastic material, a dedicated Riemann solver should be considered. First, at each step of the Richtmyer algorithm, a prediction-correction scheme should be set in order to handle the Kuhn-Tucker complementary conditions (8). An elastic constitutive behaviour is first assumed, leading to an elastic trial solution. For the first Richtmyer step, it comes:

$$\left(\sigma_{i+\frac{1}{2}}^{n+\frac{1}{2}}\right)^{\text{trial}} = \frac{\sigma_i^n + \sigma_{i+1}^n}{2} + \frac{c_e^2 \Delta t}{2\Delta x}(\rho v_{i+1}^n - \rho v_i^n) \tag{13}$$

$$v_{i+\frac{1}{2}}^{n+\frac{1}{2}} = \frac{v_i^n + v_{i+1}^n}{2} + \frac{\Delta t}{2\Delta x}\left(\frac{\sigma_{i+1}^n - \sigma_i^n}{\rho}\right) \tag{14}$$

where c_e stands for the elastic sound speed defined by $c_e = \sqrt{E/\rho}$, generally set to $\Delta t/\Delta x$ if the Courant number is set at one. Then, the criterion (7) is computed with that trial state within the grid cells i and $i+1$, provided their respective cumulated plastic strain values p_i^n and p_{i+1}^n and temperature values T_i^n and T_{i+1}^n at time t_n. Two cases thus arise for each grid cell: either the plastic criterion is satisfied, and hence the evolution is actually elastic $\sigma_{i+1/2}^{n+1/2} = \left(\sigma_{i+1/2}^{n+1/2}\right)^{\text{trial}}$, or the plastic criterion is violated $f\left(\left(\sigma_{i+1/2}^{n+1/2}\right)^{\text{trial}}\right) > 0$, and a plastic correction needs to be carried out. In the latter case, the plastically admissible stress state should be computed by matching the elastic-plastic Riemann invariants defined on the two integral curves passing by the states of the grid cells i and $i+1$ at time t_n:

$$v_{i+\frac{1}{2}}^{n+\frac{1}{2}} = v_i^n + \frac{\Delta x}{\Delta t}\left(\int_{\sigma_i^n}^{\sigma_i^*} \frac{d\sigma}{\rho c^2} + \int_{\sigma_i^*}^{\sigma_{i+\frac{1}{2}}^{n+\frac{1}{2}}} \frac{d\sigma}{\rho c^2}\right) \tag{15}$$

$$v_{i+\frac{1}{2}}^{n+\frac{1}{2}} = v_{i+1}^n - \frac{\Delta x}{\Delta t}\left(\int_{\sigma_{i+1}^n}^{\sigma_{i+1}^*} \frac{d\sigma}{\rho c^2} + \int_{\sigma_{i+1}^*}^{\sigma_{i+\frac{1}{2}}^{n+\frac{1}{2}}} \frac{d\sigma}{\rho c^2}\right) \tag{16}$$

where σ_i^* and σ_{i+1}^* stand for the tensile yield stress in each grid cell at time t_n if the trial state did not satisfy the plastic criterion, or are equal to σ_i^n (resp. σ_{i+1}^n) if the plastic criterion has been satisfied. At one cell interface $i+1/2$, the plasticity can develop from its left side, from its right side, or from both. Hence the stress at this interface is updated based on the criterion assessed at the two grid cells:

$$\sigma_{i+\frac{1}{2}}^{n+\frac{1}{2}} = \frac{1}{\frac{1}{\rho c_i^2} + \frac{1}{\rho c_{i+1}^2}}\left(\frac{\sigma_i^*}{\rho c_i^2} + \frac{\sigma_{i+1}^*}{\rho c_{i+1}^2} + \frac{1}{\rho c_e^2}(\sigma_i^n + \sigma_{i+1}^n - \sigma_i^* - \sigma_{i+1}^*) + \frac{\Delta t}{\Delta x}(v_{i+1}^n - v_i^n)\right) \tag{17}$$

where c_i and c_{i+1} denote the sound speed at grid cell i and $i+1$. These are equal to c_e if the evolution is elastic, or c_p the plastic sound speed ($= \sqrt{(d\sigma/d\varepsilon)/\rho}$) if the evolution is elastic-plastic. The second step of the Richtmyer algorithm is also based on a prediction-correction scheme; the trial state is obtained via the conservative formula (12). This trial state is also tested with the plastic criterion within each grid cell provided its cumulated plastic strain value

p_i^n and temperature value T_i^n, and the same reasoning is applied. Once the stress have been updated at time t_{n+1}, the cumulated plastic strain are updated using the criterion (7), and hence the plastic strains through the plastic flow rule (6). The temperature is updated at the end of the time step through an implicit time discretization of (9):

$$T_i^{n+1} = T_i^n + \frac{1}{\rho C}(\sigma_i^{n+1}\Delta\varepsilon_i^p - Qp_i^{n+1}\Delta p_i) \tag{18}$$

3.2 HIGH-ORDER TVD METHODS

The high order Total Variation Diminishing methods enable to meet both high order of accuracy in smooth regions and a high resolution of discontinuity without any spurious oscillations where shocks arise in the solution. Their strength relies on their ability to introduce a controlled amount of numerical viscosity locally, so that to adapt to the local regularity of the solution. Following [1] and [4], the conservative formula (12) can be rewritten in term of flux-difference splitting, plus some additional flux to reach higher order of accuracy:

$$\mathbf{U}_i^{n+1} = \mathbf{U}_i^n - \frac{\Delta t}{\Delta x}\left(\mathcal{A}^+\mathbf{U}_{i-\frac{1}{2}}^n + \mathcal{A}^-\mathbf{U}_{i+\frac{1}{2}}^n\right) - \frac{\Delta t}{\Delta x}\left(\tilde{\mathbf{F}}_{i+\frac{1}{2}}^n - \tilde{\mathbf{F}}_{i-\frac{1}{2}}^n\right) \tag{19}$$

where $\mathcal{A}^+\mathbf{U}_{i-1/2}^n = \sum_{p=1}^m (\lambda_{i-1/2}^{(p)})^+ \mathcal{W}_{i-1/2}^{(p)}$ and $\mathcal{A}^-\mathbf{U}_{i+1/2}^n = \sum_{p=1}^m (\lambda_{i+1/2}^{(p)})^- \mathcal{W}_{i-1/2}^{(p)}$ are the right-going and left-going fluctuations respectively, provided $\mathbf{U}_{i-1/2}^n = \mathbf{U}_i^n - \mathbf{U}_{i-1}^n$, $\mathcal{W}_{i-1/2}^{(p)} = \alpha_{i-1/2}^{(p)}\mathbf{K}^{(p)}$ are the waves formed of the wave strength coefficient $\alpha_{i-1/2}^{(p)}$ weighting the right eigenvectors $\mathbf{K}^{(p)}$ of the jacobian matrix $\mathbf{A} = \partial\mathbf{f}/\partial\mathbf{u}$, and $(\lambda_{i-1/2}^{(p)})^\pm$ are the characteristic speeds (the eigenvalues of $\mathbf{A}$) travelling rightward or leftward respectively. In addition, $\tilde{\mathbf{F}}_{i+1/2}^n$ and $\tilde{\mathbf{F}}_{i-1/2}^n$ stand for limited additional correction fluxes designed so that the method achieves a high order of accuracy in smooth regions and a high resolution of discontinuity in rough ones. These limited fluxes are expressed as a function of limited waves $\tilde{\mathcal{W}}_{i-1/2}^{(p)} = \tilde{\alpha}_{i-1/2}^{(p)}\mathbf{K}^{(p)}$, $1 \leq p \leq m$:

$$\tilde{\mathbf{F}}_{i-\frac{1}{2}}^n = \frac{1}{2}\sum_{p=1}^m |\lambda_p|\left(1 - \frac{\Delta t}{\Delta x}|\lambda_p|\right)\tilde{\alpha}_{i-1/2}^{(p)}\mathbf{K}^{(p)} \tag{20}$$

These waves are limited based on an upwind ratio $\theta_{i-1/2}^{(p)}$ defined for the $p-$wave as:

$$\theta_{i-1/2}^{(p)} = \frac{\mathcal{W}_{I-1/2}^{(p)}}{\mathcal{W}_{i-1/2}^{(p)}} = \frac{\alpha_{I-1/2}^{(p)}}{\alpha_{i-1/2}^{(p)}} \tag{21}$$

where the index I denotes the upwind interface of that located at $x_{i-1/2}$, that is I equals $i-1$ if $\lambda_{i-1/2}^{(p)} > 0$, $i+1$ if $\lambda_{i-1/2}^{(p)} < 0$. This ratio may be understood as a certain measure of the local regularity of the solution, the $p-$wave strength may thus be limited as a function of this measure:

$$\tilde{\alpha}_{i-1/2}^{(p)} = \phi(\theta_{i-1/2}^{(p)})\alpha_{i-1/2}^{(p)} \tag{22}$$

where $\phi(\theta_{i-1/2}^{(p)})$ is a limiting function. Among many others, Lax-Wendroff is found for $\phi(\theta) = 1$, and for instance Superbee is obtained for $\phi(\theta) = \max(0, \min(1, 2\theta), \min(2, \theta))$.

Implementing a thermo-elastic-plastic material also requires a special elastic-plastic Riemann solver. This is also based on a prediction-correction scheme. First, an elastic trial solution

$(\sigma_{i+1/2})^{\text{trial}}$ is computed at each interface, solution of an elastic Riemann problem consisting of two elastic (discontinuous) waves travelling at speeds $-c_e$ and c_e. Then, this trial stress state is tested against the yield criterion in both grid cells i and $i+1$, being given their respective cumulated plastic strain values (p_i^n, p_{i+1}^n) and temperature values (T_i^n, T_{i+1}^n). In each of these grid cells, either the plastic yield criterion is satified, and then only one elastic wave occurs, or the criterion is violated, and then a plastic wave travelling at speed $\pm c_p$ should be added to the elastic one. In all, the characteristic spectrum solution of the elastic-plastic Riemann problem may consist of (i) two elastic waves if the trial stress state satisfies the yield criterion in both adjacent grid cells, (ii) two elastic waves plus one left or right plastic (discontinuous) wave if the trial stress state has violated the yield criterion in the sole left of right grid cell adjacent to the interface, or (iii) two elastic waves plus two plastic waves if the trial stress state violates the yield criterion in both grid cells i and $i+1$, as shown in figure 1. Notice that the plastic

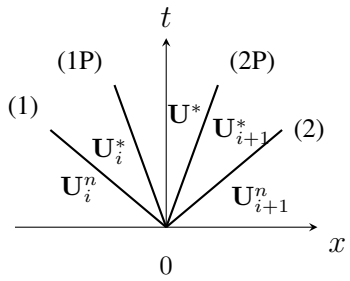

Figure 1: Characteristic structure of the elastic-plastic Riemann problem.

waves here involved in the solution of the elastic-plastic Riemann problem are actually strong discontinuous waves since a linear hardening is considered in this work. A nonlinear hardening would yield weak discontinuous plastic centered rarefaction waves: this case will be treated in a latter work.

It remains to compute the strength $\alpha_{i+1/2}^{(p)}$ of each of these waves. This is based on the decomposition of $\mathbf{U}_{i+1/2}$ on the eigenbasis of the jacobian matrix $\mathbf{A} = \partial \mathbf{f} / \partial \mathbf{u}$:

$$\mathbf{U}_{i+\frac{1}{2}} = \mathbf{U}_{i+1}^n - \mathbf{U}_i^n = \sum_{p=1}^{m} \alpha_{i+1/2}^{(p)} \mathbf{K}^{(p)} \tag{23}$$

The strength of elastic waves are first computed since the stresses in areas $\mathbf{U}_i^*$ and $\mathbf{U}_{i+1}^*$ are known and equal to the respective tensile yield stresses. Then, the strengths of plastic waves are computed by forming a system of equations with the two remaining waves. For example, if plasticity occurs from both sides, the two plastic wave strength are computed by:

$$\left[\mathbf{K}^{(1P)}\,,\,\mathbf{K}^{(2P)}\right] \begin{bmatrix} \alpha_{i+1/2}^{(1P)} \\ \alpha_{i+1/2}^{(2P)} \end{bmatrix} = \mathbf{U}_{i+1}^n - \mathbf{U}_i^n - \alpha_{i+1/2}^{(1)} \mathbf{K}^{(1)} - \alpha_{i+1/2}^{(2)} \mathbf{K}^{(2)} \tag{24}$$

The fluctuations $\mathcal{A}^+ \mathbf{U}_{i+1/2}^n$ and $\mathcal{A}^- \mathbf{U}_{i+1/2}^n$ are then computed, and the unknowns $\mathbf{U}_i^{n+1}$ are hence updated at time t_{n+1} through the formula (19). The thermomechanical coupling is treated as discussed in section 3.1.

4 SUDDEN UNLOADING OF STRONG-DISCONTINUOUS LOADING WAVE IN A LINEAR HARDENING BAR

We consider a semi-infinite bar made of a linear hardening material, in an initial natural state, suddenly loaded on its left side at time $t = 0$ with a constant tensile stress value σ^* sufficiently large to deform the bar plastically. After time t_u, the applied load is suddenly released to zero. The analytical solution of this problem can be found in [8], and is summarized in figure 2. A

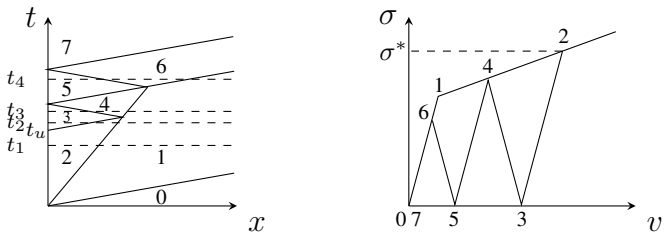

Figure 2: Analytical solution of a semi-infinite bar suddenly plastically loaded then unloaded on its end, plotted with two strain strong-discontinuities here.

stationary strong-discontinuous strain interface is formed at each unloading cycle, the righward plastic wave being weakened until it disappears. Introducing the parameter β defined by:

$$\beta = \frac{c_e + c_p}{c_e - c_p} > 1 \tag{25}$$

the length of the $(n+1)$th stationary strain-discontinuous interfaces, l_{n+1}, and its stress associated are given by:

$$\begin{aligned} l_{n+1} &= \beta l_n \\ \sigma_{2(n+1)} &= \frac{\sigma_{2n}}{\beta} \end{aligned} \qquad (n = 1, 2, \ldots) \tag{26}$$

where l_n the length of the nth stationary strain-discontinuous interfaces and σ_{2n} the stress associated.

4.1 COMPARISON WITH THE FINITE ELEMENT METHOD FOR AN ELASTIC-PLASTIC MATERIAL

The numerical results obtained for a steel (see table 1 for numerical values of parameters) with the Lax-Wendroff and the second-order TVD Superbee finite volume methods are compared here to the analytical solution of this test case and to the results obtained with the finite element method coupled with an explicit time integrator. The constitutive equations in the latter solution is integrated with a radial return algorithm [9], and the solution is computed within a larger domain than that shown in figures 3 to mimic a semi-infinite bar. For the finite volume solutions, transmittive boundary conditions have been set on the right side of the bar.

Both the stress and plastic strain fields are compared at instants t_1, t_2, t_3 and t_4 (see figure 2), in figures 3. When the bar is loaded, an elastic precursor travels at the elastic sound speed (see figure 3(a)), followed by a plastic wave. Since the Courant number has been set at one, the three numerical methods fit perfectly the analytical solution. However, the plastic wave travels slower, numerical oscillations appears for the Finite Element (the largest ones) and Lax-Wendroff solutions. For the latter one, this is due to the fact that Lax-Wendroff is not a monotone

$E = 2 \cdot 10^{11}$ Pa	$\sigma_0 = 400 \cdot 10^6$ Pa	$L = 6$ m
$\rho = 7800$ kg.m^{-3}	$A = 4$	number of grid cells/elements = 100
$C = 450$ J.kg^{-1}.K^{-1}	$T_0 = 293$ K	$t_u = 1.2 \cdot 10^{-3}$ s
$Q = 10 \cdot 10^9$ Pa	$\sigma^* = 900 \cdot 10^6$ Pa	

Table 1: Numerical values of parameters

method nor a TVD one. Moreover, the Finite element solution overestimates the plastic strain value closed to the boundary, though reduces to the right values when it departs. Superbee achieves the best resolution of the plastic wave on five cells here.

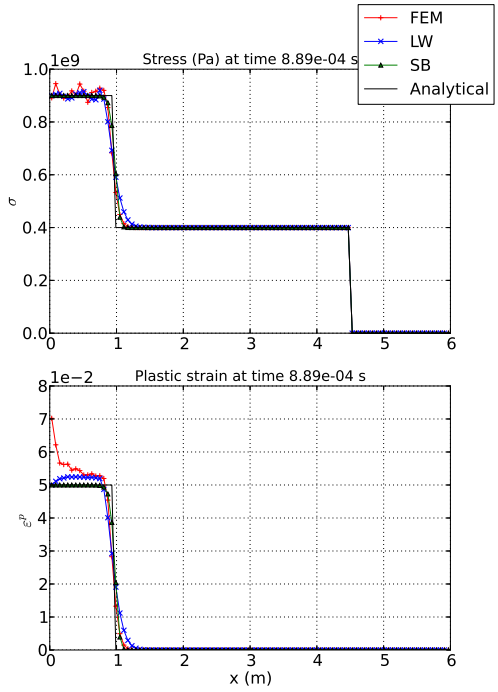
Then, the prescribed load is released to zero, and an unloading wave pursues the forerunning plastic loading disturbance (see figure 3(b)). Strong oscillations appears at integration points within the unloaded area in the Finite Element solution. Many solutions can be used to reduce these oscillations, among others (i) unload in two time steps rather than in one, (ii) reaverage at integration points the stress moved at nodes using the finite element shape functions or (iii) adding some additional numerical viscosity. Superbee achieves a proper elastic unload, superposed with the analytical solution, while Lax-Wendroff is not so bad.

When the unloading wave catches up with the plastic wave, a discontinuity of the (plastic) strain appears at this point due to the strain history difference on both sides (see figure 3(c)). Thus, a stationary discontinuous interface is generated, as well as internal reflective waves, so that the plastic strain continues to propagate rightward, but with a smaller value. The resolution of these two plastic strain fronts is quite close for these three numerical methods.

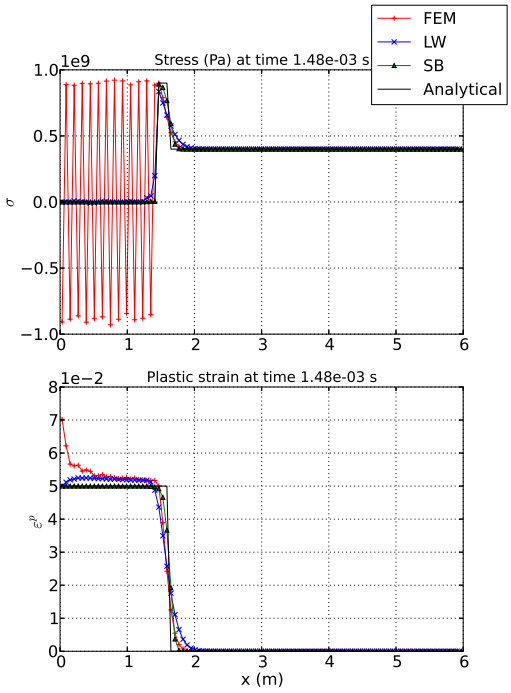
A second unload disturbance is required here to stop the progession of plastic strain (see figure 3(d)). The stress front is poorly solved by the finite element method, Lax-Wendroff has also difficulties with the left front. Only Superbee gives acceptable results after several reflexions of plastic waves.

4.2 COMPARISON WITH THE FINITE ELEMENT METHOD FOR A THERMO-ELASTIC-PLASTIC MATERIAL

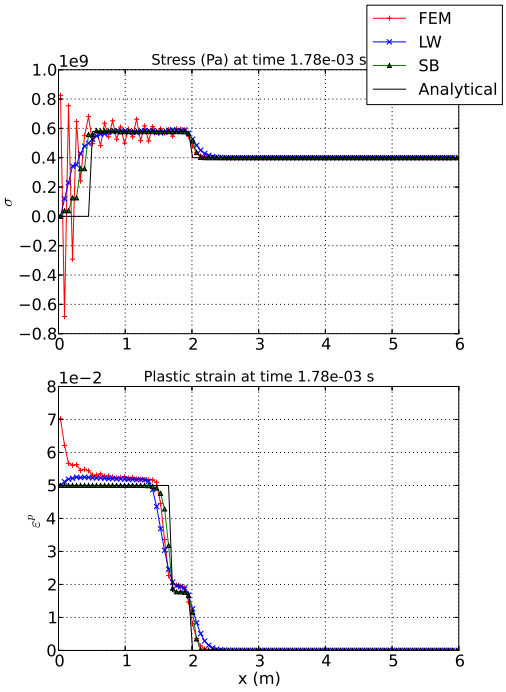
The thermomechanical coupling is here added, with numerical parameters listed in table 1. Since on the one hand a linear hardening is considered in this work, and the other hand the thermal part influences the mechanical one through the sole yield stress, the plastic sound speed is not affected by the temperature here, but the stress and the plastic strain actually depend on the temperature. With the numerical values of parameters listed in table 1, the stress does not change much with respect to figure 3 at the beginning, though more after many wave reflexions. The change in plastic strain is much pronounced. The thermo-elastic-plastic (TEP) numerical solutions are plotted in figure 4, and the plastic strains superposed with the (isothermal) elastic-plastic (EP) analytical solution to observe the effect of the thermomechanical coupling. The decrease of the tensile yield stress through thermal softening leads to an increase of the plastic flow, and hence to an increase of temperature (figures 4(a) and 4(b)). Recall that adiabatic conditions have been assumed so that no conduction effects are here accounted for. This explains why the temperature and plastic strain profiles are similar.



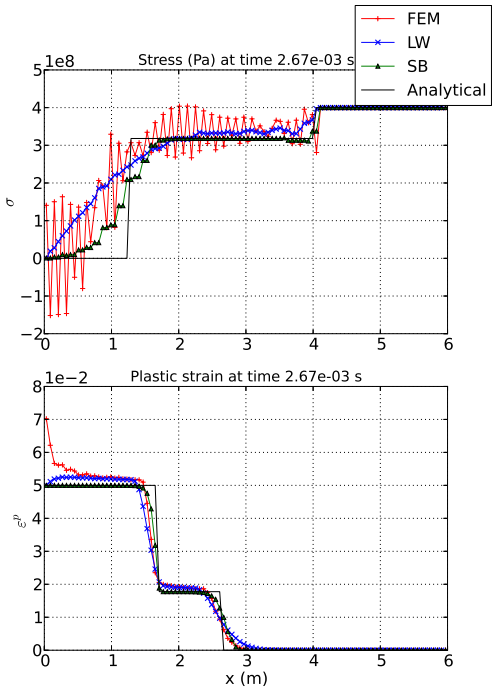
(a) Time $t_1 = 8.89 \cdot 10^{-4}$ seconds.



(b) Time $t_2 = 1.48 \cdot 10^{-3}$ seconds.

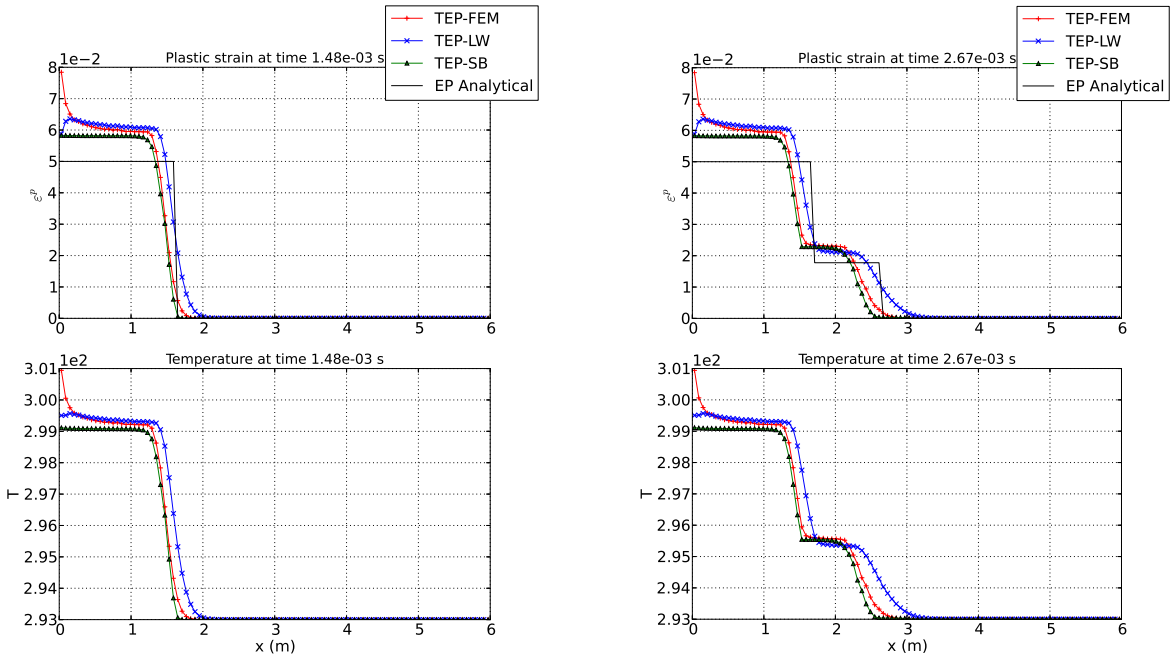


(c) Time $t_3 = 1.78 \cdot 10^{-3}$ seconds.



(d) Time $t_4 = 2.67 \cdot 10^{-3}$ seconds.

Figure 3: Comparison of the analytical, Finite Element (FEM), Lax-Wendroff (LW) and Superbee (SB) stress and plastic strain fields at different times.



(a) Time $t_2 = 1.48 \cdot 10^{-3}$ seconds.

(b) Time $t_4 = 2.67 \cdot 10^{-3}$ seconds.

Figure 4: Comparison of the analytical, Finite Element (FEM), Lax-Wendroff (LW) and Superbee (SB) plastic strain and temperature fields at different times.

5 CONCLUSIONS

In this work, two schemes of the finite volume methods (namely the Lax-Wendroff and the Superbee TVD limiter) have been implemented for the numerical simulation of impacts on thermo-elastic-plastic bars. These methods were tested against an analytical solution and the finite element method on a test case involving strong discontinuous waves. The Superbee TVD limited solution has been shown to be the best in term of accuracy, so that it improves both the track of the shock wave path, even after many reflexions of waves, and the computation of plastic strains and temperature.

Keywords: Wave Propagation, Transfer Matrix, Piezoelectric Coupling, Electrical Network.

Abstract. *Wave propagation in mechanical structures can be controlled by a coupling to an electrical network exhibiting a similar dispersion relation. The energy transfer between the two media is maximized on a broad frequency range when choosing a network that is the electrical analogue of the structure to control. In terms of structural vibration, this strategy is equivalent to a multimodal tuned mass damping. Indeed, the control is implemented thanks to a multimodal electrical network, whose modes are close enough to those of the mechanical structure. The electromechanical coupling can be achieved by using an array of piezoelectric patches, which are small enough compared to the smallest wavelength to control. Then, when considering interconnected patches, wave propagation occurs simultaneously in the mechanical and electrical media. Wave propagation in one-dimensional periodic structures can be analyzed with the transfer matrix method. In this paper, the definition of an electromechanical unit cell gives a relation between state vectors involving both mechanical and electrical degrees of freedom. As an extension of a previous work focusing on longitudinal propagation, four transfer matrix models are defined in order to describe the piezoelectric coupling of a beam to its discrete electrical analogue. Indeed, the beam can be approximated either by its discrete equivalent, a fully homogenized model, a piecewise homogenized model or a finite element model. Offering an increasing complexity, those formulations are compared in order to determine their respective limits. Depending on the frequency range of interest, it then becomes possible to choose a suitable model for the analysis of structures involving a piezoelectric coupling to their electrical analogues.*

1 INTRODUCTION

Multimodal vibration control can be implemented by coupling a mechanical structure to its electrical analogue. A practical solution is to cover the structure to control with an array of piezoelectric patches that are interconnected with a suitable electrical network. From a finite difference method applied to the continuous equations describing the mechanical medium, an electromechnical analogy provides the suitable electrical topology [1, 2]. This method was applied to the control of a beam and it led to a passive electrical network made of inductors and transformers [3, 4]. A periodic layout of the electromechanical structure allows using the transfer matrix method [5, 6]. This method has often been implemented in problems involving independent piezoelectric shunts [7, 8, 9] but rarely with an interconnection of successive patches [10]. This last case requires the definition of state vectors that combine both mechanical and electrical degrees of freedom, because a real electromechanical waveguide is considered. The electrical part is described with the discrete equations governing the lumped electrical components but the continuous mechanical medium can be approximated by various models.

The present contribution extends previous models and results that were initially dedicated to the analysis of longitudinal wave propagation in coupled analogous waveguides [11]. When considering transverse propagation, the transfer matrices are obviously different, but the methods remain the same. A first section presents the electromechanical unit cell including a beam segment and a portion of the analogous electrical network, which was presented in [4]. Then, a model describing a pair of piezoelectric patches subjected to bending motion is proposed. In a second section, we recall the transfer matrices that were obtained in [4] when considering either a discrete or a fully homogenized beam coupled to the discrete electrical analogue. Two new models are added: a piecewise homogenized model and a finite element model, which both take into account the mechanical discontinuity induced by the addition of piezoelectric patches. The last section compares the propagation constants and the frequency response functions obtained with the four transfer matrix models, which offer an increasing complexity. The main objective is to define their respective limits and to select the most appropriate depending on the frequency range of interest and the required accuracy.

2 ANALOGOUS PIEZOELECTRIC NETWORK ON BEAM

A beam is coupled to its analogous electrical network through a periodic array of piezoelectric patches. A unit cell is defined by considering both mechanical and electrical propagation media. Then, the linear piezoelectricity theory gives a model describing a pair of piezoelectric patches subjected to bending motion.

2.1 Electromechanical unit cell

A periodic array of piezoelectric patches is distributed on an homogeneous beam. An electrical network interconnects the patches, which creates an electrical waveguide. The chosen network is the periodic electrical analogue of a beam [3, 4] because it was shown that this solution can lead to a broadband control of transverse waves. As seen in Fig. 1, an electromechanical periodic structure is obtained, so that a unit cell of length a can be defined. The thickness of the main structure is h_{s} and its width is b. The piezoelectric patches have a thickness h_{p}, a width b and a length l_{p}, with $l_{\mathrm{p}} \leq a$. Then, $\dot{q}_{\mathrm{I}}$ is the current flowing from the network to the pair of patches and V_{I} is the voltage on the electrodes connected to the network. The two piezoelectric patches need to be transversely polarized in identical directions in order to generate a non-zero voltage when bending excitation occurs [12].

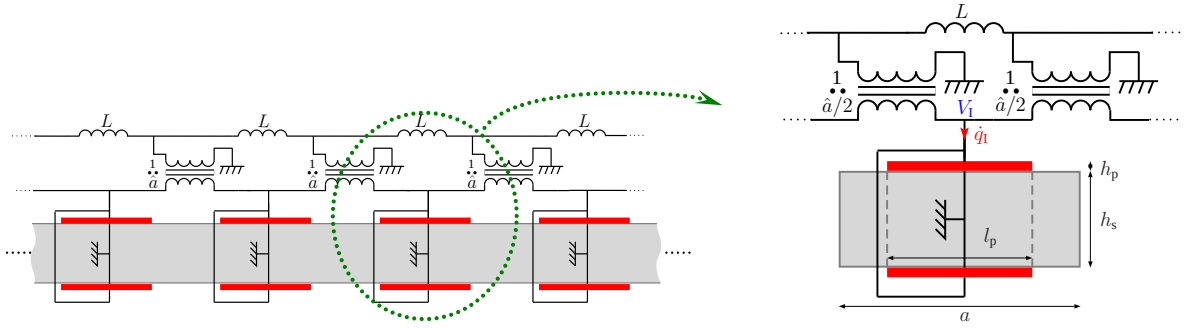

Figure 1: Beam segment coupled to its analogous electrical network through a periodic array of piezoelectric patches and corresponding electromechanical unit cell.

2.2 Bending model for a pair of thin piezoelectric patches

For a thin piezoelectric patch under plane-stress assumption and polarized in transverse direction [13], the 3D linear piezoelectricity theory is simplified into the one-dimensional formulation

$$\begin{aligned} \sigma_\mathrm{p} &= Y_\mathrm{p}^E \varepsilon_\mathrm{p} - \bar{e}_{31} E_\mathrm{p} \\ D_\mathrm{p} &= \bar{e}_{31} \varepsilon_\mathrm{p} + \bar{\epsilon}_{33}^\varepsilon E_\mathrm{p} \end{aligned}, \quad \text{where} \quad Y_\mathrm{p}^E = \frac{1}{s_{11}^E}, \quad \bar{e}_{31} = \frac{d_{31}}{s_{11}^E}, \quad \text{and} \quad \bar{\epsilon}_{33}^\varepsilon = \epsilon_{33}^\sigma - \frac{d_{31}^2}{s_{11}^E}. \tag{1}$$

ε_p and σ_p are respectively the strain and stress in the axial direction '1' of the piezoelectric patch. D_p and E_p are the electric displacement and electric field in the transverse direction '3'. s_{11}^E is the elastic compliance at constant electric field, d_{31} is the piezoelectric charge constant and ϵ_{33}^σ is the permittivity at constant stress. If we consider that the stress is constant along the thickness, the normal force N_p is obtained by multiplying σ_p by the patch cross-section area $S_\mathrm{p} = bh_\mathrm{p}$. For a thin piezoelectric patch, the electric field E_p can be seen as constant along the thickness [13], which means that E_p is equal to $-V_\mathrm{p}/h_\mathrm{p}$, where V_p is the voltage between the two electrodes. Finally, the electric charge q_p comes from the integration of $-D_\mathrm{p}$ all over the surface of the patch. It is thus found from Eq. (1) that

$$\begin{aligned} N_\mathrm{p} &= Y_\mathrm{p}^E S_\mathrm{p} \varepsilon_\mathrm{p} - e_\mathrm{p} V_\mathrm{p} \\ q_\mathrm{p} &= e_\mathrm{p} \Delta U_\mathrm{p} + C_\mathrm{p}^\varepsilon V_\mathrm{p} \end{aligned}, \quad \text{where} \quad e_\mathrm{p} = -b\bar{e}_{31}, \quad C_\mathrm{p}^\varepsilon = \frac{\bar{\epsilon}_{33}^\varepsilon A_\mathrm{p}}{h_\mathrm{p}} \quad \text{and} \quad A_\mathrm{p} = bl_\mathrm{p}. \tag{2}$$

$\Delta U_\mathrm{p} = U_\mathrm{pR} - U_\mathrm{pL}$ is the difference between the right and left end displacements of the patch and C_p^ε is the capacitance of the patch when no strain is allowed along the direction '1'.

Regarding the bending of thin piezoelectric patches, we consider that the electrical variables only depend on axial deformations [13]. Then, for two patches that offer a symmetrical positioning with respect to the neutral axis, their contribution to the bending moment, M_2p, is equal to the integration of the stress times the distance to the central axis z over the two cross-section areas. Furthermore, it is seen from the parallel electrical connection in Fig. 1 that $V_\mathrm{I} = V_\mathrm{p}$ and $q_\mathrm{I} = 2q_\mathrm{p}$. So, with $\varepsilon_\mathrm{p} = \theta_\mathrm{p}' z$, Eqs. (1) and (2) give

$$\begin{aligned} M_\mathrm{2p} &= 2Y_\mathrm{p}^E I_\mathrm{p} \theta_\mathrm{p}' - e_\mathrm{p}(h_\mathrm{s} + h_\mathrm{s}) V_\mathrm{I} \\ q_\mathrm{I} &= e_\mathrm{p}(h_\mathrm{s} + h_\mathrm{s}) \Delta\theta_\mathrm{p} + 2C_\mathrm{p}^\varepsilon V_\mathrm{I} \end{aligned}, \quad \text{where} \quad 2I_\mathrm{p} = \frac{b(h_\mathrm{s} + 2h_\mathrm{p})^3}{12} - \frac{bh_\mathrm{s}^3}{12}, \tag{3}$$

$\Delta\theta_\mathrm{p} = \theta_\mathrm{pR} - \theta_\mathrm{pL}$ is the difference between the right and left rotations at the ends of the patches and θ_p' corresponds to their curvature.

3 TRANSFER MATRIX MODELS FOR TRANSVERSE WAVE PROPAGATION

Four transfer matrix models are proposed to describe the considered electromechanical unit cell. All of them take into account a discrete electrical network but they differ in the definition of the mechanical medium. The first model consider a lumped beam, whereas the second is fully homogenized. Then, the discontinuity induced by the piezoelectric patches is introduced in a piecewise homogenized model. This third transfer matrix model is validated by the last one, which is based on a finite element method.

3.1 Discrete model based on global properties

The mechanical part of the unit cell in Fig. 1(b) is an elastic beam segment symmetrically covered with two piezoelectric patches. This structure can be firstly seen as an homogenized medium governed by a global piezoelectric coupling similar to Eq. (3). Then, if the considered wavelength is considerably longer than the length of the unit cell, the curvature can be approximated by $\theta' \approx \Delta\theta/a$, where $\Delta\theta = \theta_{\mathrm{R}} - \theta_{\mathrm{L}}$ is the difference between the right and left rotations at the ends of the unit cell. Consequently, the bending moment M depends on a global bending stiffness K_θ^E, which gives the discrete model

$$\begin{array}{l} M = K_\theta^E \Delta\theta - e_\theta V_{\mathrm{I}} \\ q_{\mathrm{I}} = e_\theta \Delta\theta + C^\varepsilon V_{\mathrm{I}} \end{array}, \quad \text{where} \quad \frac{1}{K_\theta^E} = \frac{l_{\mathrm{p}}}{Y_{\mathrm{s}} I_{\mathrm{s}} + 2 Y_{\mathrm{p}}^E I_{\mathrm{p}}} + \frac{a - l_{\mathrm{p}}}{Y_{\mathrm{s}} I_{\mathrm{s}}} \quad \text{and} \quad I_{\mathrm{s}} = \frac{b h_{\mathrm{s}}^3}{12}. \tag{4}$$

K_θ^E is obtained directly from the geometry and the material properties of the unit cell. However, the coupling e_θ and the blocked capacitance C^ε depend on global 3D considerations. C^ε is the capacitance of the pair of piezoelectric patches when $\Delta\theta = 0$. This does not mean that the patches are fixed because $\Delta\theta$ is not equal to $\Delta\theta_p$ when the patches do not cover the whole unit cell ($a \neq l_{\mathrm{p}}$). Consequently, C^ε is not equal to $2C_p^\varepsilon$ as it depends on the ratio a/l_{p}. On the other hand, C^σ is the capacitance of the pair of patches when no bending moment is applied at the ends of the unit cell ($M = 0$). This free capacitance is easier to handle because it is directly related to the free capacitance of a single piezoelectric patch: $C^\sigma = 2C_{\mathrm{p}}^\sigma$, which can be measured or approximated from 3D calculations [12]. Another global constant that can be easily obtained is K_θ^D, the stiffness in open circuit ($q_{\mathrm{I}} = 0$). It is computed in the same way as K_θ^E in Eq. (4) with Y_{p}^D instead of Y_{p}^E . Y_{p}^D is the Young modulus at constant electric displacement, which is defined from Eq. (1) by $Y_{\mathrm{p}}^D = Y_{\mathrm{p}}^E + \bar{e}_{31}^2/\bar{\epsilon}_{33}^\varepsilon$. Then, from the definition of C^σ and K_θ^D, Eq. (4) gives $C^\sigma = C^\varepsilon + e_\theta^2/K_\theta^E$ and $K_\theta^D = K_\theta^E + e_\theta^2/C^\varepsilon$. Those two equations are reorganized to finally get the global constants appearing in Eq. (4):

$$\begin{array}{l} e_\theta = \sqrt{K_\theta^E \left(1 - \dfrac{K_\theta^E}{K_\theta^D}\right) C^\sigma} \\ C^\varepsilon = C^\sigma \dfrac{K_\theta^E}{K_\theta^D} \end{array}. \tag{5}$$

The mechanical part of the discrete model is illustrated in Fig. 2(a), where the torsional spring refers to the bending stiffness and the lumped mass m is the mass of the unit cell. If ρ_{s} is the density of the beam and ρ_{p} is the density of the piezoelectric material, $m = \rho_{\mathrm{s}} S_{\mathrm{s}} a + 2\rho_{\mathrm{p}} S_{\mathrm{p}} l_{\mathrm{p}}$. The shear force is not represented because it does not depend directly on the piezoelectric coupling, contrary to the total bending moment, which is increased by $e_\theta V_{\mathrm{I}}$ according to Eq. (4). When the discrete mechanical unit cell is coupled to its analogous electrical network, the resulting electromechanical unit cell can be represented by the electric scheme in Fig. 3 [4]. The relation

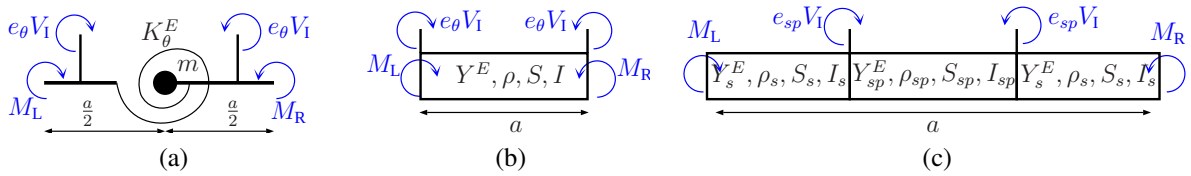

Figure 2: Three models for the mechanical part of the unit cell: (a) Discrete model. (b) Fully homogenized model. (c) Piecewise homogenized model.

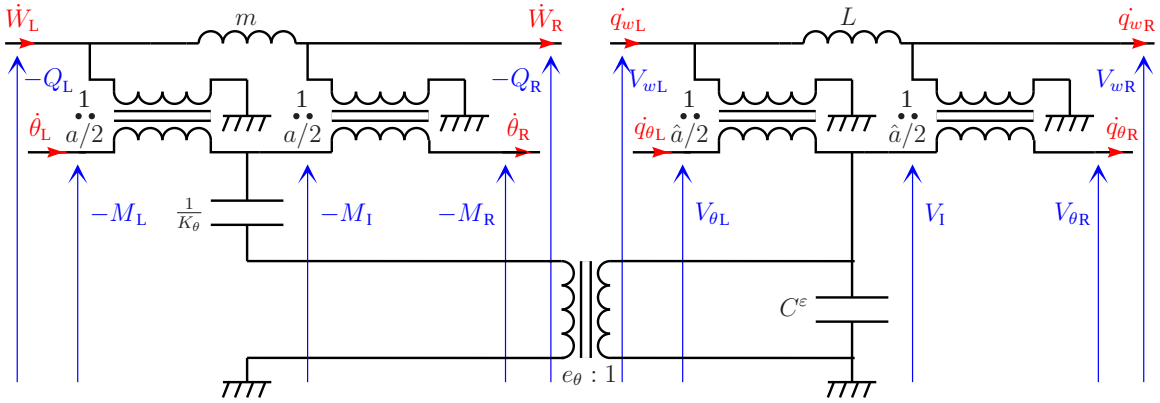

Figure 3: Electrical model of the discrete electromechanical unit cell.

between the electromechanical state vectors at the right and left ends of the unit cell is thus given by the following transfer matrix formulation [4]:

$$\begin{bmatrix} W_\mathrm{R}^\star \\ \theta_\mathrm{R}^\star \\ q_{w\mathrm{R}}^\star \\ q_{\theta\mathrm{R}}^\star \\ M_\mathrm{R}^\star \\ Q_\mathrm{R}^\star \\ V_{\theta\mathrm{R}}^\star \\ V_{w\mathrm{R}}^\star \end{bmatrix} = \begin{bmatrix} 1 & 1 & 0 & 0 & \frac{1}{2} & -\frac{1}{4} & \frac{\Lambda}{2e_\theta} & -\frac{\Lambda}{4e_\theta} \\ 0 & 1 & 0 & 0 & 1 & -\frac{1}{2} & \frac{\Lambda}{e_\theta} & -\frac{\Lambda}{2e_\theta} \\ 0 & 0 & 1 & 1 & -\frac{e_\theta}{2} & \frac{e_\theta}{4} & -\frac{1+\Lambda}{2} & \frac{1+\Lambda}{4} \\ 0 & 0 & 0 & 1 & -e_\theta & \frac{e_\theta}{2} & -(1+\Lambda) & \frac{1+\Lambda}{2} \\ \frac{f}{2} & \frac{f}{4} & 0 & 0 & 1 & -1 & 0 & 0 \\ -f & -\frac{f}{2} & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & -\frac{\tilde{f}}{2} & -\frac{\tilde{f}}{4} & 0 & 0 & 1 & -1 \\ 0 & 0 & \tilde{f} & \frac{\tilde{f}}{2} & 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} W_\mathrm{L}^\star \\ \theta_\mathrm{L}^\star \\ q_{w\mathrm{L}}^\star \\ q_{\theta\mathrm{L}}^\star \\ M_\mathrm{L}^\star \\ Q_\mathrm{L}^\star \\ V_{\theta\mathrm{L}}^\star \\ V_{w\mathrm{L}}^\star \end{bmatrix}, \tag{6}$$

where $f = \omega^2 m a^2 / K_\theta^E$, $\tilde{f} = \omega^2 L C^\varepsilon \hat{a}^2$ and $\Lambda = e_\theta^2 / (K_\theta^E C^\varepsilon)$. The symbol "$\star$" denotes dimensionless state variables, which are highlighted for the sake of conciseness of the transfer matrix: $W^\star = W/a$, $\theta^\star = \theta$, $M^\star = M/K_\theta^E$, $Q^\star = aQ/K_\theta^E$, $q_w^\star = q_w/\hat{a}$, $q_\theta^\star = q_\theta$, $V_\theta^\star = C^\varepsilon V_\theta$ and $V_w^\star = \hat{a} C^\varepsilon V_w$.

3.2 Fully homogenized model for the mechanical part

When considering wavelengths that are not considerably longer than the length of the unit cell, the assumption $\theta' \approx \Delta\theta / a$ is no more valid and the mechanical model involving lumped mass and stiffness needs to be improved. A first solution is to ensure the continuity of the mechanical structure by considering an homogenized beam segment as the one represented in Fig. 2(b). The electrical network is still discrete, which gives a semi-continuous model, where

the definition of e_θ and C^ε remains the same as in the discrete model:

$$\begin{array}{l} M = Y^E I\theta' - e_\theta V_\mathrm{I} \\ q_\mathrm{I} = e_\theta \Delta\theta + C^\varepsilon V_\mathrm{I} \end{array}, \quad \text{where} \quad Y^E I = K_\theta^E a. \tag{7}$$

Figure 2(b) shows that a bending moment $M_\mathrm{R} + e_\theta V_\mathrm{I}$ is applied to the right side of the beam segment and a bending moment $-(M_\mathrm{L} + e_\theta V_\mathrm{I})$ is applied to its left side. After a modification of the state vector, a purely mechanical transfer matrix $\boldsymbol{T_m}$ can thus be used to described the relation between the dimensionless forces and displacements at both ends as

$$\begin{bmatrix} W_\mathrm{R}^\star \\ \theta_\mathrm{R}^\star \\ M_\mathrm{R}^\star + \dfrac{\Lambda}{e_\theta} V_\mathrm{I}^\star \\ Q_\mathrm{R}^\star \end{bmatrix} = \boldsymbol{T_m} \begin{bmatrix} W_\mathrm{L}^\star \\ \theta_\mathrm{L}^\star \\ M_\mathrm{L}^\star + \dfrac{\Lambda}{e_\theta} V_\mathrm{I}^\star \\ Q_\mathrm{L}^\star \end{bmatrix}, \quad \text{where} \quad V_\mathrm{I}^\star = C^\varepsilon V_\mathrm{I}. \tag{8}$$

Here, we focus on an homogeneous Euler-Bernouilli beam segment [10, 4], which means that the mechanical transfer matrix is

$$\boldsymbol{T_m} = \begin{bmatrix} \frac{\mathrm{c}+\mathrm{ch}}{2} & \frac{1}{ka}\frac{\mathrm{s}+\mathrm{sh}}{2} & -\frac{1}{(ka)^2}\frac{\mathrm{c}-\mathrm{ch}}{2} & \frac{1}{(ka)^3}\frac{\mathrm{s}-\mathrm{sh}}{2} \\ -ka\frac{\mathrm{s}-\mathrm{sh}}{2} & \frac{\mathrm{c}+\mathrm{ch}}{2} & \frac{1}{ka}\frac{\mathrm{s}+\mathrm{sh}}{2} & \frac{1}{(ka)^2}\frac{\mathrm{c}-\mathrm{ch}}{2} \\ -(ka)^2\frac{\mathrm{c}-\mathrm{ch}}{2} & -ka\frac{\mathrm{s}-\mathrm{sh}}{2} & \frac{\mathrm{c}+\mathrm{ch}}{2} & -\frac{1}{ka}\frac{\mathrm{s}+\mathrm{sh}}{2} \\ -(ka)^3\frac{\mathrm{s}+\mathrm{sh}}{2} & (ka)^2\frac{\mathrm{c}-\mathrm{ch}}{2} & ka\frac{\mathrm{s}-\mathrm{sh}}{2} & \frac{\mathrm{c}+\mathrm{ch}}{2} \end{bmatrix}, \tag{9}$$

where $\mathrm{c} = \cos(ka)$, $\mathrm{ch} = \cosh(ka)$, $\mathrm{s} = \sin(ka)$, $\mathrm{sh} = \sinh(ka)$. The wave number k is obtained from the beam dispersion relation $k = \omega\sqrt[4]{\rho S/Y^E I}$, where $\rho = m/(aS_\mathrm{s} + 2l_\mathrm{p}S_\mathrm{p})$ is the homogenized density of the unit cell. Concerning the electrical part, note from Fig. 3 that

$$V_\mathrm{I}^\star = \begin{bmatrix} 0 \\ 0 \\ 1 \\ -\frac{1}{2} \end{bmatrix}^T \begin{bmatrix} q_{w\mathrm{L}}^\star \\ q_{\theta\mathrm{L}}^\star \\ V_{\theta\mathrm{L}}^\star \\ V_{w\mathrm{L}}^\star \end{bmatrix} \tag{10}$$

Furthermore, Fig. 3 shows that the electrical propagation results from the superposition of a purely electrical contribution, involving a transfer matrix $\boldsymbol{T_e}$, and a second contribution due to the coupling e_θ:

$$\begin{bmatrix} q_{w\mathrm{R}}^\star \\ q_{\theta\mathrm{R}}^\star \\ V_{\theta\mathrm{R}}^\star \\ V_{w\mathrm{R}}^\star \end{bmatrix} = \boldsymbol{T_e} \begin{bmatrix} q_{w\mathrm{L}}^\star \\ q_{\theta\mathrm{L}}^\star \\ V_{\theta\mathrm{L}}^\star \\ V_{w\mathrm{L}}^\star \end{bmatrix} + e_\theta(\theta_\mathrm{L}^\star - \theta_\mathrm{R}^\star) \begin{bmatrix} \frac{1}{2} \\ 1 \\ 0 \\ 0 \end{bmatrix}, \quad \text{where} \quad \boldsymbol{T_e} = \begin{bmatrix} 1 & 1 & -\frac{1}{2} & \frac{1}{4} \\ 0 & 1 & -1 & \frac{1}{2} \\ -\frac{\tilde{f}}{2} & -\frac{\tilde{f}}{4} & 1 & -1 \\ \tilde{f} & \frac{\tilde{f}}{2} & 0 & 1 \end{bmatrix}. \tag{11}$$

Finally, Eqs. (8), (10) and (11) give a transfer matrix formulation between the left and right electromechanical state vectors, which can be written as

$$\begin{bmatrix} W_\mathrm{R}^\star \\ \theta_R^\star \\ M_\mathrm{R}^\star \\ Q_\mathrm{R}^\star \\ q_{w\mathrm{R}}^\star \\ q_{\theta\mathrm{R}}^\star \\ V_{\theta\mathrm{R}}^\star \\ V_{w\mathrm{R}}^\star \end{bmatrix} = \begin{bmatrix} \boldsymbol{I_4} & \boldsymbol{0_4} \\ -e_\theta \begin{bmatrix} \begin{bmatrix} 0 & \frac{1}{2} \\ 0 & 1 \end{bmatrix} & \boldsymbol{0_2} \\ \boldsymbol{0_2} & \boldsymbol{0_2} \end{bmatrix} & \boldsymbol{I_4} \end{bmatrix} \begin{bmatrix} \boldsymbol{T_m} & \dfrac{\Lambda}{e_\theta}(\boldsymbol{T_m} - \boldsymbol{I_4}) \begin{bmatrix} \boldsymbol{0_2} & \boldsymbol{0_2} \\ \boldsymbol{0_2} & \begin{bmatrix} 1 & -\frac{1}{2} \\ 0 & 0 \end{bmatrix} \end{bmatrix} \\ e_\theta \begin{bmatrix} \begin{bmatrix} 0 & \frac{1}{2} \\ 0 & 1 \end{bmatrix} & \boldsymbol{0_2} \\ \boldsymbol{0_2} & \boldsymbol{0_2} \end{bmatrix} & \boldsymbol{T_e} \end{bmatrix} \begin{bmatrix} W_\mathrm{L}^\star \\ \theta_\mathrm{L}^\star \\ M_\mathrm{L}^\star \\ Q_\mathrm{L}^\star \\ q_{w\mathrm{L}}^\star \\ q_{\theta\mathrm{L}}^\star \\ V_{\theta\mathrm{L}}^\star \\ V_{w\mathrm{L}}^\star \end{bmatrix}. \tag{12}$$

3.3 Piecewise homogenized model for the mechanical part

The previous homogenized model does not take into account the mechanical discontinuity induced by the addition of piezoelectric patches on the beam. This can be rectified by discriminating the purely elastic segments "s" from the segments "sp" involving a piezoelectric contribution. The piecewise homogenized model is thus made of three beam segments, as presented in Fig. 2(c). In the "sp" segment covered by the pair of piezoelectric patches, the problem can be expressed under the same form as in Eq. (7):

$$\begin{array}{l} M_{\text{sp}} = Y_{\text{sp}}^{E} I_{\text{sp}} \theta_{\text{p}}' - e_{sp} V_{\text{I}} \\ q_{\text{I}} = e_{\text{sp}} \Delta\theta_{\text{p}} + C_{\text{sp}}^{\varepsilon} V_{\text{I}} \end{array}, \quad \text{where} \quad Y_{\text{sp}}^{E} I_{\text{sp}} = Y_{\text{s}} I_{\text{s}} + 2 Y_{\text{p}}^{E} I_{\text{p}}. \tag{13}$$

The "sp" constants appearing in the previous system of equations are not equal to the ones in Eq. (7) because they refer to the central segment of the unit cell, without considering the purely elastic segments. Nevertheless, e_{sp} and $C_{\text{sp}}^{\varepsilon}$ can be computed with the same method as in Eq. (5) by considering a global stiffness that refer to the sole "sp" segment.

As the problem focusing on the "sp" beam segment is equivalent to the one presented in Sec. 3.2, a 8×8 transfer matrix $\boldsymbol{T}_{\text{sp}}$ is built on the same form as Eq. (12) but with homogenized constants referring to the "sp" segment. The two "s" beam segments are purely elastic, so that their 4×4 mechanical transfer matrices $\boldsymbol{T}_{\text{s}}$ are obtained as $\boldsymbol{T_m}$ but with the use of the constants Y_{s}, ρ_{s}, S_{s} and I_{s}. At the end, the piecewise homogenized model of the electromechanical unit cell is given by

$$\begin{bmatrix} W_{\text{R}}^{\star} \\ \theta_{\text{R}}^{\star} \\ M_{\text{R}}^{\star} \\ Q_{\text{R}}^{\star} \\ q_{w\text{R}}^{\star} \\ q_{\theta\text{R}}^{\star} \\ V_{\theta\text{R}}^{\star} \\ V_{w\text{R}}^{\star} \end{bmatrix} = \begin{bmatrix} \boldsymbol{T}_{\text{s}} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{I_4} \end{bmatrix} \boldsymbol{T}_{\text{sp}} \begin{bmatrix} \boldsymbol{T}_{\text{s}} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{I_4} \end{bmatrix} \begin{bmatrix} W_{\text{L}}^{\star} \\ \theta_{\text{L}}^{\star} \\ M_{\text{L}}^{\star} \\ Q_{\text{L}}^{\star} \\ q_{w\text{L}}^{\star} \\ q_{\theta\text{L}}^{\star} \\ V_{\theta\text{L}}^{\star} \\ V_{w\text{L}}^{\star} \end{bmatrix}, \quad \text{where} \quad \boldsymbol{I_4} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}. \tag{14}$$

3.4 Finite element model

A convenient finite element model was proposed by Thomas et al. [13], who focused on thin piezoelectric patches shunted with independent electrical circuits. The model is based on a condensation of the electrical degrees of freedom in order to recast the system into a standard elastic vibration problem. However, this method is not applicable when considering connections of different patches with an electrical network. There are electrical nodes that interconnect successive unit cells, which means that the corresponding electrical degrees of freedom cannot be condensed. Before condensation, the finite element formulation is expressed as follows

$$\begin{bmatrix} \boldsymbol{M_m} & \boldsymbol{0} \\ \boldsymbol{0} & 0 \end{bmatrix} \begin{bmatrix} \ddot{\boldsymbol{q}}_{\boldsymbol{m}} \\ \ddot{V}_{\text{I}} \end{bmatrix} + \begin{bmatrix} \boldsymbol{K_m} & \boldsymbol{K_c} \\ -\boldsymbol{K_c}^{\boldsymbol{T}} & C_{\text{sp}}^{\varepsilon} \end{bmatrix} \begin{bmatrix} \boldsymbol{q_m} \\ V_{\text{I}} \end{bmatrix} = \begin{bmatrix} \boldsymbol{F_m} \\ q_{\text{I}} \end{bmatrix}, \tag{15}$$

where $\boldsymbol{M_m}$, $\boldsymbol{K_m}$ and $\boldsymbol{K_c}$ are respectively the mass, stiffness and coupling matrices that are defined in [13]. The electric charge q_{I} flowing toward the pair of piezoelectric patches is obtained from the topology of the analogous network as

$$q_{\text{I}} = \boldsymbol{S_q q_e} \quad \text{where} \quad \boldsymbol{S_q} = \begin{bmatrix} 0 & 1 & 0 & -1 \end{bmatrix} \quad \text{and} \quad \boldsymbol{q_e} = \begin{bmatrix} q_{w\text{L}} & q_{\theta\text{L}} & q_{w\text{R}} & q_{\theta\text{R}} \end{bmatrix}^{T} \tag{16}$$

By analogy with the force vector $\boldsymbol{F_m}$ and the displacement vector $\boldsymbol{q_m}$, the voltage vector $\boldsymbol{F_e} = \begin{bmatrix} V_{w\mathrm{L}} & V_{\theta\mathrm{L}} & -V_{w\mathrm{R}} & -V_{\theta\mathrm{R}} \end{bmatrix}^T$ is defined as the dual of the electric charge vector $\boldsymbol{q_e}$. The principle of superposition allows considering that the voltage vector $\boldsymbol{F_e}$ is a sum of two contributions. The first contribution is obtained when no mechanical displacement is allowed ($\boldsymbol{q_m} = \boldsymbol{0}$) and the second contribution excludes external charge displacements ($\boldsymbol{q_e} = \boldsymbol{0}$): $\boldsymbol{F_e} = \boldsymbol{F_e^e} + \boldsymbol{F_e^m}$. The purely electrical contribution $\boldsymbol{F_e^e}$ only depends on the choice of the electrical network. Similarly to established practices in mechanical problems, we define the electrical matrices $\boldsymbol{K_e}$ and $\boldsymbol{M_e}$ as equivalents of stiffness and mass matrices:

$$\boldsymbol{F_e^e} = \left[\boldsymbol{K_e} - \omega^2 \boldsymbol{M_e}\right] \boldsymbol{q_e} \tag{17}$$

When considering the electrical analogue of a beam, $\boldsymbol{M_e}$ can be found from the network in Fig. 3 with $e_\theta = 0$ and $C^\varepsilon \to \infty$, i.e. $V_\mathrm{I} = 0$. However, the matrix $\boldsymbol{K_e}$ cannot be obtained directly from Fig. 3 with $e_\theta = 0$ and $L = 0$. Actually, $\boldsymbol{K_e}$ is not defined, unless we introduce additional degrees of freedom. This is performed by adding two virtual capacitors $C_0/2$ in the "θ" electrical line, on both sides of the unit cell. In the end, we get

$$\boldsymbol{K_e} = \frac{4}{\hat{a}^2 C_0} \begin{bmatrix} 1 & \frac{\hat{a}}{2} & -1 & \frac{\hat{a}}{2} \\ \frac{\hat{a}}{2} & \frac{\hat{a}^2}{4}\frac{C_{\mathrm{sp}}^\varepsilon + 2C_0}{C_{\mathrm{sp}}^\varepsilon + C_0} & -\frac{\hat{a}}{2} & \frac{\hat{a}^2}{4}\frac{C_{\mathrm{sp}}^\varepsilon}{C_{\mathrm{sp}}^\varepsilon + C_0} \\ -1 & -\frac{\hat{a}}{2} & 1 & -\frac{\hat{a}}{2} \\ \frac{\hat{a}}{2} & \frac{\hat{a}^2}{4}\frac{C_{\mathrm{sp}}^\varepsilon}{C_{\mathrm{sp}}^\varepsilon + C_0} & -\frac{\hat{a}}{2} & \frac{\hat{a}^2}{4}\frac{C_{\mathrm{sp}}^\varepsilon + 2C_0}{C_{\mathrm{sp}}^\varepsilon + C_0} \end{bmatrix} \quad \text{and} \quad \boldsymbol{M_e} = \frac{L}{2} \begin{bmatrix} 1 & \frac{\hat{a}}{2} & 0 & 0 \\ \frac{\hat{a}}{2} & \frac{\hat{a}^2}{4} & 0 & 0 \\ 0 & 0 & 1 & -\frac{\hat{a}}{2} \\ 0 & 0 & -\frac{\hat{a}}{2} & \frac{\hat{a}^2}{4} \end{bmatrix}. \tag{18}$$

Note that the capacitance C_0 is a numerical parameter that has to be small compared to $C_{\mathrm{sp}}^\varepsilon$. A good practice is to set C_0 between $C_{\mathrm{sp}}^\varepsilon \times 10^{-3}$ and $C_{\mathrm{sp}}^\varepsilon \times 10^{-9}$ to conceal its influence on electrical propagation and to avoid numerical issues.

The contribution $\boldsymbol{F_e^m}$ is equal to $\boldsymbol{F_e}$ when $\boldsymbol{q_e} = \boldsymbol{0}$. Fig. 3 shows that $\boldsymbol{q_e} = \boldsymbol{0}$ induces that $q_\mathrm{I} = 0$. Then, $q_\mathrm{I} = 0$ induces that $V_{w\mathrm{L}} = V_{w\mathrm{R}} = 0$ and $V_{\theta\mathrm{L}} = V_{\theta\mathrm{R}} = V_\mathrm{I}$. Furthermore, Eq. (15) gives $V_\mathrm{I} = \boldsymbol{K_c}^{\boldsymbol{T}} \boldsymbol{q_m} / C_{\mathrm{sp}}^\varepsilon$ when $q_\mathrm{I} = 0$. As a consequence,

$$\boldsymbol{F_e^m} = \frac{1}{C_{\mathrm{sp}}^\varepsilon} \boldsymbol{S_V} \boldsymbol{K_c}^{\boldsymbol{T}} \boldsymbol{q_m} \quad \text{where} \quad \boldsymbol{S_V} = \begin{bmatrix} 0 & 1 & 0 & -1 \end{bmatrix}^T. \tag{19}$$

Finally, Eqs. (15), (16), (17), (18) and (19) lead to the following dynamic stiffness matrix formulation involving a combination of mechanical and electrical degrees of freedom:

$$\left[\begin{bmatrix} \boldsymbol{K_m} + \frac{1}{C_{\mathrm{sp}}^\varepsilon} \boldsymbol{K_c} \boldsymbol{K_c}^{\boldsymbol{T}} & \frac{1}{C_{\mathrm{sp}}^\varepsilon} \boldsymbol{K_c} \boldsymbol{S_q} \\ \frac{1}{C_{\mathrm{sp}}^\varepsilon} \boldsymbol{S_V} \boldsymbol{K_c}^{\boldsymbol{T}} & \boldsymbol{K_e} \end{bmatrix} - \omega^2 \begin{bmatrix} \boldsymbol{M_m} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{M_e} \end{bmatrix} \right] \begin{bmatrix} \boldsymbol{q_m} \\ \boldsymbol{q_e} \end{bmatrix} = \begin{bmatrix} \boldsymbol{F_m} \\ \boldsymbol{F_e} \end{bmatrix}, \tag{20}$$

With a restriction to the transverse case, $\boldsymbol{q_m} = \begin{bmatrix} W_\mathrm{L} & \theta_\mathrm{L} & \boldsymbol{q_\mathrm{I}} & W_\mathrm{R} & \theta_\mathrm{R} \end{bmatrix}^T$ and $\boldsymbol{F_m} = \begin{bmatrix} -Q_\mathrm{L} & -M_\mathrm{L} & \boldsymbol{0} & Q_\mathrm{R} & M_\mathrm{R} \end{bmatrix}^T$, where $\boldsymbol{q}_\mathrm{I}$ is the mechanical displacement vector of the internal nodes of the unit cell [13]. So, the dynamic stiffness matrix in Eq. (20) can be reorganized in order to distinguish the left, right and internal degrees of freedom:

$$\begin{bmatrix} \boldsymbol{\tilde{D}_{LL}} & \boldsymbol{\tilde{D}_{LI}} & \boldsymbol{\tilde{D}_{LR}} \\ \boldsymbol{\tilde{D}_{IL}} & \boldsymbol{\tilde{D}_{II}} & \boldsymbol{\tilde{D}_{IR}} \\ \boldsymbol{\tilde{D}_{RL}} & \boldsymbol{\tilde{D}_{RI}} & \boldsymbol{\tilde{D}_{RR}} \end{bmatrix} \begin{bmatrix} \boldsymbol{q}_\mathrm{L} \\ \boldsymbol{q}_\mathrm{I} \\ \boldsymbol{q}_\mathrm{R} \end{bmatrix} = \begin{bmatrix} \boldsymbol{F}_\mathrm{L} \\ \boldsymbol{0} \\ \boldsymbol{F}_\mathrm{R} \end{bmatrix} \quad \text{where} \quad \boldsymbol{F}_\mathrm{L} = \begin{bmatrix} -Q_\mathrm{L} \\ -M_\mathrm{L} \\ V_{w\mathrm{L}} \\ V_{\theta\mathrm{L}} \end{bmatrix}, \quad \boldsymbol{F}_\mathrm{R} = \begin{bmatrix} Q_\mathrm{R} \\ M_\mathrm{R} \\ -V_{w\mathrm{R}} \\ -V_{\theta\mathrm{R}} \end{bmatrix}, \tag{21}$$

$\boldsymbol{q}_{\mathrm{L}} = \left[\begin{array}{cccc} W_{\mathrm{L}} & \theta_{\mathrm{L}} & q_{w\mathrm{L}} & q_{\theta\mathrm{L}} \end{array}\right]^T$ and $\boldsymbol{q}_{\mathrm{R}} = \left[\begin{array}{cccc} W_{\mathrm{R}} & \theta_{\mathrm{R}} & q_{w\mathrm{R}} & q_{\theta\mathrm{R}} \end{array}\right]^T$. With this partitioning, the waveguide finite element methods [6] can be applied. First, the internal degrees of freedoms are eliminated through

$$\left[\begin{array}{cc} \boldsymbol{D_{LL}} & \boldsymbol{D_{LR}} \\ \boldsymbol{D_{RL}} & \boldsymbol{D_{RR}} \end{array}\right] \left[\begin{array}{c} \boldsymbol{q}_{\mathrm{L}} \\ \boldsymbol{q}_{\mathrm{R}} \end{array}\right] = \left[\begin{array}{c} \boldsymbol{F}_{\mathrm{L}} \\ \boldsymbol{F}_{\mathrm{R}} \end{array}\right], \quad \text{where} \quad \begin{array}{l} \boldsymbol{D_{LL}} = \tilde{\boldsymbol{D}}_{\boldsymbol{LL}} - \tilde{\boldsymbol{D}}_{\boldsymbol{LI}}\tilde{\boldsymbol{D}}_{\boldsymbol{II}}^{-1}\tilde{\boldsymbol{D}}_{\boldsymbol{IL}} \\ \boldsymbol{D_{LR}} = \tilde{\boldsymbol{D}}_{\boldsymbol{LR}} - \tilde{\boldsymbol{D}}_{\boldsymbol{LI}}\tilde{\boldsymbol{D}}_{\boldsymbol{II}}^{-1}\tilde{\boldsymbol{D}}_{\boldsymbol{IR}} \\ \boldsymbol{D_{RL}} = \tilde{\boldsymbol{D}}_{\boldsymbol{RL}} - \tilde{\boldsymbol{D}}_{\boldsymbol{RI}}\tilde{\boldsymbol{D}}_{\boldsymbol{II}}^{-1}\tilde{\boldsymbol{D}}_{\boldsymbol{IL}} \\ \boldsymbol{D_{RR}} = \tilde{\boldsymbol{D}}_{\boldsymbol{RR}} - \tilde{\boldsymbol{D}}_{\boldsymbol{RI}}\tilde{\boldsymbol{D}}_{\boldsymbol{II}}^{-1}\tilde{\boldsymbol{D}}_{\boldsymbol{IR}} \end{array}. \tag{22}$$

Then, the condensed dynamic stiffness matrix is transformed into a transfer matrix [6, 8]:

$$\left[\begin{array}{c} W_{\mathrm{R}} \\ \theta_{\mathrm{R}} \\ q_{w\mathrm{R}} \\ q_{\theta\mathrm{R}} \\ Q_{\mathrm{R}} \\ M_{\mathrm{R}} \\ -V_{w\mathrm{R}} \\ -V_{\theta\mathrm{R}} \end{array}\right] = \left[\begin{array}{cc} -\boldsymbol{D_{LR}^{-1}D_{LL}} & \boldsymbol{D_{LR}^{-1}} \\ -\boldsymbol{D_{RL}} + \boldsymbol{D_{RR}D_{LR}^{-1}D_{LL}} & -\boldsymbol{D_{RR}D_{LR}^{-1}} \end{array}\right] \left[\begin{array}{c} W_{\mathrm{L}} \\ \theta_{\mathrm{L}} \\ q_{w\mathrm{L}} \\ q_{\theta\mathrm{L}} \\ Q_{\mathrm{L}} \\ M_{\mathrm{L}} \\ -V_{w\mathrm{L}} \\ -V_{\theta\mathrm{L}} \end{array}\right]. \tag{23}$$

4 COMPARISON OF THE TRANSFER MATRIX MODELS

The propagation constants of the proposed transfer matrices are compared. Depending on the frequency range of interest, we note differences between the models. Those differences are confirmed by the observation of frequency response functions, which lead to guidelines concerning the choice of a suitable model.

4.1 Propagation constants

The computation of the eigenvalues λ of a transfer matrix gives access to the propagation constants $\mu = \ln(\lambda) = \delta + i\eta$ [5, 8]. The real part δ is the attenuation constant, which represents the exponential decay of the amplitude of a wave propagating along one unit cell. The imaginary part η is the phase constant, i.e. the phase shift between the two ends of the unit cell. Table 1 gives the geometry and the material properties of the considered unit cell. Concerning the electrical network, the transformer ratio $\hat{a}$ is set arbitrarily to 1 and the inductance value is tuned to $L = a^2 m/(\hat{a}^2 K_\theta^E C^\varepsilon)$ in order to satisfy the multimodal coupling condition defined in [4]. This condition induces that the electrical network approximates the dispersion relation

	Beam (Aluminum 2017)	Patches (PZT)
Length (mm)	$a = 50$	$l_{\mathrm{p}} = 30$
Width (mm)	$b = 20$	$b = 20$
Thickness (mm)	$h_{\mathrm{s}} = 20$	$h_{\mathrm{p}} = 5$
Density (kg/m^3)	$\rho_{\mathrm{s}} = 2780$	$\rho_{\mathrm{p}} = 7800$
Young modulus (GPa)	$Y_{\mathrm{s}} = 73.9$	$1/s_{11}^E = 66.7$
Charge constant (pC/N)	-	$d_{31} = -210$
Permittivity (nF/m)	-	$\epsilon_{33}^\sigma = 21.2$

Table 1: Geometry and material properties of the beam and the piezoelectric patches.

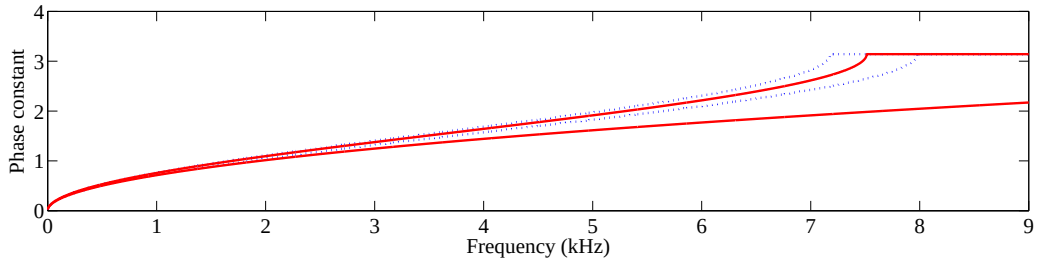

Figure 4: Phase constants - ($\cdots$) for the discrete model, (—) for the piecewise homogenized model.

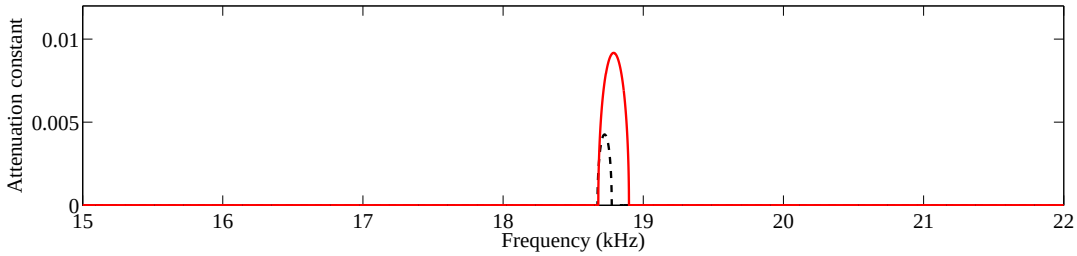

Figure 5: Attenuation constants - ($--$) for the fully homogenized model, (—) for the piecewise homogenized model.

of the beam segment, which is required to implement the analogous coupling. Once the mechanical and electrical properties are defined, the propagation constants of the transfer matrices in Eqs.(6), (12), (14) and (23) can be compared. For each model, the 8×8 transfer matrices give eight propagation constants μ. Two opposite sets of four constants refer to propagation in opposite directions of the electromechanical waveguide. So, only four propagations constants need to be considered to analyze the phase or the attenuation.

First, the phase constants in Fig. 4 show that, below 9 kHz, the discrete model differs significantly from the other ones. Note that the finite element model tends to the piecewise homogenized model when increasing the number of elements. Furthermore, the results obtained with the fully homogenized model are very close to those of the piecewise homogenized model over the frequency range of interest. This is the reason why the fully homogenized and finite element models are not represented in Fig. 4. For each of the other models, only two phase constants are represented because the two other ones are equal to zero. For the piecewise homogenized model, one phase constant approaches a classical beam dispersion relation while the other phase constant reach a step when $\eta = \pi$. This last phase constant thus represents a propagation in a discrete medium [14], which is actually the discrete electrical network. On the other hand, the discrete model offers two phase constants related to discrete waveguides, i.e. with a step at $\eta = \pi$. This is simply explained by the fact that, in the discrete model, the mechanical medium is also represented by a lumped model. Around 7.5 kHz, $\eta = \pi$ means that the wavelength is equal to two unit cells and Fig. 4 shows large differences between the models. So, the discrete model is no more valid when the considered wavelength approaches the length of the unit cell.

The difference between the piecewise homogenized model and the fully homogenized model clearly appears when looking at the smallest attenuation constant for each model around 19 kHz, as seen in Fig. 5. Over this frequency range, the discrete electrical network does not influence

the results anymore because no ellectrical propagation occurs above 7.5 kHz, which was predicted from Fig. 4. However the effect of the mechanical discontinuity induced by the addition of piezoelectric patches creates a stop band for transverse propagation in the beam. Note that a stop band also appears with the fully homogenized model. This is explained by the fact that, even without considering structural discontinuity, the patches induces additional moments on both sides of the unit cell, as represented in Fig. 2(b). This generates a periodic discontinuity that leads to a moderate stop band effect. This stop band is not negligible compared to the one obtained with the piecewise homogenized model because the effect of the mechanical discontinuity is actually quite small in the present example. With the same geometry, the stop band for longitudinal waves was significant [11], but a similar effect for transverse wave would require a considerably thicker discontinuity. In conclusion, strong structural modification would be needed to benefit from structural stop bands in transverse propagation and, anyway, this effect does not occur on the same frequency range as the proposed analogous control.

4.2 Frequency response functions

Frequency response functions (FRFs) are compared for a free-free beam, which is periodically covered with 20 pairs of piezoelectric patches. The two electrical lines of the network needs to be short-circuited at both ends in order to satisfy analogous boundary conditions [4]. Then, the modal coupling condition tunes the electrical modes to the modes of the discrete mechanical model. A tuned mass control is then observed on several modes together and the vibration amplitude is reduced by introducing damping in the network. Here, a resistance $R_s = 20\ \Omega$ is added in series to the inductors by replacing L by $L - jR_s/\omega$, where $j^2 = -1$. The finite electromechanical structure consists of $n = 20$ identical unit cells. A solution to get the relation between the state vectors at both ends of the beam is to raise the transfer matrix to the power of n [4]. The only excitation is a transverse force at one end of the beam. All the other forces, moments and voltages at the ends of the structure are equal to zero. This simplify the problem and it becomes possible to get FRFs as the ratio of the velocity at one end over the excitation force at the other end.

The models are first compared in a low-frequency range. The FRFs obtained with the discrete and the piecewise homogenized model are represented in Fig 6 from 0 to 3.3 kHz. This frequency range covers the first eight bending modes of the beam when no coupling occurs. Again, the FRFs obtained with the homogenized and the finite element model are not represented because they cannot be distinguished from the piecewise homogenized model. As predicted by Fig 4, it is observed that the discrete model is no more reliable when the wavelength approaches the length of the unit cell. A limit of validity can be set to 1 kHz, which corresponds to about ten

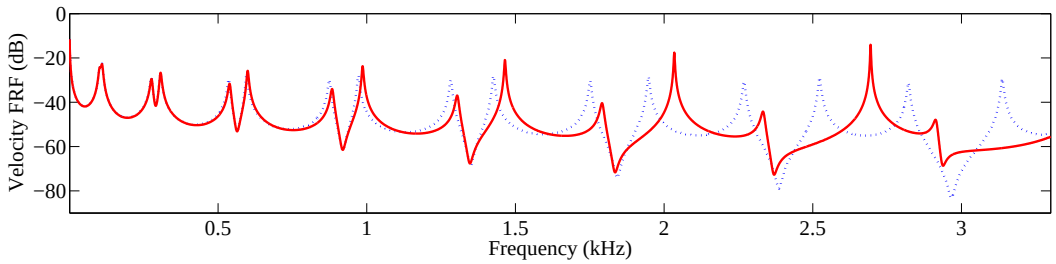

Figure 6: Frequency response functions at low frequencies - (· · ·) for the discrete model, (—) for the piecewise homogenized model.

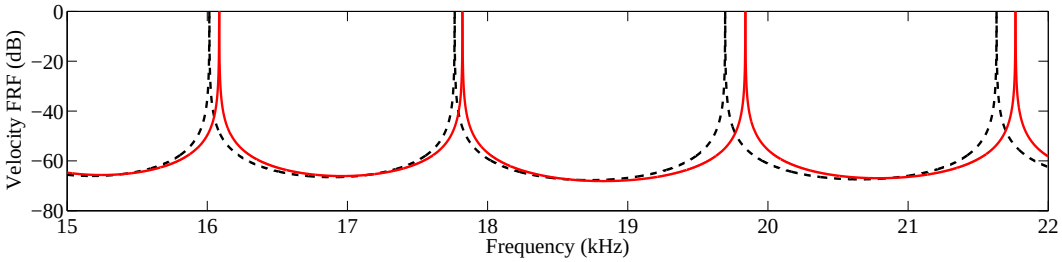

Figure 7: Frequency response functions at higher frequencies - (− −) for the fully homogenized model, (—) for the piecewise homogenized model.

unit cells per wavelength according to Fig 4. With the discrete model, the position of the mechanical resonances are shifted because the mechanical medium is modeled by a lattice. Thus, it does not take into account the increasing mistuning between the continuous and the discrete media.

The second comparison is performed at higher frequencies. Actually, we want to observe the FRFs when the wavelength in the beam is close to two times the length of a unit cell ($\eta = \pi$). This condition occurs between 18 and 19 kHz and it comes with the stop band effect, which was shown in the analysis of the attenuation constants in Fig 5. The finite element model still tends to the piecewise homogenized model, but the homogenized model now presents a slightly different response, as seen in Fig 7. Below 18 kHz, there is already a difference in the positioning of the resonances, but it is even more pronounced after the stop band, which is larger with the piecewise homogenized model. Nevertheless, the effect of the stop band is quite negligible, especially when considering that the approximations of the Euler-Bernoulli model are questionable at such high frequencies. It is also remarked that the considered frequency range is clearly beyond the last electrical resonances. Here, the control strategy involving an analogous discrete network has no effect and the FRFs are essentially due to propagation in the mechanical waveguide.

5 CONCLUSIONS

- Four transfer matrix models are proposed and compared. They differ in the definition of the mechanical medium which can be discrete, fully homogenized, piecewise homogenized or based on a finite element model.
- The finite element model tends to the piecewise homogenized model which is the most accurate because it takes into account the mechanical discontinuity induced by the piezoelectric patches.
- For problems involving analogous control with a discrete electrical network, the fully homogenized model is generally sufficient because the eventual stop band effects occur at frequencies where the proposed control is no more efficient.
- The discrete model is convenient because of its easy implementation but it should be limited to wavelength above ten times the length of the unit cell.
- A future work will consist in the extension of the proposed finite element model to the case of a plate coupled to an analogous electrical network.

Keywords: Buckling, Annular Plate, Eigenvalue Problem, Asymptotic Technique, The Ritz Method.

Abstract. *Buckling of an annular elastic thin plate joint with circular beam under the action of radial stresses is studied. Such plate can be considered as a model of the supporting ring of a cylindrical shell in the case when the ring has a T-shaped cross-section. First the initial stress-resultants are found. Then assuming that the plate is narrow buckling equations and boundary conditions are simplified by means of an asymptotic technique. The approximate eigenvalue problem has analytical solutions for particular cases. In the general case, for its solution the Rayleigh-Ritz method and the shooting procedure are used.*

1 INTRODUCTION

The external pressure acting on a circular cylindrical shell may cause buckling of the shell. Reinforcing of the shell by rings leads to raising its critical pressure. If the width of the rings is sufficiently small the buckling mode is similar to the buckling mode of the shell without rings, and the shell surface is covered by a series of pits stretched along the generatrix of the cylinder. In the case of this typical buckling the rings may be considered as circular beams. Almost in all studies of ring-stiffened shells the beam model of the ring is used (see [1]-[3] and references there).

If the width of a ring grows, the critical pressure increases until the typical buckling mode will be replaced with the buckling mode consisting of small pits formed on the surface of the ring while the cylindrical shell itself does not actually deform (see, [4]). The buckling of the plate occurs under the action of radial stresses arising on the plate edge joined with the cylindrical shell. These stresses are caused by the pressure acting on a circular cylindrical shell. The beam model can not be used for studying the buckling of the wide ring which should be considered as an annular plate. Buckling of annular thin plates is well enough studied (see, for example, [5]-[7]). The aim of this paper is the solution of the buckling problem for the annular plate stiffened by a circular beam.

In [8] by means of an asymptotic analysis the approximate boundary conditions on the plate edge joined with the cylindrical shell are obtained. If the plate is thin these conditions coincide with the conditions on the clamped edge. In the paper [4] for the ring with the rectangular cross-section on the other plate edge the free edge conditions were introduced. The approximate values of the critical pressure found by the solution of the eigenvalue problem for the annular plate are in good agreement with the numerical ones obtained by FEM for the ring-stiffened shell.

In this paper we consider buckling under the action of radial stresses of the ring with the T-shaped cross-section joined with the cylindrical shell and located outside the shell. As a model of such a ring we use a circular plate. We assume that the edge joined with the shell is clamped and the other plate edge is stiffened by the circular beam.

Two cases are analyzed. In the first case the shell is under the internal pressure p (see Figure $1a$) and in the second case the pressure is external (see Figure $1b$).

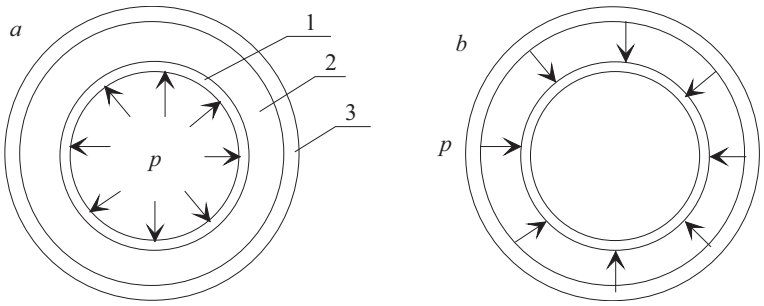

Figure 1: Pressure acting on the shell; 1 — shell, 2 — plate, 3 — beam.

In the work [9] the buckling of a circular plate under the action of radial stresses on the inner edge was considered. For the specific pre-buckling stresses the analytical solution was obtained.

2 BASIC EQUATIONS

Let r be the radial coordinate on the middle surface of the plate and σ_0 the radial stress at the edge $r = r_0$ causing buckling, where r_0 is the radius of the shell. The compressive stresses are regarded as positive. After separation of variables equations describing the buckling of the annular plate can be written in the following form

$$\begin{gathered} Q_1' + \frac{1}{r}Q_1 + \frac{m}{r}Q_2 = T_1 w'' + T_2\left(\frac{w'}{r} - \frac{m^2}{r^2}w\right), \\ Q_1 = M_1' + \frac{1}{r}(M_1 - M_2) + 2\frac{m}{r}H, \quad Q_2 = -\frac{m}{r}M_2 + \frac{2}{r}H, \\ M_1 = D(\kappa_1 + \nu\kappa_2), \quad M_2 = D(\kappa_2 + \nu\kappa_1), \quad H = D(1-\nu)\kappa_{12}, \quad D = \frac{Eh^3}{12(1-\nu^2)}, \\ \kappa_1 = -w'', \quad \kappa_2 = \frac{m^2}{r^2}w - \frac{w'}{r}, \quad \kappa_{12} = \left(\frac{m}{r}w\right)', \end{gathered} \tag{1}$$

where $(')$ denotes the derivative with respect to the radial coordinate r, m is the circumferential wave number, w is the normal deflection, Q_1, Q_2 and M_1, M_2, H are the stress-resultants and stress-couples, T_1 and T_2 are the pre-buckling stress-resultants, E is Young's modulus, h is the plate thickness, ν is Poisson's ratio, κ_1, κ_2, κ_{12} are the changes of curvature.

We assume that the loaded edge of the plate $r = r_0$ is clamped:

$$w = w' = 0, \quad r = r_0. \tag{2}$$

At the other plate edge $r = r_1$ stiffened by the circular beam the boundary conditions have the form

$$M_1 = \frac{EJ_r}{r_0^2}w', \quad Q_1 = T_1 w', \quad r = r_1, \tag{3}$$

where J_r is the moment of inertia of the beam cross-section. For the beam with rectangular cross-section $J_r = a^3 b/12$ (see Figure 2).

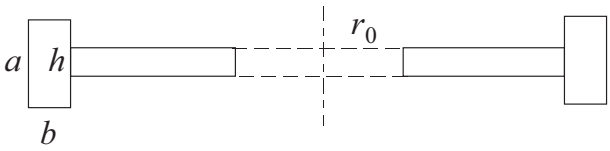

Figure 2: The cross-section of the annular plate joint with the beam

System (1) can be reduced to the equation

$$\frac{d^4w}{ds^4} + \frac{2}{s}\frac{d^3w}{ds^3} - \frac{2m^2 + 1 - \beta t_1}{s^2}\frac{d^2w}{ds^2} + \frac{2m^2 + 1 + \beta t_2}{s^3}\frac{dw}{ds} + \frac{m^2(m^2 - 4 - \beta t_2)}{s^4}w = 0, \tag{4}$$

where

$$\beta = \frac{h\sigma_0 r_0^2}{D}$$

is the buckling stress parameter,

$$s = \frac{r}{r_0}, \quad t_k = \frac{r^2 T_k}{h\sigma_0 r_0^2}, \quad k = 1, 2. \tag{5}$$

3 PRE-BUCKLING STRESS-RESULTANTS

To find the pre-buckling stress-resultants T_1 and T_2 we use equations of axisymmetric tangential deformation of the plate:

$$T_1' + \frac{1}{r}(T_1 - T_2) = 0, \quad T_1 = B\left(u' + \nu\frac{u}{r}\right), \quad T_2 = B\left(\frac{u}{r} + \nu u'\right), \tag{6}$$

where u is the radial displacement and $B = Eh/(1-\nu^2)$. The general solution of equations (6) has the form

$$u = C_1 r + \frac{C_2}{r}, \quad T_{1,2} = B\left(\gamma_0 C_1 \mp \delta_0 \frac{C_2}{r^2}\right), \tag{7}$$

where $\gamma_0 = 1 + \nu$, $\delta_0 = 1 - \nu$.

In the first case corresponding to the Figure 1a the boundary conditions for equations (6) are

$$T_1(r_0) = h\sigma_0, \quad T_1(r_1) = -\frac{ES}{r_1^2}u(r_1), \tag{8}$$

where S is the area of the ring cross-section. Substituting solution (7) into boundary conditions (8) we get

$$(\gamma_0 + \delta_0 S_0)C_1 - \frac{\delta_0(1-S_0)}{r_1^2}C_2 = 0, \quad \gamma_0 C_1 - \frac{\delta_0}{r_0^2}C_2 = \frac{(1-\nu^2)\sigma_0}{E}, \tag{9}$$

where $S_0 = (1+\nu)S/(hr_1)$. The solution of equations (9) has the form

$$C_1 = \frac{(1-S_0)(1-\nu^2)\sigma_0}{dr_1^2 E}, \quad C_2 = \frac{(\gamma_0 + \delta_0 S_0)(1-\nu^2)\sigma_0}{d\delta_0 E}, \quad d = \frac{(1-S_0)\gamma_0}{r_1^2} - \frac{\gamma_0 + \delta_0 S_0}{r_0^2}.$$

Taking into account formulas (7) we obtain

$$T_{1,2} = \frac{h\sigma_0 r_0^2}{r^2}\left(\frac{r^2(1-S_0)\gamma_0 \mp r_1^2(\gamma_0 + \delta_0 S_0)}{r_0^2(1-S_0)\gamma_0 - r_1^2(\gamma_0 + \delta_0 S_0)}\right). \tag{10}$$

In the second case corresponding to the Figure 1b the stresses are tensile. We get the pre-buckling stress-resultants for the second case substituting $-\sigma_0$ instead σ_0 in formulas (10).

If $S_0 = 1$ then

$$T_{1,2} = \pm\frac{h\sigma_0 r_0^2}{r^2}. \tag{11}$$

The analytical solution of equations (1) for the pre-buckling stress-resultants (11) was obtained in [9], however the condition $S_0 = 1$ is unlikely in a real structure.

Taking $S_0 = 0$ in formulas (10), we get the pre-buckling stress-resultants for the plate without the beam which corresponds to a ring with the rectangular cross-section.

4 APPROXIMATE SOLUTION FOR THE FIRST CASE

Consider the buckling of the annular plate under the action of compressive radial stresses applied to the inner clamped plate edge (see Figure 1a). The outer plate edge is joined with circular beam.

Let us suppose that the plate is narrow, i.e. the non-dimensional width of the plate is $\varepsilon = r_1/r_0 - 1 \ll 1$. Usually this condition holds for the rings supporting a shell.

Assume that $m \sim 1$. Then after replacing the variable

$$s = 1 + \varepsilon x \tag{12}$$

in equations (4) and neglecting small terms we get the approximate equation

$$\frac{d^4w}{dx^4} + \beta\varepsilon^2 t_1 \frac{d^2w}{dx^2} + \beta\varepsilon^3 t_2 \frac{dw}{dx} = 0. \tag{13}$$

Replacing variable in relations (2) and (3) according to (12) we obtain the following approximate boundary conditions

$$\begin{gathered} w = w' = 0, \quad x = 0, \\ w'' + cw' = 0, \quad w''' + \beta\varepsilon^2 t_1 w' = 0, \quad x = 1, \end{gathered} \tag{14}$$

where

$$c = \frac{12\varepsilon(1-\nu^2)J_n}{h_n^3}, \quad J_n = \frac{J_r}{r_0^4}, \quad h_n = \frac{h}{r_0}.$$

In the case $S_0 = 1$ it follows from (11) and (5) that $t_{1,2} = \pm 1$. Hence in the first approximation equation (13) and boundary conditions (14) can be written as

$$\frac{d^4w}{dx^4} + \beta_0^2 \frac{d^2w}{dx^2} = 0, \quad \beta_0^2 = \beta\varepsilon^2 \tag{15}$$

$$\begin{gathered} w = w' = 0, \quad x = 0, \\ w'' + cw' = 0, \quad w''' + \beta_0^2 w' = 0, \quad x = 1. \end{gathered} \tag{16}$$

Substituting the general solution of equation (15)

$$w(x) = C_1 \sin\beta_0 x + C_2 \cos\beta_0 x + C_3 x + C_4$$

into boundary conditions (16) we obtain that eigenvalue problem (15), (16) has a nontrivial solution if

$$\beta_0 \cos\beta_0 + c \sin\beta_0 = 0. \tag{17}$$

The non-dimensional critical load β_c may be found by means of the formula

$$\beta_c = \beta_0^2/\varepsilon^2, \tag{18}$$

where β_0 is the minimal positive root of equation (17).

In the case of arbitrary S_0 we get the following approximate expressions for the narrow plate taking into account formulas (10), (5) and (12):

$$t_1 = 1 - \frac{\varepsilon h_n x}{\varepsilon h_n + S_n}, \quad t_2 = \frac{\nu S_n - h_n}{\varepsilon h_n + S_n}, \quad S_n = \frac{S}{r_0^2} = \frac{h_n r_{1n} S_0}{1+\nu}. \tag{19}$$

Equation (13) and boundary conditions (14) take the form

$$\frac{d^4w}{dx^4} + \beta_0^2 t_1(x) \frac{d^2w}{dx^2} + \varepsilon\beta_0^2 t_2 \frac{dw}{dx} = 0. \tag{20}$$

$$\begin{gathered} w = w' = 0, \quad x = 0, \\ w'' + cw' = 0, \quad w''' + \beta_0^2 t_1(1) w' = 0, \quad x = 1. \end{gathered} \tag{21}$$

Eigenvalue problem (20), (21) does not have an analytical solution. To find an approximate value of β_0 we use the Rayleigh-Ritz method. Multiplying equations (20) by w and integrating by parts over the interval $[0, 1]$ we obtain

$$[w'''w - w''w']_0^1 + \int_0^1 (w'')^2\, dx + \beta_0^2 \int_0^1 t_1 w''w\, dx + \varepsilon\beta_0^2 t_2 \int_0^1 w'w\, dx = 0. \tag{22}$$

Taking into account boundary conditions (21) from equation (22) we find

$$\beta_0^2 = \frac{G_1 + I_1}{G_2 + I_2 + I_3}, \tag{23}$$

where

$$\begin{gathered} G_1 = c[w'(1)]^2, \quad G_2 = t_1(1)w'(1)w(1), \quad I_1 = \int_0^1 (w'')^2\, dx, \\ I_2 = -\varepsilon t_2 \int_0^1 w'w\, dx, \quad I_3 = -\int_0^1 t_1 w''w\, dx. \end{gathered} \tag{24}$$

The substituting in formulas (23), (24) instead exact solution $w(x)$ an arbitrary function $W(x)$ satisfying boundary conditions $W(0) = W'(0) = 0$ get an approximate value of β_0. Accuracy of the approximation will be high if we take the function $W(x)$ close to $w(x)$. To choose the function $W(x)$ we consider solutions of eigenvalue problem (15), (16). If $c = 0$ then the minimal positive root of equation (17) is $\beta_1 = \pi/2$. Corresponding to $\beta_1 = \pi/2$ buckling mode has the form $W_1(x) = 1 - \cos(\pi x/2)$. In the case $c = \infty$ the buckling mode is $W_2(x) = 1 - \cos(\pi x)$. Let for any dimensionless stiffness c

$$W(x) = 1 - \cos kx, \tag{25}$$

where $k(c) = \pi(c + 1)/(c + 2)$, $k(0) = \pi/2$, $k(\infty) = \pi$.

Formula (23) for eigenvalue problem (15), (16) after sustituting function (25) in relation (24) and neglecting small terms may be written in the form

$$\beta_0^2 = \frac{4ck \sin k + k^2(2k + \sin 2k)}{2k - \sin 2k}. \tag{26}$$

Comparison of the minimal positive roots of equation (17) and the approximate values of β_0 obtained from formula (26) for $c \in [0, 10]$ shows that the relative error of approximate results is less than 0.1%.

We use function (25) also for the calculation eigenvalues of buckling problem (20), (21). Substituting this function instead $w(x)$ in relations (24), we obtain

$$\begin{gathered} G_1 = c(k \sin k)^2, \quad G_2 = \frac{S_n k \sin k(1 - \cos k)}{S_n + \varepsilon}, \\ I_1 = \frac{k^3}{4}(2k + \sin 2k), \quad I_2 = \varepsilon \frac{1 - \nu S_n}{2(S_n + \varepsilon)}(1 - \cos k)^2, \\ I_3 = \frac{2k^2(2S_n + \varepsilon) - 2kS_n(4 \sin k - \sin 2k) - \varepsilon(7 - 8 \cos k + \cos 2k)}{8(S_n + \varepsilon)}. \end{gathered} \tag{27}$$

Formulas (23) and (27) get an approximate minimal positive eigenvalue β_0 of problem (20), (21). The non-dimensional critical load β_c may be found by means of relation (18).

Consider an annular plate with the parameters $\varepsilon = 0.1$, $\nu = 0.3$, $h_n = h_p/r_0 = 0.01$, which outer edge is stiffened by the circular beam of a rectangular cross-section. The width and height of the beam cross-section are $a = a_n r_0$ and $b = b_n r_0$ correspondingly (see Figure 2). Then $S_n = a_n b_n / h_n$, $J = a^3 b/12$. Values of the dimensionless stiffness c and the non-dimensional critical load β_c for different values of a_n and b_n are given in the Table 1. The last column of

a_n	b_n	c	Values of β_c	
			Ritz method	Shooting

0.12	0.09	14.15	915	915

Table 1: Results of calculation for various dimensions of beam cross-section.

the Table 1 contains values β_c obtained by the numerical solution of eigenvalue problem (20), (21). These results are found by means of the initial-value or shooting procedure represented in [10]. The approximate results calculated from formula (23) are given in the penultimate column. Comparison of the numerical and the approximate results shows that the relative error of the approximate results is less than 6%.

In Fig. 3, for the plate stiffened by the beam of a square cross-section the parameter β_0 vs. $a_n = b_n$ is plotted.

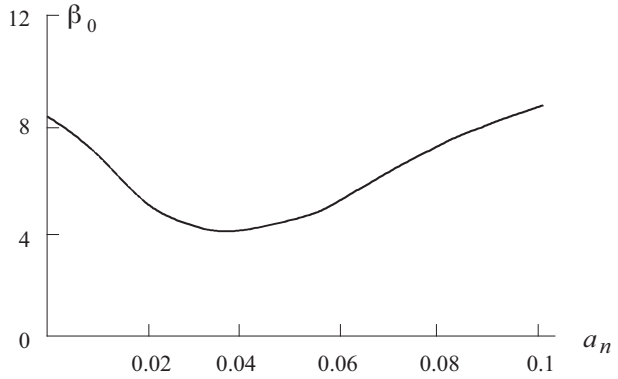

Figure 3: Parameter β_0 vs. dimension of beam cross-section a_n.

At increase in the sizes of the beam cross-section section the parameter of the critical load $\beta_c = \beta_0^2/\varepsilon^2$ decreases, and then increases. Decrease of the critical load β_c with growth of the sizes a_n and b_n is connected with increase in the pre-buckling stress-resultants t_1 at the external

edge of the plate, and its increase is caused by increase in stiffness of a beam c. Hence, by the local buckling under an internal pressure the ring with the rectangular cross-section for which $a_n = b_n = 0$ is more effective than the ring with the T-shaped cross-section.

5 APPROXIMATE SOLUTION FOR THE SECOND CASE

The second case differs from the first case only in that the radial stress at the edge $r = r_0$ is tensile i.e. its has opposite sign. Therefore to obtain in the second case an approximate equation and boundary conditions for the narrow plate and $m \sim 1$ we should change β to $-\beta$ in formulas (13) and (14). Then for $m \sim 1$ by means of relation (23) we obtain that $\beta < 0$, and plate buckling does not occur.

Consider the case of the large circumferential wave number: $m \sim 1/\varepsilon$. Then for a narrow plate the approximate buckling equation and the boundary conditions are

$$\frac{d^4w}{dx^4} - (2m_0^2 + \beta_0 t_1)\frac{d^2w}{dx^2} + m_0^2(m_0^2 + \beta_0 t_2)w = 0, \tag{28}$$

$$\begin{gathered} w = w' = 0, \quad x = 0, \\ w'' + cw' - \nu m_0^2 w = 0, \quad w''' - [(2-\nu)m_0^2 + \beta_0 t_1]w' = 0, \quad x = 1. \end{gathered} \tag{29}$$

where

$$m_0 = \varepsilon m, \quad \beta_0 = \varepsilon^2 \beta, \quad t_1 = 1 - \frac{\varepsilon h_n x}{\varepsilon h_n + S_n}, \quad t_2 = \frac{\nu S_n - h_n}{\varepsilon h_n + S_n}, \quad S_n = \frac{h_n r_{1n} S_0}{1+\nu}.$$

Equation (28) has analytical solutions only in the cases $S_0 = 0$ and $S_0 = 1$ (see [4] and [9]). In the general case we search approximate value of β_0 by means of the Rayleigh-Ritz method. We multiply equations (28) by w, integrate by parts over the interval $[0, 1]$ and obtain

$$[w'''w - w''w']_0^1 + I_2 + 2m_0(I_1 - [w'w]_0^1) - \beta_0 I_3 + m_0^2(m_0^2 + \beta_0 t_2)I_0 = 0. \tag{30}$$

Here

$$I_2 = \int_0^1 (w'')^2\,dx, \quad I_1 = \int_0^1 (w')^2\,dx, \quad I_0 = \int_0^1 w^2\,dx, \quad I_3 = \int_0^1 t_1 w''w\,dx.$$

Using boundary conditions (29) from equation (30) we find

$$\beta_0 = \frac{I_2 + m_0^2 I_1 + m_0^4 I_0 - 2\nu m_0^2 w(1)w'(1) + c(w'(1))^2}{I_3 - t_2 m_0^2 I_0 - t_1(1)w(1)w'(1)}. \tag{31}$$

As a Ritz function $W(x)$ we use the solution of following eigenvalue problem

$$\frac{d^4w}{dx^4} - (2m_0^2 + \beta_0)\frac{d^2w}{dx^2} + m_0^2(m_0^2 + \beta_0 t_2)w = 0, \tag{32}$$

$$\begin{gathered} w = w' = 0, \quad x = 0, \\ w'' + cw' - \nu m_0^2 w = 0, \quad w''' - [(2-\nu)m_0^2 + \beta_0 t_1]w' = 0, \quad x = 1. \end{gathered} \tag{33}$$

Substituting $w = e^{\lambda x}$ into equation (32) we obtain the biquadratic equation

$$\lambda^4 - (2m_0^2 + \beta_0)\lambda^2 + m_0^2(m_0^2 + \beta_0 t_2) = 0$$

which has the following roots:

$$\lambda_{1,2} = \pm\sqrt{b_0 - a_0}, \quad \lambda_{3,4} = \pm\sqrt{b_0 + a_0},$$

where

$$a_0 = \sqrt{(1 - t_2)m_0^2\beta_0 + \beta_0^2/4}, \quad b_0 = m_0^2 + \beta_0/2.$$

In the case $\beta_0 \le m_0^2/t_2$ all roots are real and eigenvalue problem (32), (33) does not have a nontrivial solution. Let us search $\beta_0 > m_0^2/t_2$. Then equation (32) has the general solution

$$w = C_1 \sin\alpha x + C_2 \cos\alpha x + C_3 \sinh\gamma x + C_4 \cosh\gamma x,$$

where C_k, $k = 1, 2, 3, 4$ are arbitrary constants,

$$\alpha = \sqrt{a_0 - b_0}, \quad \gamma = \sqrt{a_0 + b_0}.$$

To obtain the constants C_k we substitute the general solution into boundary conditions (33) and get a system of linear homogeneous algebraic equations. The determinant of this system may be written as

$$D(\beta_0) = \begin{vmatrix} 0 & 1 & 0 & 1 \\ \alpha & 0 & \gamma & 0 \\ (A-\alpha^2)s_1 + c\alpha c_1 & (A-\alpha^2)c_1 - c\alpha s_1 & (A+\gamma^2)s_2 + c\gamma c_2 & (A+\gamma^2)c_2 + c\gamma s_2 \\ \alpha(B-\alpha^2)c_1 & -\alpha(B-\alpha^2)s_1 & \gamma(B+\gamma^2)c_2 & \gamma(B+\gamma^2)s_2 \end{vmatrix}$$

where

$$A = -\nu_0^2, \quad B = m_0^2(\nu - 2) - \beta_0 t_1(1),$$

$$s_1 = \sin\alpha, \quad s_2 = \sinh\gamma, \quad c_1 = \cos\alpha, \quad c_2 = \cosh\gamma.$$

After transformations, we get

$$D(\beta_0) = Fs_1s_2 + Gc_1c_2 + H + c\alpha\gamma(\alpha^2 + \gamma^2)(\alpha s_1c_2 + \gamma c_1s_2).$$

Here

$$F = \gamma^2(A-\alpha^2)(B+\gamma^2) - \alpha^2(A+\gamma^2)(B-\alpha^2),$$
$$G = -\alpha\gamma[(A-\alpha^2)(B+\gamma^2) + (A+\gamma^2)(B-\alpha^2)],$$
$$H = \alpha\gamma[(A+\gamma^2)(B+\gamma^2) + (A-\alpha^2)(B-\alpha^2).$$

If $\beta_0(m_0)$ is the minimal positive root of equation $D(\beta_0) = 0$ then we can find the parameter of the critical load β_c from the following formulas

$$\beta_c = \beta_m/\varepsilon^2, \quad \beta_m = \min_{m_0} b_0(m_0). \tag{34}$$

Since $D(\beta_m) = 0$, the system of linear homogeneous algebraic equations with the unknowns C_k has nontrivial solution for $\beta_0 = \beta_m$. As such solution we take the minors of elements of the third row of a determinant $D(\beta_m)$:

$$C_1^* = \alpha\gamma(B-\alpha^2)s_1 + \gamma^2(B+\gamma^2)s_2, \quad C_2^* = \alpha\gamma(B-\alpha^2)c_1 - \alpha\gamma(B+\gamma^2)c_2,$$
$$C_3^* = -\alpha^2(B-\alpha^2)s_1 - \alpha\gamma(B+\gamma^2)s_2, \quad C_4^* = -\alpha\gamma(B-\alpha^2)c_1 + \alpha\gamma(B+\gamma^2)c_2,$$

Hence, the buckling mode of the problem (32), (33) is

$$W = C_1^* \sin\alpha x + C_2^* \cos\alpha x + C_3^* \sinh\gamma x + C_4^* \cosh\gamma x.$$

Substituting in formula (30) instead the exact solution $w(x)$ the function $W(x)$ we obtain the approximate value of the non-dimesion critical load of problem (28), (29):

$$\beta_0 = \frac{I_2 + m_0^2 I_1 + m_0^4 I_0 - 2\nu m_0^2 W(1)W'(1) + c(W'(1))^2}{I_3 - t_2 m_0^2 I_0 - t_1(1)W(1)W'(1)}, \tag{35}$$

where

$$I_2 = \int_0^1 (W'')^2\,dx, \quad I_1 = \int_0^1 (W')^2\,dx, \quad I_0 = \int_0^1 W^2\,dx, \quad I_3 = \int_0^1 t_1 W''W\,dx.$$

The relative error of approximate results, obtain from formula (28), in comparison with numerical results, found by means of the shooting procedure, is less than 0.1%.

In Fig. 4, for the plate with the parameters $\varepsilon = 0.1$, $\nu = 0.3$, $h_n = 0.01$ stiffened by the beam of a square cross-section the critical load β_0 vs. the dimensionless sizes of the beam cross-section a_n is plotted.

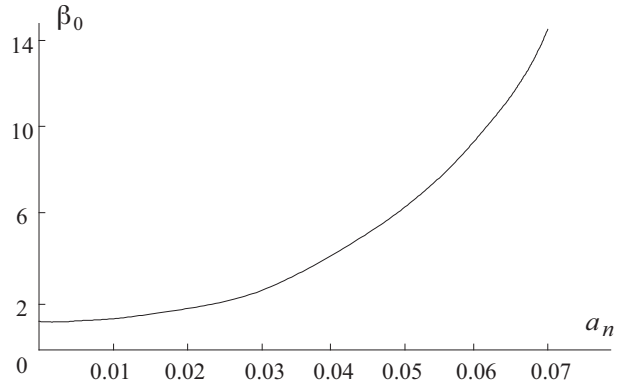

Figure 4: Parameter β_0 vs. sizes of beam a_n.

At increase in the sizes of the beam cross-section the parameter of critical load $\beta_c = \beta_0^2/\varepsilon^2$ increases. Therefore, by the local buckling under an external pressure the ring with the T-shaped cross-section is more effective than the ring with rectangular cross-section.

6 CONCLUSIONS

We discussed buckling of rings with the T-shaped cross-section supporting a circular cylindrical shell. The cases of internal and external uniform pressures acting on the shell are analyzed. As a model of the ring the annular thin narrow plate joint with a circular beam is used. Buckling equations and boundary conditions are simplified by means of an asymptotic technique. To find the approximate critical load the Rayleigh-Ritz method is used. The solutions of the approximate eigenvalue problems are obtained in closed form. Comparison of the numerical results found by means of the shooting procedure and the approximate results shows that the relative error of the approximate results is small.

The dependence of the critical load on the dimensions of the beam cross-section is studied. In case of the internal pressure with the increase in these dimensions the critical load decreases, and then increases. Therefore, by the local buckling under an internal pressure the ring with the rectangular cross-section is more effective than the ring with the T-shaped cross-section. If the pressure is external then the increase in the dimensions of beam cross-section caused the

increase of critical load, and the ring with the T-shaped cross-section is more effective than the ring with rectangular cross-section.

The results obtained in the current paper may be used for optimal design of the cylindrical shell stiffened by rings.

Keywords: Elasto-plasticity, Hygroexpansivity, Paper, Finite Element Method, Curl, Fluting.

Abstract. *An in-plane elasto-plastic material model and a hygroexpansivity model were applied for paper. The input parameters for both models are fiber orientation and dry solids content. A finite element model was constructed offering possibilities for studying different structural variations of an orthotropic sheet as well as buckling behavior and internal stress situations under through-thickness strain differences. Examples related to the curl and web-fluting phenomena of paper are presented. Both studied cases presented in this paper indicates the usefulness of the hygro-elasto-plastic model in predicting the challenging deformation phenomena of orthotropic paper sheets. The application possibilities of the hygro-elasto-plastic model are diverse, including the investigation into several phenomena and defects appearing in drying, converting and printing process conditions.*

1 INTRODUCTION

There are several undesired phenomena that can be considered to be connected to hygroscopic and stress-strain behavior of the paper web or sheet during production processes and in end-use. Examples of such phenomena are the development of shrinkage profiles, loose edges of web, baggy paper web causing possible wrinkling and misregistration in printing, out-of-plane deformations such as cockling, curl and fluting in heatset-web-offset (HSWO) printing process or distortion of shape of product such as sheet or box (see Fig. 1). Natural fibers and their treatments, bonds between fibers and their orientation in the fiber network, additives and manufacturing conditions all affect the sorption based dimensional instability and the mechanical properties of paper or board [1, 2, 3, 4, 5, 6, 7, 8, 9, 10].

Several models to predict in-plane mechanical and rheological properties, shrinkage and hygroexpansivity of paper and board have been introduced. Nonlinear elastic models, orthotropic elasto-plastic approaches and viscoelastic models have been used for studying bending, buckling, failure, tensile response, and creep and relaxation behavior of paper sheet, see, for example [11, 12, 13, 14, 15, 16] and [17, 18, 19, 20, 21, 22, 23, 24]. The formula for the hygroexpansion of paper has been derived from the hygroexpansion of a single fiber and the efficiency of the stress transfer between fibers in [25]. In the reference [26], the traditional theory for linear thermoelasticity was applied to estimate hygroexpansion strains. An orthotropic hypoelastic constitutive model has been proposed for studies of phenomena behind the shrinkage profile [27]. In that model, the total strain including the hygroscopic strain component and the elastic modulus dependent on the moisture ratio are described by an exponential relation. The relation between strain history and tensile stiffness was assumed to be linear, and the model and isotropic inputs were calibrated by laboratory scale experiments. In the reference [28], the measured moisture dependency of material constants was utilized in the nonlinear elastic model to investigate the effect of moisture on mechanical behavior. Some studies on the buckling of paper have been introduced in [12, 29, 30]. Low tension streaks, having longer dimension, appear as buckling to baggy embodiment and may cause runnability problems [31, 32]. Plastic strains caused by moisture streaks or some mechanical unevenness result in uneven tension profiles of the web. Buckling streakiness i.e. bagginess of paper web has been simulated using hygro-elasto-plastic model (LE-model) introduced in [33]. In the LE-model, the in-plane elasto-plastic constitutive material model and hygroexpansivity model as a function of dry solids content (DSC) and the anisotropy index of fiber orientation are applied for numerical solutions of the finite element method. The use of the anisotropy index parameter instead of the traditional fiber orientation anisotropy simplifies the handling of different directions in the case of anisotropic sheet and, for example, the determination of Hill's yield surface for the finite element approach is straightforward.

In this study, the LE-model is utilized to simulate results connected to two out-of-plane deformations: curl and fluting. Paper or board curl is the tendency of a flat paper or board sheet to distort and form curved surfaces of cylindrical shape (see Fig. 1). Although the basic cause of curl is simply a deformation variation of paper in its thickness direction, the processes causing the different deformations in different layers are complex and variable [34]. In the references [35] and [34], an analytical equation for sheet curl resulting from the hygroexpansion coefficients and elastic properties of the layers using elastic lamination theory has been derived. In the studies [36], [37] and [38], the hygroscopic out-of-plane deformations using the elastic constitutive model have been presented, while the elasto-plastic model has been applied in [39]. Twisted or diagonal curl modes are usually considered very harmful; an analytical equation is

Figure 1: Examples of out-of-plane deformations of paper: picture of fine paper curl (left) and fluting in a printed area of a HSWO printed product (right).

given by Uesaka, see, for example [40]. In this paper, the LE-model is utilized to study the effect of through-thickness variation of fiber orientation and dry solids content on curl amplitude and mode.

Fluting appears as permanent, regularly spaced waves arising during heatset-web-offset printing process in the running direction of the printing machine and the machine direction (MD) of paper, see Fig. 1. Generally, two stages can be distinguished in the fluting phenomenon: fluting formation and fluting retention. There is, however, no final conclusion of the mechanisms of these two stages. For fluting formation, at least three more or less different explanations have been offered. A phenomenon related to tension wrinkles [41, 42] and differential shrinkage of inked and non-inked areas due the moisture difference [43, 44] are two of the proposed reasons. The occurrence of moisture difference is also confirmed by measurements [45, 46]. Thirdly, small local in-plane moisture content variations have been linked to the formation of fluting [47]. It has been suggested that the ink layer has an effect on the permanency of fluting [41, 43]. However, in [47] it has been estimated that ink stiffening alone cannot explain the amplitudes observed in practice. Based on simulations and experimental study, he suggests that irreversible shrinkage and thermal plastic deformations of paper may be additional mechanisms for fluting to achieve a required retention. Earlier simulation studies concerning the fluting phenomenon are based on elastic material models, see for example [44, 38, 47]. However, when fluting retention and trough-thickness moisture gradients are concerned, an elasto-plastic modeling approach could be very convenient, as simulation results of the LE-model presented in this paper indicates.

2 MEASUREMENTS

2.1 Fiber orientation anisotropy

The fiber orientation parameters are measured using the layered fiber orientation method developed by Erkkilä [48, 49, 50]. Adhesive or lamination tape splitting was applied to paper sheet to separate approximately 10 individual layers from a paper sheet. Then the sample layers were placed against a black background, and an image of a suitable area was captured by scanner using reflective illumination. In analyzing the layer images, the aim is to detect the edges of fibers or fiber bundles and to determine their orientations. The detection of edges is based on the computation of image gradients in every image element. For a discrete digital image, the derivatives $\frac{\partial f}{\partial x}$ and $\frac{\partial f}{\partial y}$ can be approximated through a discrete differentiation operator. The operator uses two kernels $k_x(i,j)$ and $k_y(i,j)$ that are convolved with the original image $f(x,y)$ to calculate approximations of the horizontal and vertical derivatives by

$$\frac{\partial f(x,y)}{\partial x} \approx D_x(x,y) = (f * k_x)(x,y), \tag{1}$$

$$\frac{\partial f(x,y)}{\partial y} \approx D_y(x,y) = (f * k_y)(x,y), \tag{2}$$

where $*$ denotes the 2-dimensional convolution operation. The coefficients of the kernels used are based on the principle of binomial filter design [50]. The magnitude (length) $|\nabla f(x,y)|$ and direction $\theta_f(x,y)$ of gradient vectors at each local image point are calculated by applying Eqs. (3) and (4)

$$|\nabla f(x,y)| = \sqrt{D_x^2 + D_y^2}, \tag{3}$$

$$\theta_f(x,y) = \tan^{-1}\frac{D_y}{D_x}. \tag{4}$$

The magnitude of gradient vector is directly related to the probability that the part of the image examined represents the edge of the fiber. At the fiber edge, the direction of the gradient corresponds to the direction normal to that segment of fiber edge. The discrete orientation distribution is then formed as a weighted probability density function of the local orientations $P(\theta_P)$, where the weighting factor is the gradient magnitude $|\nabla f(x,y)|$. The direction histogram is

$$P(\theta_P) = \frac{\Sigma_{x,y}\left(|\nabla f(x,y)|\,\delta_{\theta_{f(x,y)},\theta_P}\right)}{\Sigma_{x,y}\,|\nabla f(x,y)|} \tag{5}$$

where $\delta_{\theta_{f(x,y)},\theta_P}$ is Kronecker's delta function and $\{\theta_P, \theta_f \in Z : 0 \leq \theta_P, \theta_f < 360\}$. The main direction of the orientation (orientation angle) θ is defined as the deviation of the longer symmetry axis from the machine direction. The anisotropy of the fiber orientation distribution ξ is defined as a ratio of the maximum distribution value $P(\theta)$ and the value in the perpendicular direction to the maximum value $P(\theta + 90)$. Examples of the layer image, the gradient magnitude, and the direction histogram are presented in Fig. 2.

2.2 Hygroexpansion coefficient measurements

A mixture of two pulps containing 71% thermomechanical pulp and 29% bleached softwood draft pulp was used in this study. The oriented laboratory sheets were formed using a dynamic sheet former with the target basis weight 65 g/m^2. The sheets were wet-pressed according to ISO5269-1:2005, and then were either air-dried freely or under restraint in standard atmosphere conditions (23 Celsius, 50% RH). The procedure for the hygroexpansivity measurements followed the general guidelines stated in ISO 8226-1:1994 for maximum relative humidity up to 68%. According to ISO 8226-1:1994, the hygroexpansive strain X is

$$X = \frac{l_{66} - l_{33}}{l_{50}} 100\% \tag{6}$$

where l is the length in the specific RH% indicated by the subscript. However, the hygroexpansion coefficient β (%/%), defined as

$$\beta = \frac{X}{\Delta M} \tag{7}$$

where ΔM (%) is the moisture content change, was used in this study. At least seven parallel samples were measured in each anisotropy level. The same image analysis based method

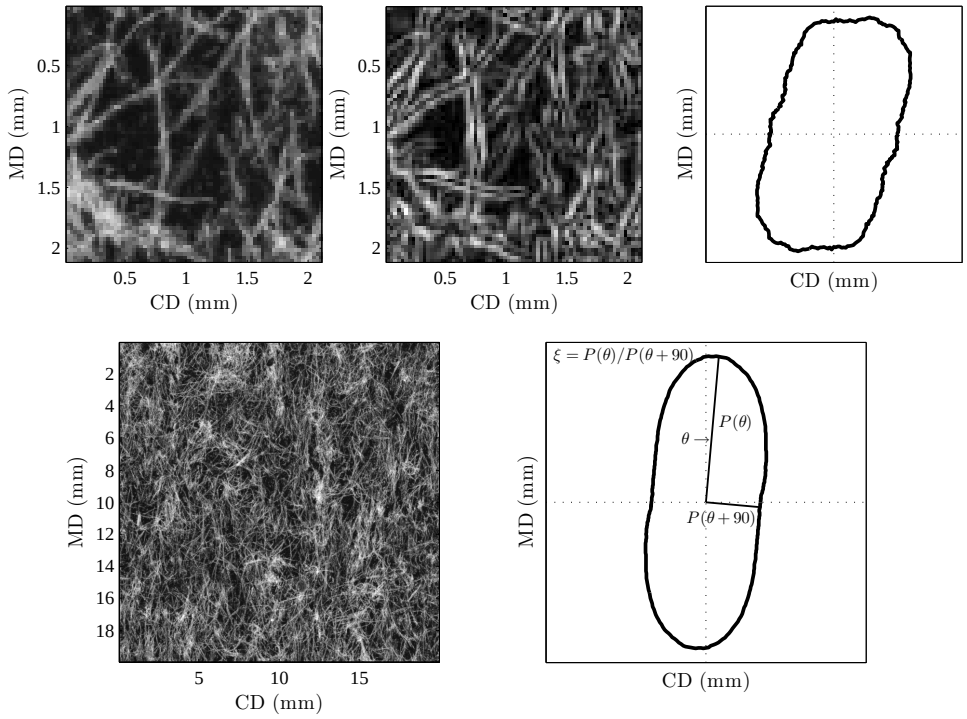

Figure 2: A 2.1 mm $\times$ 2.1 mm region of newsprint layer image (top left), corresponding magnitude of gradient (top middle) and orientation distribution i.e. direction histogram (top right). A 20 mm $\times$ 20 mm region of layer image (bottom left) and corresponding direction histogram, direction 1 (P(θ)), direction 2 (P(θ + 90)), orientation angle θ and anisotropy ξ (bottom right).

was also applied to determine the drying shrinkage of freely dried samples as a percent relative in-plane dimensional change (%) during drying. Sheet forming and measurements of hygroexpansivity as well as drying shrinkage are described in detail in [51].

2.3 Stress-strain tests

The fine paper samples with three different fiber orientation anisotropy levels were produced by pilot machine. The measured averaged anisotropy values of the studied samples was 1.20, 1.51 and 2.02. The dry solids contents varied from 53% to 56% at the initial stage. The basis weight of samples was from 77 g/m^2 to 80 g/m^2. The stress-strain curves were measured from paper strips (width 20 mm) with a span length of 180 mm. Strips were cut from the long side along four different in-plane directions γ: 0, 45, 70 and 90 degrees in relation to cross direction (CD) perpendicular to MD. The samples were dried in a tensile test machine to five target DSC levels: 55%, 65%, 75%, 85% and 95%. However, the measured DSC values during each measurement were read and used in studies instead of the target DSC values. Drying shrinkage was prevented in the loading direction. The tensile stress caused by restrained shrinkage was, however, released by unloading a tensile test specimen before the load-elongation measurement was started. Three repetitions of measurements on each anisotropy, cutting direction and dry solids content combinations were performed. A description of the measuring method is presented in reference [39]. In this study, the parallel results were used as individual test points so that the total amount of data in the fitting procedure was 180 individual stress-strain curves.

Table 1: The fitting parameters of Eq. (10) for the yield stress σ_y, the yield strain ε_y and the hardening constant H [33].

	A_1	A_2	A_3	n
σ_y	-5.9030 (Pa^n)	3.1959 (Pa^n)	18.3077 (Pa^n)	0.1760 (-)
ε_y	380.4181 (-)	14.3408 (-)	-269.8327 (-)	-0.7720 (-)
H	-0.6021 (Pa^{2n})	4.0423 (Pa^{2n})	11.3795 (Pa^{2n})	0.0715 (-)

3 MODELS FOR MATERIAL BEHAVIOR

Material behavior under external and internal tensions and dry solids content changes are described by elasto-plastic material model and the hygroexpansivity model. Elasto-plastic material model is based on the curve fittings presented in [52] where equation

$$\sigma = \begin{cases} E\varepsilon & \text{if} \quad \varepsilon \leq \varepsilon_y \\ E\varepsilon_y - \frac{H}{2E} + \sqrt{H\left(\frac{H}{4E^2} + \varepsilon - \varepsilon_y\right)} & \text{if} \quad \varepsilon > \varepsilon_y \end{cases} \tag{8}$$

was found suitable for describing all the uniaxial stress-strain relationships considered. In Eq. (8), σ and ε are the stress and strain, respectively; the dry solids content $R_{sc} = [0, 1]$ and the anisotropy index ϕ dependent fitting parameters are the elastic modulus E, the yield strain ε_y and the hardening constant H. The anisotropy index ϕ is defined as [52]

$$\phi = \sqrt{\frac{1 - \xi^2}{\xi + \tan^2 \gamma / \xi} + \xi} \tag{9}$$

where ξ is the fiber orientation anisotropy and γ is the angle from the minor axis of the fiber orientation distribution [52]. The material model was constructed by fitting the equation [33]

$$P = (A_1 + A_2\phi + A_3 R_{sc})^{1/n} \quad P = \{\sigma_y, \varepsilon_y, H\} \tag{10}$$

for the dry solids content and the anisotropy index dependence. In Eq. (10), the parameters A_1, A_2, A_3 and n are the fitting constants, see Table 1.

The hygroexpansivity model is based on the measurements and fitting procedures presented in [53] and [33]. The hygroexpansion coefficients β for every in-plane direction are defined by the equation

$$\beta = \frac{k\phi^v}{R_{sc}^2} \exp\left(\frac{k\phi^v}{-\frac{1}{a}k\phi^v + \frac{b}{a}\left(1 - \exp\left(-100\frac{k\phi^v}{a}\right)\right)}\left(\frac{1}{R_{sc}} - 1\right)\right) \tag{11}$$

where the fitting parameters have values $k = 0.0439$, $v = -0.9015$, $a = 2.5054$ and $b = 0.0250$ [33].

In the continuum mechanical model, plane stress is assumed and the yield surface is described by the Hill's yield function [54]. When the Hoffman's approximation is used as in [39] the yield surface has the form

$$f(\sigma) = \sqrt{\sigma_1^2 - \sigma_1\sigma_2 + \left(\frac{\sigma_{y,1}}{\sigma_{y,2}}\right)^2(\sigma_2^2 - \sigma_{12}^2) + \left(\frac{2\sigma_{y,1}}{\sigma_{y,45°}}\right)^2\sigma_{12}^2} \tag{12}$$

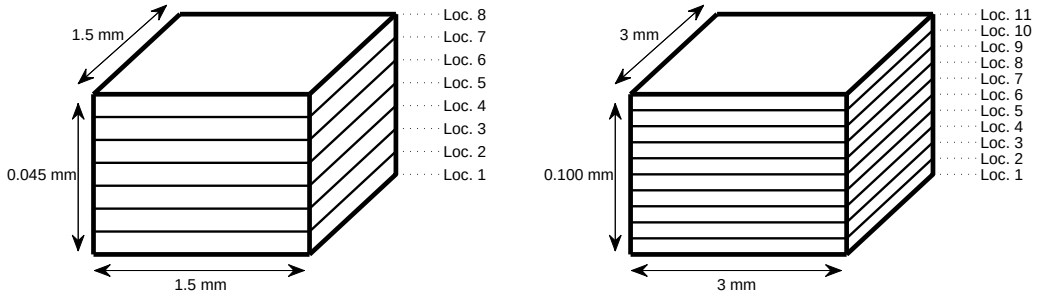

Figure 3: Elements used for the fluting (left) and the curl (right) simulations. Thickness directional DSC profile is defined by the locations shown.

where σ_1, σ_2 and σ_{12} are the stress tensor components and $\sigma_{y,1}$, $\sigma_{y,2}$ and $\sigma_{y,45^\circ}$ are the yield stresses in the main direction, cross direction and the direction deviating 45 degrees from the main direction, respectively. The elastic modulus is defined for directions 1, 2 and 45° by the yield stresses $\sigma_{y,i}$ and the yield strains $\varepsilon_{y,i}$ as

$$E_i = \frac{\sigma_{y,i}}{\varepsilon_{y,i}}. \tag{13}$$

The direction is specified by the subscript i. The in-plane yield stress and yield strain parameters are defined by Eq. (10) and the shear modulus is approximated by the equation [55]

$$G_{12} = \frac{1}{\left(\frac{4}{E_{45^\circ}} - \frac{1}{E_1} - \frac{1}{E_2} - \frac{2\nu_{12}}{E_1}\right)} \tag{14}$$

where ν_{12} is the Poisson ratio defined as

$$\nu_{12} = \left(0.015\left(1 - R_{sc}\right) + 0.15\right)\phi_1. \tag{15}$$

In Eq. (15), ϕ_1 is the anisotropy index of the main direction. The dependence of ν_{12} on the anisotropy index and dry solids content is roughly based on the results presented in [28] and by Maxwell relation the Poisson ratio ν_{21} is defined as $\nu_{21} = \nu_{12}E_2/E_1$.

4 NUMERICAL SOLUTION AND SAMPLE SETUP

Finite element method (FEM) was used to obtain the numerical solutions. Simulations were performed by the commercial software ABAQUS/Standard using shell element S4R with composite structure, see [56]. Two different phenomena were considered: fluting and curl of paper. The element size and thickness of the simulated sample are given in Fig. 3. In both cases, one element is used in the thickness direction of the sample. In the fluting simulations, the element was divided in the thickness direction into 7 layers with equal thicknesses, whereas in the curl simulations, the element was divided into 10 layers. The in-plane layouts used in the simulations are shown in Fig. 4. Automatic incrementation control and volume-proportional damping were utilized to obtain the numerical solutions [56]. For the fluting and curl simulations the damping factors 10^{-8} and 10^{-12} were used, respectively.

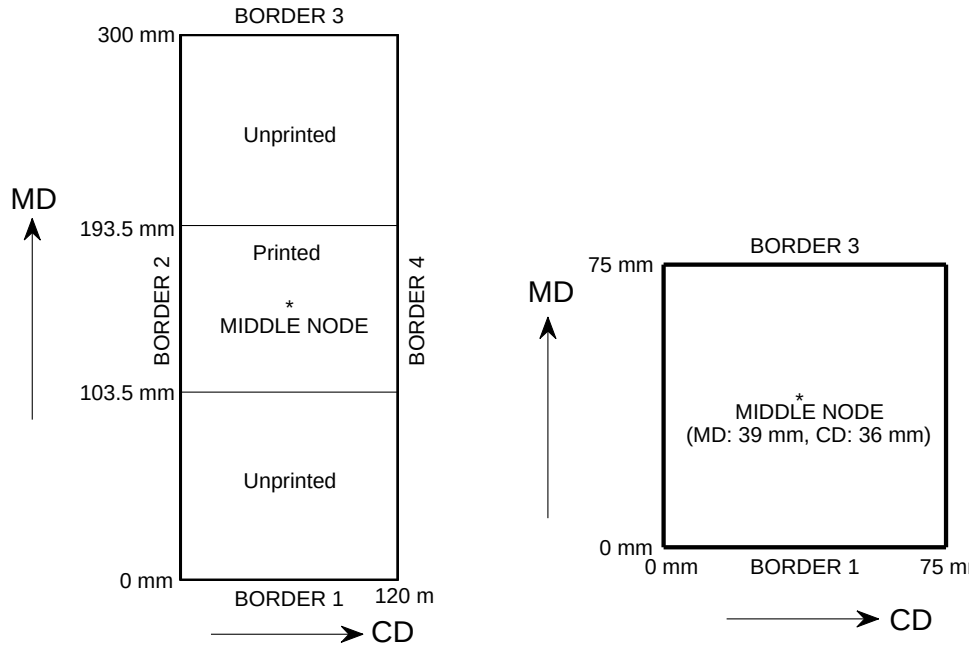

Figure 4: Layouts for fluting (left) and curl (right) simulations.

4.1 Curl simulations

The through-thickness variation of the fiber orientation of the samples is presented in Fig. 5. The initial DSC was 85% throughout the sample. In step 1, MD tension 200 N/m was applied via borders 1 and 3 and the following boundary conditions were applied:

- Boundary condition 1: Out-of-plane displacement (u_3) was restrained in all nodes.
- Boundary condition 2: In the middle node (not located into geometrical middle point, see Fig. 4) all displacements and rotations were restrained.

In step 2, the DSC profile were applied to the sample. Different DSC profiles used in step 2 are presented in Fig. 6. In step 3, the whole sample was dried into DSC 95%. In step 4, the external tension was removed and in step 5, the boundary condition 1 was removed.

4.2 Fluting simulations

In the fluting simulations, a homogeneous strongly MD-orientated sample ($\theta = 0$, $\xi = 4$) was used. The initial DSC was 96% throughout the sample. In the following, the displacements and the rotations are marked as u_1 (coincides with the MD when $\theta = 0$), u_2 (coincides with the CD when $\theta = 0$), u_3 and ur_1, ur_2, ur_3, respectively, see [56]. The boundary conditions were defined as (see Fig. 4):

- Out-of-plane displacement (u_3) was restrained in the borders 1, 2, 3 and 4.
- The rotation ur_1 was restrained in the borders 2 and 4.
- The rotation ur_2 was restrained in the borders 1 and 3.
- In the middle node the displacements u_1 and u_2 and rotation ur_3 were restrained.

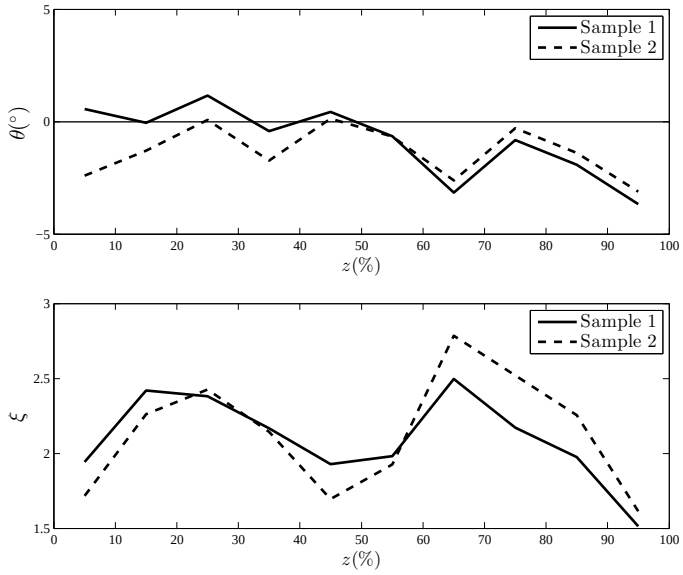

Figure 5: Through-thickness (z) variation of the orientation angle θ (top) and the anisotropy ξ (bottom) of the samples used in the curl simulations.

In step 1, the DSC profile (see Fig. 7) was applied to the printed area and the through-thickness symmetry was nullified by setting the out-of-plane directional force with value 10^{-3} N to the node located at position MD = 190.5 mm, CD = 42 mm. In step 2, this force was removed. In step 3, MD tension 400 N/m was applied via borders 1 and 3 and in step 4, the DSC profile applied to the printed area in step 1 was replaced by the initial dry solids content 96 %. The simulations were ended by step 5 where the external tension was removed from borders 1 and 3.

5 RESULTS AND DISCUSSION

Curl may have different modes: curl toward surface 1 or surface 2 and cylindrical shape main axis along MD (MD curl), along CD (CD curl) or to some other angle (diagonal curl).

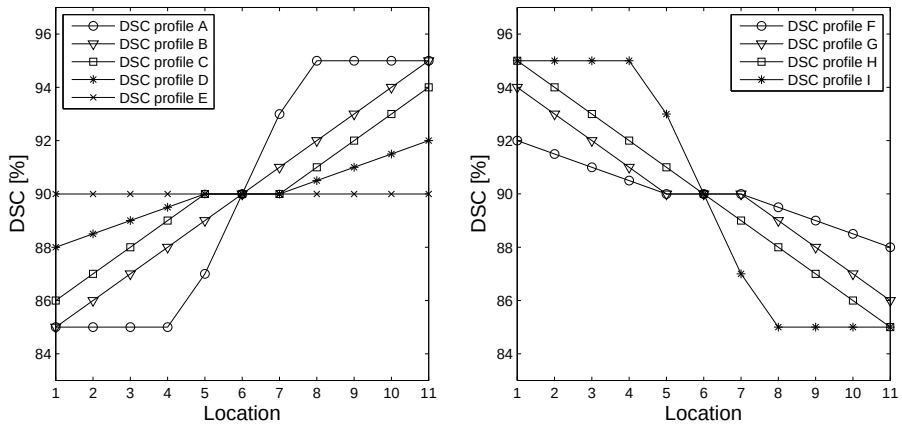

Figure 6: Curl simulations: DSC profiles.

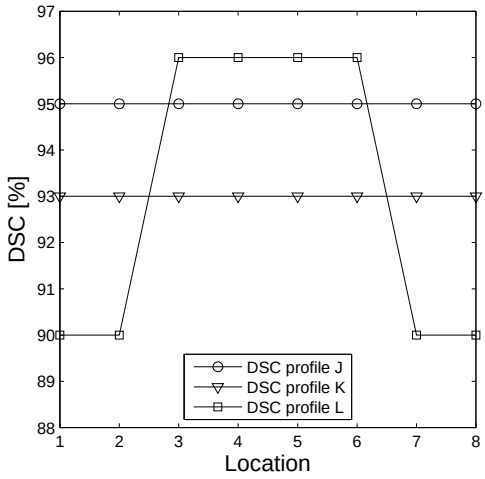

Figure 7: Fluting simulations: DSC profiles.

The simulated curl of samples 1 and 2 with all DSC profiles A-I is presented in Figs. 8 and 9. With flat drying profile E, the curl amplitude of both samples is minor, because of fairy symmetrical anisotropy profile between sides of the samples. When drying includes profiles D or F no significant change in curl can be detected. This indicates that no plastic strains either at surface 1 or 2 have been induced. However, higher gradient in DSC profiles (A-C and G-I) generates plastic strains that change the curl. Generally, paper curls toward the surface dried last [9], i.e. dryings using DSC profiles A, B and C turn curl more toward surface 1 and DSC profiles G, H, I toward surface 2. The equivalency of strain at both sides of samples can be adjusted by drying two-sidedness. However, near the equivalent strain condition, the sample is at risk to manifest diagonal or CD mode of curl. Diagonal and CD curl are harmful modes of curl in many applications and there have been attempts to control this by adjusting the two-sidedness of orientation angle. Obviously, zero orientation angles at both sides of samples would provide the best results, but even when there is only minor orientation angle two-sidedness, as in sample 2, there is no guarantee of maintaining MD curl mode at every drying profile. The clearest example of this phenomenon can be observed in tests carried out in single-sided and double-sided printing by either side toward heated roller of the copier or printer, see, for example [57].

Out-of-plane deformations of steps 3, 4 and 5 of fluting simulation with DSC profile L are presented in Fig. 10. Corresponding plastic deformations in MD and CD at step 5 are presented in Fig. 11. Due to the higher moisture content the printed area expands according to the hygroexpansion tendency. The tension and dryer unprinted areas constrain the printed area in CD and force it to buckle to a wavy form. The strong waviness at the printed area in step 3 can generate plastic strain especially to concave positions of waves. The leveling of the moisture difference in step 4 does not remove the plastic deformations formed already and permanent wavy deformations are produced to the sample. A higher moisture difference between printed and unprinted areas and unevenness of the moisture content profile increase severity of fluting waviness, see Fig. 12. The wavelength of simulated fluting is around 20 mm (see Fig. 12), which fit into the range of typically observed fluting wavelength approximately between 5 and 30 mm, see, for example [58]. However, the wavelength is dependent on boundary conditions, sample and element size, disturbances, etc.

6 CONCLUSIONS

There are several undesired phenomena that can be considered to be connected to hygroscopic and stress-strain behavior of paper web or sheet during production processes and in end-use. Out-of-plane deformation defects such as curl and fluting in heatset-web-offset printing have been studied widely by different experimental and modeling approaches, but there are still features left unknown.

The objective of this work was to apply a hygro-elasto-plastic model to the out-of-plane deformation phenomenon corresponding to copy curl and HSWO fluting conditions. In both cases, the simulations predict the behavior of hygroscopic orthotropic sheet under moisture change during different external in-plane stretch or stress conditions. The model includes two experimental models: elasto-plastic material model and hygroexpansivity model. In both models, the structural properties of the sheet are described by fiber orientation probability distribution, and both models are functions of the dry solids content and fiber orientation anisotropy index. The anisotropy index simplifies the procedure of determining the constitutive parameters of the material model and hygroexpansion coefficients in different directions of an anisotropic sheet. For studies of the combined and more complicated effects of hygro-elasto-plastic behavior, these two models were implemented in a finite element program for numerical solution.

The behavior of two orientated structures was simulated using different z-directional DSC profiles. The plastic strains were generated at least 8% and higher differences between surfaces in DSC profiles. It has been noticed that DSC differences between surfaces of paper can reach over 10% in a paper machine drying [59, 60]. The equivalency of strain at both sides of samples can be adjusted by drying two-sidedness. This is a practically utilized method to control curl amplitude, but has not been predicted by simulation before. Near the equivalent strain condition, however, the sample is at risk to manifest diagonal or CD mode of curl. Results also predict phenomena that are commonly observed in copier printing tests.

Although the generation of HSWO fluting have been successfully predicted by modeling, the mechanisms behind permanency of HSWO fluting has been a demanding task to solve. The presented elasto-plastic model indicated that permanent waviness/fluting can be generated with elasto-plastic model simulations. Both studied cases presented in this paper, together with earlier studies at [33], proved the usefulness of the model in predicting the challenging deformation phenomena of orthotropic paper sheets.

Abstract. *This paper deals with statics and stability problems of steel structures with the emphasis on their sensitivity to initial imperfections and clearances. The main aim is to performed an indication as the state of stress, displacement and the critical load. The paper presents theoretical studies involving linear and nonlinear behavior of thin-walled steel structures with a special reference to the interactive buckling, initial geometric imperfections and clearances which is in the scope of the modern approach to design. For this purpose authors proposed model structures composed of rigid bars where strains are concentrated in connecting elastic joints These model structures enable to derive nonlinear algebraic equilibrium equations which strictly describe pre- and post-buckling behavior of structures with various combinations of imperfections and clearances. Numerous examples demonstrate variable types of structural response depending on the modes and amplitudes of imperfections in relation with clearances. In the case of large clearances the model structure behaves like a typical Euler column characterized by a stable and symmetric bifurcation point. However, clearances combined with certain patterns of imperfections can result in unstable post buckling behavior and also in snap through phenomena. The developed model structures, which illustrate complex structural stability response accounting for initial geometric imperfections and clearances, due to its simplicity makes possibility to describe the exact close form solutions for both linear and nonlinear stability analysis. Based on the proposed model structure it is shown, that interaction between initial clearances and initial geometric imperfections can strongly affect the structural stability response.*

1 INTRODUCTION

In the last decades permanent development of light-weight structures is observed. They are esthetic and economic. Important is also that small weight of structural materials well matches the requirements of sustainable development. From among structural materials steel is particularly attractive in application to light weight-structures. A great variety of hot- and cold-formed steel sections is at designers' disposal. Modern highly automated cutting, drilling welding and corrosion protection make possible to design and prefabricate optimal structural elements, which can be easily assembled using pre-stressed bolts. It must be underlined here that two special aspects in design of light-weight steel structures must be seriously taken into account, namely fire protection and protection against local and global instability.

The fact that steel structures are apt to fail by loss of stability belongs to the textbook's knowledge for decades. This tendency towards instability is a direct consequence of high slenderness of steel structural elements. Designers can find practical recommendations in design codes [3, 4, 5] with theoretical and experimental background in the literature [6, 12] how to overcome the problems of instability. Professional computer programs supporting design of steel structures implement many of these recommendations. However, modern light-weight steel structures gave rise to new stability problems. Application of thin-walled cold formed sections and welded I sections with slender webs increased the importance of local instability phenomena which often appeared at a similar load level as global instability. The case when two or more different modes in stability and dynamic analyses are associated with the same or similar eigenvalues is termed a bimodal or multimodal solution. Designers' concern is that these solutions are very sensitive to imperfections. Design codes and scientific papers [1, 2, 7,13] contain recommendations with respect to forms and magnitude of global geometric imperfections which can be taken into account. There is definitely not so much information and recommendations with respect to local imperfections .

New stability problems were also originated when roof cladding elements were assumed to provide support for compressed top flanges of purlins or beams of frames [8, 9, 10, 11]. Roof cladding are often made of profiled steel plates. They are point-wise connected to the beams by self-tapping screws or by rivets. Thickness of steel plates is small, therefore variable loads and hence variable interaction forces often result in increasing diameter of the holes in thin walls of the plate. In this case we have slotted connections with unilateral constraints. Similar type of unilateral constraints can also appear in a bolted connection with a clearance between structural elements. These imperfect connections can strongly influence the structural response. Moreover, there can be unfavorable combinations of clearances and initial geometric imperfections.

Economic and safe design must be based on a reliable structural analysis where all essential imperfections are taken into consideration. On the other hand a numerical model of the actual structure cannot be too complicated. Otherwise computer time would be too great. Keeping this in mind, the author presents in this book stability behavior of structures with various combinations of global and local initial geometric imperfections, combinations of clearances and simultaneous appearance of geometric imperfections and clearances. Of course, in order to demonstrate these phenomena nonlinear stability problems must be formulated and solved. The author proposed model structures composed of rigid bars where strains are concentrated in connecting elastic joints. These model structures make possible to derive nonlinear algebraic equations which strictly describe pre- and post-buckling behavior of structures with various combinations of imperfections and clearances. By the way of numerous examples influence of imperfections and clearances on the structural behavior is discussed.

`

2 THEORETICAL BACKGROUND

In order to illustrate the phenomenon of the interaction of initial geometric imperfections and clearances a model structure is developed. It consists of *n* incompressible rods connected by elastic hinges with the rotational stiffness k_n [N·m/rad]. At the position of internal hinges the elastic intermediate supports with the stiffness $k_{n\Delta}$ [N/m] and clearances Δ_0 are imposed. Now Δ_0 *i* Δ denote, respectively, the clearance and the total transverse displacement of the structures at the position of internal hinges. This model enables the derivation of the exact nonlinear equilibrium equations, taking into account large displacements. At the same time, this simple model well illustrates the real structural response in terms of its stability problems. The geometry of the proposed model structure shows Figure 1.

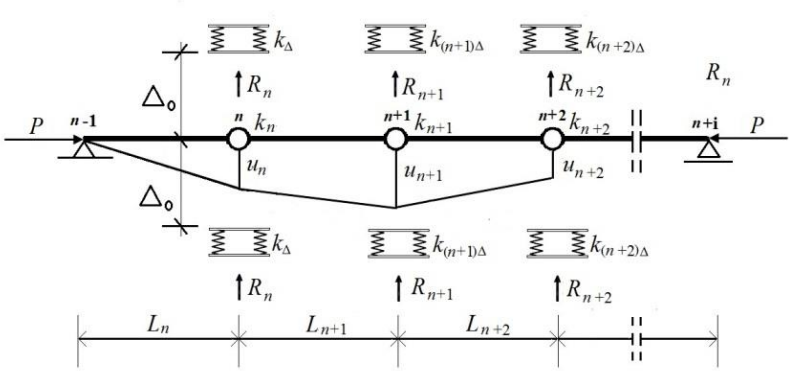

Figure 1: Geometry of the proposed model structure

2.1 Eigenvalue problem

At the first stage, the initial clearance is very large and the gap remains open: $|u_n| < \Delta_0$. Then the supports positioned at the elastic hinges do not switch on to cooperate with the bar, which is supported only at its ends. At this stage, the equation describing displacement u_n and rotation angles of nodes ϕ_n may be derived from geometries that are illustrated graphically in Figure 2.

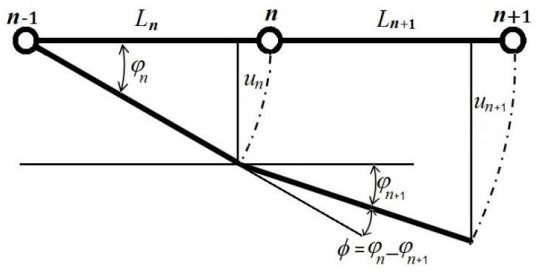

Figure 2: Geometric relation of the model structure

Hence we obtain the following geometrical relationships:

$$\varphi_n = \arcsin\frac{u_n - u_{n-1}}{L_n} \quad and \quad \phi_n = \arcsin\frac{u_n - u_{n-1}}{L_n} - \arcsin\frac{u_{n+1} - u_n}{L_{n+1}}, \tag{1}$$

where: φ_n – rotation of angle *n*-th bar. The set of equilibrium equations takes the form:

$$k_n \cdot \phi_n^{\,e} = P \cdot u_n . \tag{2}$$

Equation (2) can be written in matrix form:

$$\left(\boldsymbol{K} - PL\boldsymbol{I}\right)\bar{u} = 0, \tag{3}$$

where $\boldsymbol{I}$ is a unit matrix. The solution of (3) are the eigenvalues λ_n^{cr} and associated with it the normalized eigenvectors $\boldsymbol{u}_n^{\mathrm{cr}}$.

2.2 Initial imperfections

The initial geometric imperfections u_n^i are introduced in to the model as a linear combination of eigenvectors u_n^{cr} derived from the solution of the linear eigenvalue problem:

$$u_n^i = \alpha_m \cdot u_m^{\mathrm{cr}} . \tag{4}$$

By changing the value of the proportionality factor α_m, associated with various forms of buckling modes, enables to obtain all possible combinations of imperfection. It is worth to note that imperfections developed as the linear combinations of the eigenvectors are considered as the most dangerous.

The displacement caused by geometrical imperfections u_n^i induce initial rotations of the bars φ_n^i and rotations of the hinges ϕ_n^i. These deformations are kinematically admissible and does not induce any stress.

As a result of the action of the external load elastic part of displacements and rotations, represent by the superscript *e*, appeared. They are inducing elastic internal moments at the elastic hinges $M_n = k_n \phi_n^e$. In the initial phase, when the external load $P = 0$, the geometric relationships shown in Figure 3 take the form:

$$\varphi_n^i = \arcsin\frac{u_n^{\,i} - u_{n-1}^{\,i}}{L_n} \quad and \quad \phi_n^i = \arcsin\frac{u_n^{\,i} - u_{n-1}^{\,i}}{L_n} - \arcsin\frac{u_{n+1}^{\,i} - u_n^{\,i}}{L_{n+1}} . \tag{5}$$

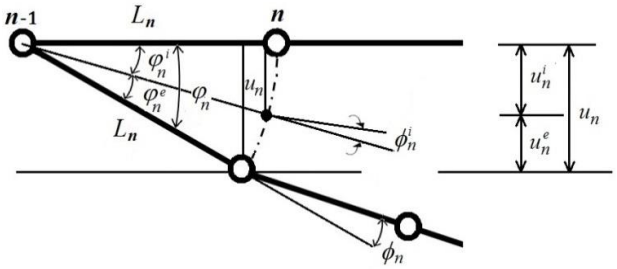

Figure 3: Geometric imperfections in model structure

In the next phase, when the load $P > 0$, it is obtained:

$$u_n = u_n^{\,i} + u_n^e \quad \text{and} \quad M_n = k_n \cdot \phi_n^{\,e} = P \cdot \left(u_n^{\,i} + u_n^e\right) \tag{6}$$

$$\varphi_n = \varphi_n^{\,i} + \varphi_n^{\,e} \quad \text{and} \quad \phi_n = \phi_n^i + \phi_n^e . \tag{7}$$

`

Now the set of nonlinear equilibrium equations takes the form:

$$k_n \cdot \varphi_n^{\,e} = P \cdot \left(u_n^{\,i} + u_n^e \right) \tag{8}$$

of unknowns elastic part of displacements u_n^e. Elastic part of hinge rotation ϕ_n^e is determine using the following relationship:

$$\phi_n^e = \phi_n - \phi_n^i. \tag{9}$$

2.3 Nonlinear equilibrium equations

In the second stage, depending on the value of the initial clearance Δ_0 and total lateral displacement of structures u_n, at the points of elastic hinges presence the cooperation with the intermediate supports is observed. When the gap is closing ($|u_n| \geq \Delta_0$), then the appropriate intermediate support with the stiffness $k_{n\Delta}$ is switched on to the cooperation. Hence, the equilibrium equation should be written in the general form. Until now, the bending moment in the elastic joint has been described as $M = k_n \cdot \phi_n^{\,e} = P \cdot u_n$. Now, in equilibrium equations must be taken into account the reactions of intermediate supports $R_n = k_{n\Delta}\left(u_n - \Delta_0\right)$. Equilibrium equations will be written in the form of an equation of virtual work. For this purpose, the virtual displacement δu_n is introduced to the model, so that the hinge No. *n* moves vertically and horizontally, while the hinge No. *n+2* moves only in the horizontal direction (Fig. 4).

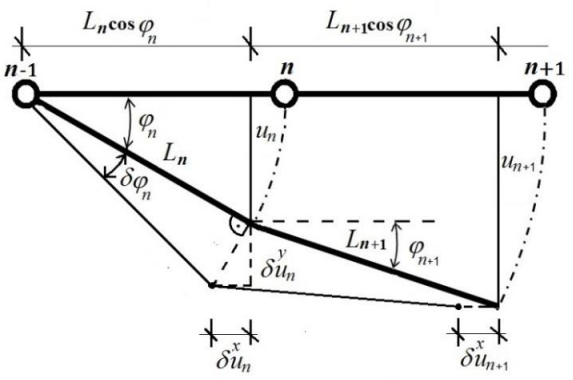

Figure 4: Geometric relation of the model structure - virtual displacement δu_n

Thus, the virtual displacement of the hinge No. *n+1* in the vertical direction $\delta^y u_{n+1} = 0$. The vertical $\delta^y u_n$ and horizontal $\delta^x u_n$ components of virtual displacement of the hinge No. *n* can be determined using the following relationship:

$$\delta^y u_n = L_n \cos\varphi_n \delta\varphi_n, \tag{10}$$

$$\delta^x u_n = L_n \sin\varphi_n \delta\varphi_n = u_n \delta\varphi_n. \tag{11}$$

The horizontal component of virtual displacement $\delta^x u_{n+1}$ of hinge No. *n+1* is calculated from the kinematic chain relation in the following form:

$$\delta^x u_{n+1} = \delta^x u_n + L_{n+1} \sin\varphi_{n+1} \delta\varphi_{n+1}. \tag{12}$$

The unknown value of the virtual rotation $\delta\varphi_{n+1}$ can be determined from the kinematic chain of vertical displacement:

$$\delta^y u_{n+1} = L_n \cos\varphi_n \delta\varphi_n + L_{n+1} \cos\varphi_{n+1} \delta\varphi_{n+1}. \tag{13}$$

Hence:

$$\delta\varphi_{n+1} = -\frac{L_n \cos\varphi_n}{L_{n+1} \cos\varphi_{n+1}} \delta\varphi_n. \tag{14}$$

For $L_n = L_{n+1}$ equation (14) takes the form:

$$\delta\varphi_{n+1} = -\frac{\cos\varphi_n}{\cos\varphi_{n+1}} \delta\varphi_n. \tag{15}$$

Thus, the horizontal displacement hinge No. *n+1* can be written as:

$$\delta^x u_{n+1} = u_n \delta\varphi_n + \left(u_{n+1} - u_n\right)\left(-\frac{\cos\varphi_n}{\cos\varphi_{n+1}}\right)\delta\varphi_n. \tag{16}$$

The equilibrium equations are derived in a week form and take into consideration the moments in hinges, reactions R_n and compressive force P:

$$M_n \delta\phi_n + M_{n+1}\delta\phi_{n+1} = P\ \delta^x u_{n+1} - R_n \delta^y u_n, \tag{17}$$

where: $M_n = k_n \phi_n^e$ i $M_{n+1} = k_{n+1}\phi_{n+1}^e$ and $\delta^y u_n$ is vertical displacement of hinge No. n which amplitude exceeds the respective value of the clearance Δ_0.

Total rotation of the hinge can be expressed as $\phi_n = \varphi_n - \varphi_{n+1}$, thus similarly total virtual rotation of the hinge can be obtained as:

$$\delta\phi_n = \delta\varphi_n - \delta\varphi_{n+1} = \left(1 + \frac{\cos\varphi_n}{\cos\varphi_{n+1}}\right)\delta\varphi_n \tag{18}$$

and

$$\delta\phi_{n+1} = \delta\varphi_{n+1} = -\frac{\cos\varphi_n}{\cos\varphi_{n+1}} \delta\varphi_n. \tag{19}$$

Thus, the equation of virtual work takes the form:

$$\begin{aligned} &k_n \phi_n^e \left(1 + \frac{\cos\varphi_n}{\cos\varphi_{n+1}}\right)\delta\varphi_n + k_{n+1}\phi_{n+1}^e \left(-\frac{\cos\varphi_n}{\cos\varphi_{n+1}}\right)\delta\varphi_n = \\ &= P\left[u_n\left(1 + \frac{\cos\varphi_n}{\cos\varphi_{n+1}}\right)\delta\varphi_n - u_{n+1}\frac{\cos\varphi_n}{\cos\varphi_{n+1}}\right]\delta\varphi_n - R_n L_n \cos\varphi_n \delta\varphi_n\ . \end{aligned} \tag{20}$$

It is worth to note that equation (20) is a set of n equilibrium equations. The type of equilibrium path can be evaluated using the energy approach involving the analysis of the variation of potential energy:

`

$$\delta \Pi = 0 \quad \text{oraz}$$
$$\delta^2 \Pi \begin{cases} > 0 & \text{stan stateczny} \\ = 0 & \text{stan krytyczny} \\ < 0 & \text{stan niestateczny.} \end{cases} \tag{21}$$

3 NUMERICAL EXAMPLES

Numerical examples are solved for various amplitudes of initial imperfections α_m, normalized amplitudes of clearances $\overline{\Delta}_0 = \Delta_0 / L$ and elastic supports stiffness k_Δ, where L is taken as the unit value.

The first example refers to a structure with initial imperfection pattern developed according to first buckling mode with small amplitude $\alpha_1 = 0{,}001$ (Fig. 5). At nodes 1, 2 and 3 with the initial intermediate support clearances of two different amplitudes $\overline{\Delta}_0^1 = 0{,}13\overline{u_2}$ and $\overline{\Delta}_0^2 = 0{,}5\overline{u_2}$ were introduced. The curve *m1* shows the equilibrium path obtained for the structure without intermediate supports (solid line – stable; dashed line - unstable equilibrium path). On the other hand, curves *1a, b, c* and *2a, b, c* represent behavior of structures with intermediate supports in distances of a clearance $\overline{\Delta}_0^1$ and $\overline{\Delta}_0^2$. Symbols *a, b* and *c* refer to increasing value of intermediate support stiffness, expressed as a relation $\eta = k_1 / k_\Delta$, where k_1 is elastic rotational hinge stiffness and k_Δ is elastic intermediate supports stiffness (a – $\eta_1 = 0{,}4$, b – $\eta_2 = 0{,}5$, c – $\eta_3 = 1$). In the first case the clearance $\overline{\Delta}_0^1$ is so small that the intermediate supports switch on before the bifurcation point, so all equilibrium paths are stable.

In the second case the clearance $\overline{\Delta}_0^2$ is large, so there is possible stable and unstable post-buckling behavior as well. It is worth to note that for both small and large clearance the cooperation with intermediate supports resulting in increased stiffness of whole structure in proportion to the supports stiffness.

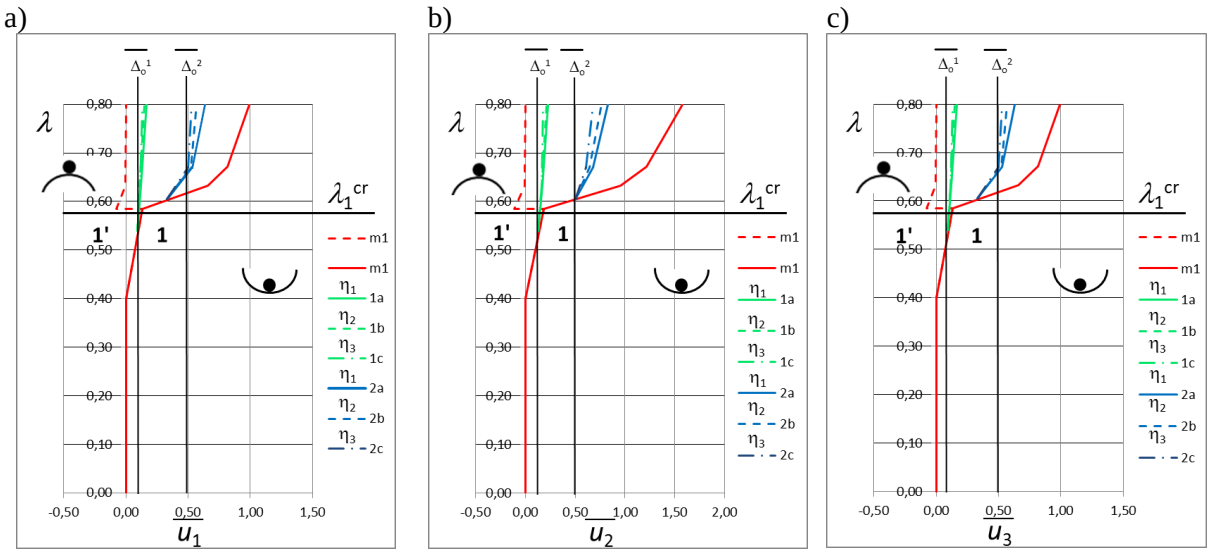

Figure 5: Equilibrium path for the initial geometric imperfections $\alpha_1 = 0{,}001$ and clearances $\overline{\Delta}_0^1 = 0{,}13\overline{u_2}$, $\overline{\Delta}_0^2 = 0{,}5\overline{u_2}$; displacement of the hinge: a) No. 1, b) No. 2, c) No. 3

Figure 6 shows the displacement obtained for the model structure with geometric imperfections pattern developed according to second buckling mode with small amplitude $\alpha_2 = 0{,}001$. Since the displacement of the bar is asymmetrical due to the asymmetric shape of imperfections, positive and negative value of the clearances have to be taken into consideration. One can notice that in this case both stable and unstable equilibrium path may occur. The last example refers to the initial geometric imperfections developed according to three different buckling modes with amplitudes $\alpha_1 = 0{,}001$, $\alpha_2 = 0{,}1$ i $\alpha_3 = 0{,}045$. The curve *(m1d2s3)* shows the equilibrium path obtained for the structure without intermediate supports. In this case several bifurcation points associated with the three buckling modes and stable and unstable post-buckling behavior is observed. Small amplitude of clearance (Δ_0) result in switching on the intermediate supports into cooperation before the bifurcation point, then all equilibrium paths are stable paths and increase of whole structure stiffness occurs (Fig. 7).

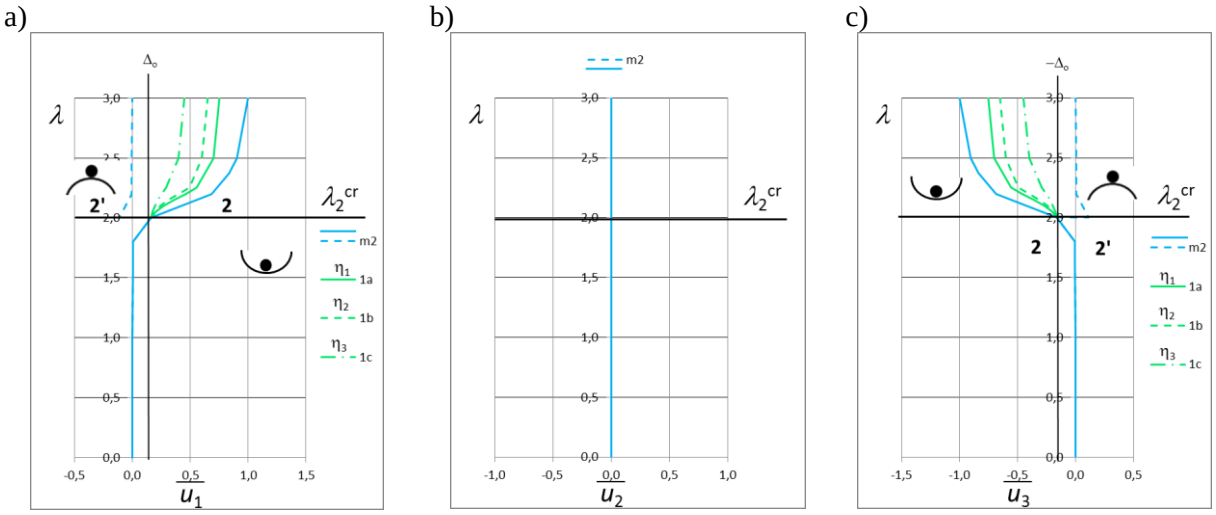

Figure 6: Equilibrium path for the initial geometric imperfections $\alpha_2 = 0{,}001$ and clearance $\overline{\Delta}_0 = \pm 0{,}18\overline{u}_1$; displacement of the hinge: a) No. 1, b) No. 2, c) No. 3

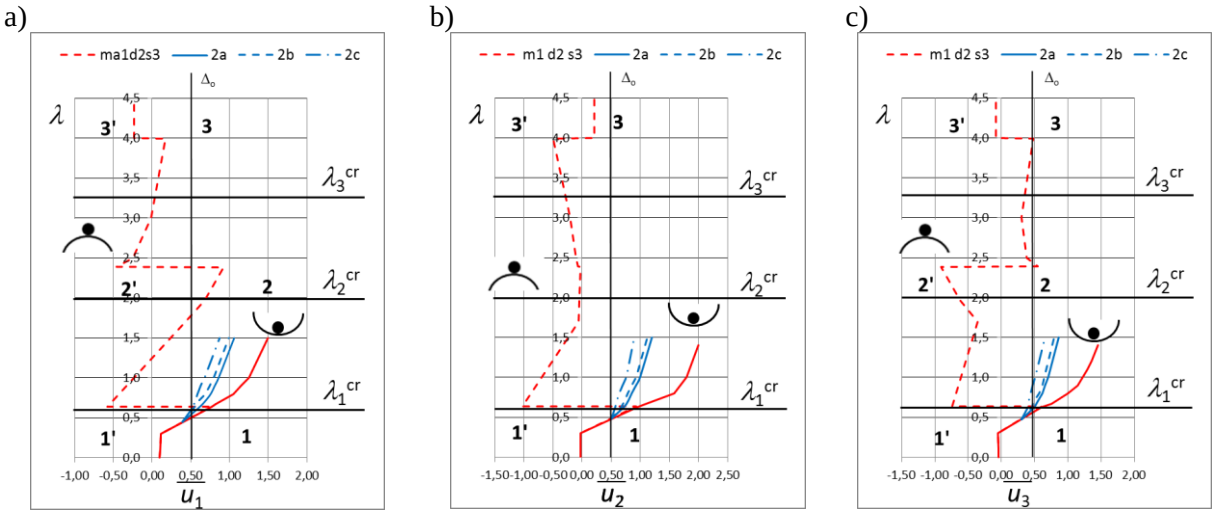

Figure 7: Equilibrium path for the initial geometric imperfections $\alpha_2 = 0{,}001$, $\alpha_2 == 0{,}1$, $\alpha_2 = 0{,}45$ and clearance $\overline{\Delta}_0 = 0{,}5\overline{u}_2$; displacement of the hinge: a) No. 1, b) No. 2, c) No. 3

`

4 CONCLUSIONS

In the paper interaction of initial geometric imperfections and clearances for the structural model consisting of *n*-compressible bars connected by means of elastic hinges is discussed. The proposed model illustrates the behavior of real structures in terms of stability and enables the derivation of exact nonlinear equilibrium equations taking into account large displacements.

In summary the following conclusions can be drawn:

- In the first stage, when the initial clearance is very large, intermediate supports do not switch on to cooperate and the stable equilibrium path is observed.
- For the very small amplitudes of geometric imperfections, developed according first, second or third buckling mode, single points of bifurcation accompanied by the unstable equilibrium path appeared.
- The increase in the amplitude of the initial geometric imperfection results in an increase in the value of the critical load defining the bifurcation point, where it is possible the snap through to the configuration described by unstable equilibrium path.
- The observed snap through is caused by transition of the structure from a high to a low level of potential energy. In this case, the initial geometric imperfections play a positive role resulting in a stable post-buckling behavior.
- In the case of small clearance, depending on the shape of initial geometric imperfections and intermediate supports stiffness, different equilibrium paths are possible. If clearance is very small and intermediate supports switch on before the bifurcation point, all equilibrium path are stable. When the intermediate supports switch on after bifurcation point both stable and unstable post-buckling behavior of the structure is observed.
- It is shown, that interaction between initial clearances and initial geometric imperfections can strongly affect the structural stability response. Therefore, the proper design of clearance, taking into account the initial geometric imperfection, is extremely important in order to obtain a safe the structure characterized by stable equilibrium paths.

Keywords: Prestressed concrete sleeper, Railway track, Rail joint, Impact load, Numerical analysis, Dynamic interaction.

Abstract. *The Prestressed concrete sleeper (PC sleeper) has many advantages over the wooden sleeper in terms of maintenance, load bending capacity, weight and lateral ballast resistance force. In Japan, the PC sleeper has been widely used since 1951. The PC sleeper is designed in consideration of the impact wheel load which is mainly caused by a rail joint or wheel flat. This research focused on the impact wheel load at rail joints. By field measurements in an operating line and numerical analyses, the dynamic response characteristic of the PC sleeper was clarified. The field measurement of PC sleeper behavior shows that the maximum bending moment of a PC sleeper with a rail joint during train running is almost 4 times larger than that in plain sections, and the maximum bending moment of the PC sleeper adjacent to the rail joint is almost 2.7 times larger than that in plain sections. The numerical analysis shows that support condition has the greatest influence on the bending moment of the PC sleeper among various parameters. Furthermore, the impact wheel load caused by a rail joint affects dynamic behavior of PC sleepers within 4m from the rail joint.*

1 INTRODUCTION

A prestressed concrete sleeper (PC sleeper) is designed mainly in consideration of an impact wheel load during the train running. The impact load is generally caused by the wheel flat, the rail joint, the welded joint irregularity of the rail and the railhead corrugation. Among those defects, the wheel flat and the rail joint have the greatest the influence on the dynamic response of the PC sleeper. At the beginning of the development of the PC sleeper, it had been thought that the enormous impact wheel load was mainly induced by the wheel flat [1, 2]. For this reason, a large number of researches into the wheel flat have been conducted [3, 4]. Through the running test and the impact load examination of the PC sleepers, these researches made clear that the design load of the PC sleeper shall be the 4 times larger than the static load in order to allow no tensile stress (full prestressing) under the assumed maximum impact load by wheel flat. Such knowledge and information have been used for the design of PC sleepers in Japan [1]. Recently, various kings of research and development have been promoted from the viewpoint of the optimization of the sleeper [5-10].

On the other hand, particularly in Japan, though the rail joint has been recognized as another serious source of the impact wheel load, the research into the effect of the impact wheel load generated by the rail joint has been insufficient. This is due to the fact that the suspended rail joint, that is, the rail joint installed between adjacent two sleepers has been widely introduced in an attempt to prevent the impact wheel load as a standard installation method of the rail with wooden or PC sleepers. For example, though the PC sleepers that are adjacent to the rail joint are affected by the impact wheel load caused by the rail joint, the longitudinal span of the influence of the impact wheel load and the effect of the rail joint irregularity have not been sufficiently investigated. Recently, in Japan, a specified type of PC sleeper which is installed directly under the rail joint has been increasingly used. Thus, the phenomenon elucidation of the dynamic response of the PC sleepers at or adjacent to the rail joint is required. Furthermore, the most suitable design of the PC sleeper according to the track condition is also being required [11].

The dynamic response of the PC sleeper at rail joints includes a high frequency phenomenon within 1/1000 seconds. Recently, tools for the phenomenon elucidation of the dynamic response of the PC sleeper at rail joints are gradually being provided such as high quality measurement systems (high frequency and multi-channel synchronized measurement) of the spread of high spec. supercomputers.

Against these backgrounds, this research focused on the impact wheel load at rail joints paying attention to the following points.

(1) Conduct the field measurement in an operating line in order to elucidate the bending moment of the PC sleeper during the train running at rail joints and in plain track sections.
(2) Develop three dimensional numerical analysis models by a finite element method.
(3) Evaluate the effect of the various parameters of the vehicle or track on the bending moment of the PC sleeper quantitatively.
(4) Evaluate the longitudinal span of the influence of the impact wheel load at rail joints.

2 INVESTIGATION METHOD

2.1 Field measurement method

Figure 1 shows the outline of the track. In this section, standard rails of 25m in length and 60kg/m in weight are used and there are rail joints at an interval of 25m. PC sleepers are type-6 PC sleepers in the plain section and PC sleepers at the rail joints are those standardized in Japanese Industrial Standard (JIS). The numbers of PC sleepers per rail (25m in length) is 41.

The field measurement of the bending moment of PC sleepers during the train passing was conducted on two rail joint PC sleepers (Joint 1, Joint 2), two type-6 PC sleepers adjacent to the rail joint (A and B) and two type-6 PC sleepers (C and D). The type-6 PC sleepers C and D are in the plain section. Trains running in this section are Japanese standard commuter trains with the static nominal wheel load of almost 50kN.

Figure 2 shows the positions of strain gauge on the PC sleeper. In total, four strain gauges per sleeper were used, two of which were attached on the side of the PC sleeper (one at an upper position and the other at a lower position) at its longitudinal center and the other two strain gauges were attached in the same manner at its rail seat position. Strain gauges made in KYOWA ELECTRONIC INSTRUMENTS CO. were used for the field measurement, and a built-in chassis made in NATIONAL INSTRUMENTS CO. were used to acquire the experimental signals from 32-channel strain gauge units. The sampling rate is 5000Hz.

Figure 3 shows the measurement method of the vibration mode of the PC sleeper. Seven piezoelectric accelerometers were installed on the top of the PC sleeper. The piezoelectric accelerometers were made in RION CO. (PV-85). Measured response of the accelerometer was recorded in a laptop PC with 5000Hz sampling via preamplifier and A/D converter. Vibration characteristics were identified by the ERA (Eigensystem Realization Algorithm) method [12, 13], which can identify the character matrix of linear time-invariant systems with the principles of minimal realization. The MAC (Modal Amplitude Coherence) value on the controllability was applied to the accuracy evaluation of the vibration characteristics. 40 degrees of freedom were set in order to identify the major modes of the PC sleeper. When the MAC value is 0.99 or more, it is judged to be the vibration mode characteristic of the PC sleeper.

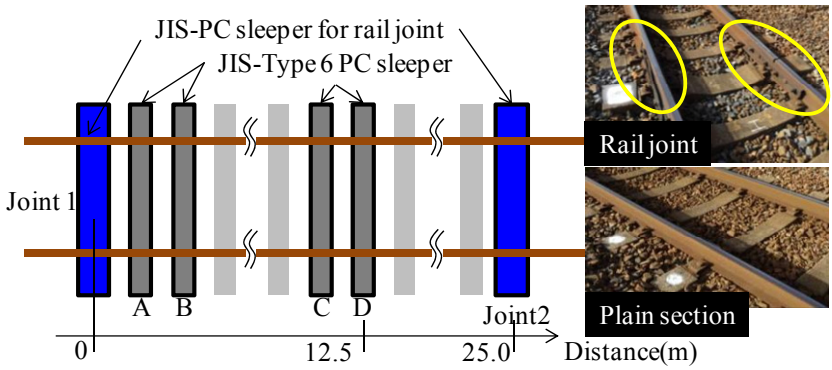

Figure 1: Outline of the track.

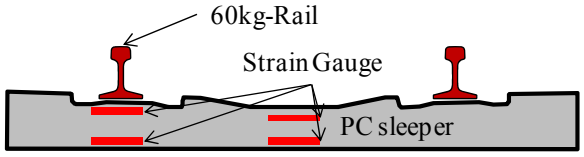

Figure 2: Positions at which to attach the strain gauges to the PC sleeper.

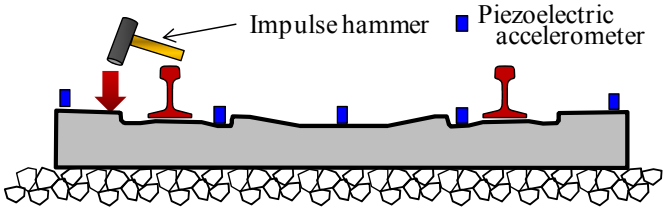

Figure 3: Measurement method of the vibration mode of the PC sleeper on the impulse hammer test.

2.2 Numerical analysis method

(1) Dynamic model of the track

Figure 4 shows the outline of the three dimensional numerical analysis model of the target track. The DIASTARSIII program developed by the Railway Technical Research Institute was used for numerical analysis [14, 15].

The track was modeled using the finite element method. Assembling all elements in the total model, the equation of motion of the track is obtained in a standard matrix form as

$$M^B\ddot{X}^B + C^B\dot{X}^B + K^BX^B = F_L^B + F_I^B(X^V, X^B) + F_N^B(X^B) \quad (1)$$

where X^B is the displacement vector of the track, and M^B, C^B and K^B are the mass, damping and stiffness matrices, respectively; F_L^B is load vectors; $F_I^B(X^V, X^B)$ is the interaction force between the rail and the car, $F_N^B(X^B)$ is the load vectors of non-linear spring force in the track.

As shown in Figure 4, the rail and sleepers were modeled using beam elements, and the rail pads, the ballast and the roadbed were modeled using spring elements. The basic rail mesh size was set at 35mm and the PC sleeper mesh size was set at 55mm. The total number of nodal points is 8338 and the total numbers of elements is 13012.

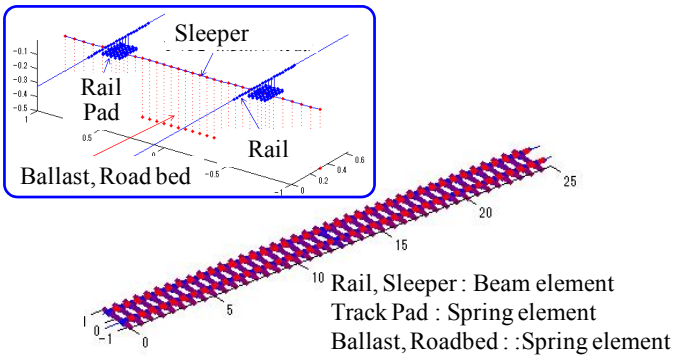

Figure 4: Outline of the three dimensional numerical analysis model of the target track.

(2) Dynamic model of the vehicle

Figure 5 shows the dynamic model of the vehicle assuming that a body, bogies and wheelsets are rigid. These three-dimensional rigid elements are linked by springs K_N and dampers C_N (N is a suffix in Figure 5) according to their respective characteristics. The train has 31 degrees of freedom (5 degrees of freedom for the body, 5 degrees of freedom for the bogies, and 4 degrees of freedom for the wheelset) per one car. The train consists of multiple vehicle models linked together by springs K_C and dampers C_C attached to the ends of the vehicle models. Assuming that the train runs at a constant speed, the equation of three dimensional motion of the train with N vehicles is written in a matrix form as shown in reference [16].

$$M^V\ddot{X}^V + C^V\dot{X}^V + K^VX^V = F_L^V + F_I^V(X^V, X^B) + F_N^V(X^V) \quad (2)$$

where, superscript V and B are the vehicle and the track, respectively; X^V is the displacement vector of the vehicle; M^V, C^V and K^V are the mass, damping and stiffness matrices of the vehicle, respectively; F_L^V is load vectors; $F_I^V(X^V, X^B)$ is the interaction force between the rail and the vehicle, $F_N^V(X^V)$ is the load vectors of non-linear spring force in the car. In this research, the train consists of six Japanese standard commuter vehicles with a length of 20 m and an axle load of almost 50 kN.

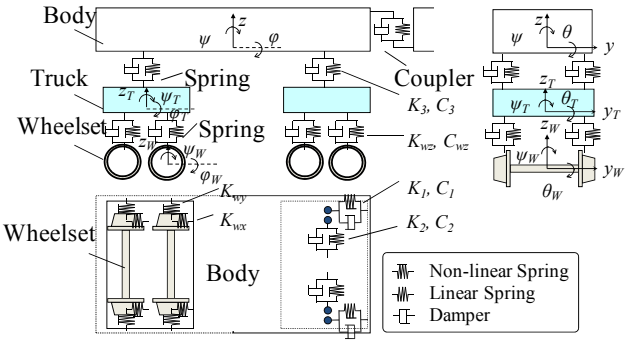

Figure 5: Dynamic model of vehicle.

(3) Dynamic model of the interaction force between the wheel and the rail

Figure 6 shows the wheel/rail model. We focused on relative displacement between the wheel and the rail. The vertical interaction force between these components was modeled by *Hertzian* contact springs so that it is possible to judge the contact condition between the wheel and rail. The vertical relative displacement between the rail and the wheel δ_z is expressed by equation (3).

$$\delta_z = z_R - z_W + e_Z + e_{z0}(y) \tag{3}$$

where z_R is the rail vertical displacement, z_W is the wheel vertical displacement, e_Z is the vertical track irregularity. $e_{z0}(y)$ is the wheel radius variation in the current wheel contact point. When $\delta_Z \geq 0$, the wheel is in contact with the rail, and $\delta_Z \leq 0$, the wheel is loss of contact with the rail. The z-direction interaction force H produced due to the contact of the wheel and the rail is expressed by equation (4).

$$H = H(\delta_Z) \tag{4}$$

The interaction force in the horizontal direction is expressed as creep force in the case that the wheel flange has no contact with the rail. In contract, if the wheel flange is in contact with the rail, the wheel load and horizontal pressure act on the rail, causing the rail crown to move in the horizontal direction. In this case, torsion of the rail occurs. The torsion resistance generated by the rail and the rail fastener is expressed by a spring element.

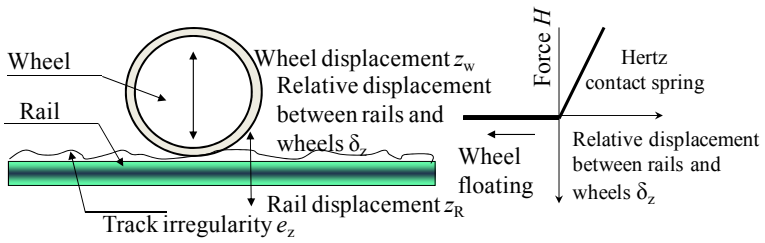

Figure 6: Wheel/ rail model.

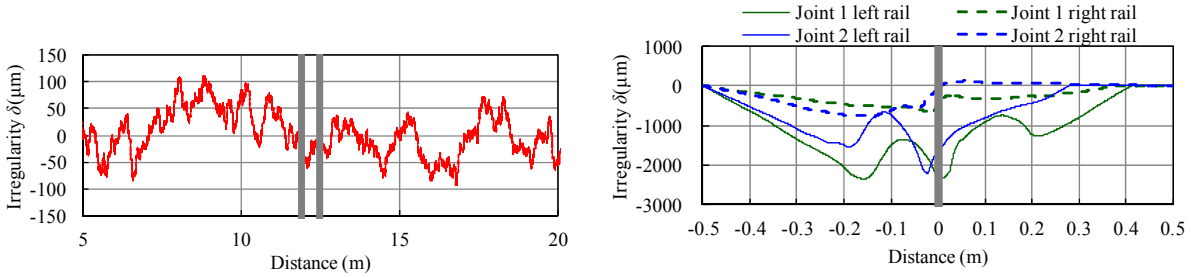
Figure 7 shows the irregularities used for the numerical analysis. These irregularities consist of the combination of the rail irregularity and the wheel irregularity. The rail irregularity was measured on the track by a measuring device of 1m-chord versine and as for the wheel we referred to a previous research [17].



(a) Plain section (b) Rail joint section

Figure 7: Irregularities used for numerical analysis.

(4) Solution method

In the previous paragraph, the equation of motion of the vehicle and that of the track are derived in the vehicle's coordinate system and the global coordinate system respectively. Coupling of these equations is conducted by applying the compatibility and equilibrium conditions to the sub region where both systems are connected with each other. At every moment during the train moving, the compatibility condition is evaluated using a fictitious nodal point at the center of the left and right rails where the wheelset exists.

In order to carry out efficient numerical analysis, the equations of motion concerning the vehicle and track described as equation (1) and equation (2) are transformed to modal coordinate system. The resultant equations are progressively solved in time increment Δt by using the *Newmark* method. However, because the equation of motion is non-linear, iterative calculation has to be carried out within Δt until the unbalanced force becomes sufficiently small. The mode order in the analysis is set at a value that enabled vibration up to about 2000Hz to be reproduced, and the analysis time step is set at 0.0001 sec.

(5) Numerical analysis condition

Table 1 shows the material dimensions and properties. Though basically the values used in the numerical analysis were derived from the Japanese design standards and the nominal values [18, 19], the spring constant of the rail pad was set at two times larger than the nominal value because of the degree of the agreement between the numerical analysis result and the measurement result of bending moment of the PC sleeper. The PC sleeper support condition was not assumed to be uniform over the whole length of the sleeper but to be nonuniform as shown in Figure 8.

Table 2 shows the numerical analysis cases. The numerical analyses were conducted with a focus on the effect of the various parameters. Basic case is underlined. The sleeper support conditions 2 and 4 were considered to be roughly corresponding to that immediate after the track maintenance. On the other hand, the sleeper support conditions 1 and 3 were considered to be corresponding to that a few days after the track maintenance.

Rail	60kg rail Young modulus E_S = 200MPa
Rail Pad	Spring constant D_P = 220MN/m (Nominal value = 110MN/m)
PC sleeper	Type-6 PC sleeper PC wire = φ2.9mm 3-strand cable 12-wires Length L_P = 2000mm, Width B_P = 240mm Height H_P = 170mm(Rail seat), 150mm(Center) Concrete Young modulus E_C = 33MPa
	Rail joint PC sleeper PC wire = φ2.9mm 3-strand cable 16-wires Length L_P = 2000mm, Width B_P = 300mm Height H_P = 170mm(Rail seat), 145mm(Center) Concrete Young modulus E_C = 33MPa
Ballast	Thickness h = 250mm Support spring constant D_B = 180MN/m(1 rail)
Roadbed	Coefficient of subgrade reaction K_{30} = 110MN/m^3 Support spring constant D_S = 111MN/m(1 rail) $D_T = 1/((1/D_B)+(1/D_S))$

Table 2: Numerical analysis cases.

3 INVESTIGATION RESULT

3.1 Vibration mode of PC sleeper

Table 3 shows the comparison of natural frequencies of the PC sleeper vibration modes. The natural frequencies given by the numerical analyses are coincident with the measurement results excluding the rotation mode. In order to decrease this discrepancy, the accurate evaluation of the PC sleeper support condition is in need. As might be expected, the natural frequency of the rail joint PC sleeper is higher than that of the type-6 PC sleeper because the cross section and the PC wire volume of the rail joint PC sleeper are larger than that of the type-6 PC sleeper.

Mode	Type-6 PC sleeper		Rail joint PC sleeper	
	Measurement (Hz)	Numerical analysis (Hz)	Measurement (Hz)	Numerical analysis (Hz)
Vertical rigid mode	92	86	101	105
Rotation mode	102	86	74	95
1st bending mode	173	174	202	203
2nd bending mode	497	478	534	520
3rd bending mode	813	817	907	939

Table 3: Comparison of the natural frequencies of the PC sleeper vibration modes.

3.2 Bending moment of the PC sleeper

Figures 9 and 10 show the comparison of the bending moments of the PC sleeper during the train running. Numerical analyses were conducted under the condition that the train speed is 80km/h and the passenger occupancy is 50%. From these figures, it can be seen that the absolute value of negative bending moments of the center of the PC sleeper are larger than that of positive bending moments of the rail seat of the PC sleeper.

Regarding the positive bending moment, the differences between “Support 1” and “Support 2” is not clear. On the other hand, regarding the negative bending moment, the bending moment of “Support 1” is almost two times larger than that of “Support 2”. In addition, the negative bending moment of “Support 1” is also coincident with the measurement result. One possible reason may be that more than one year has passed since the track maintenance, and therefore, the PC sleeper support condition has been gradually transferring from “Support 1” to “Support 2” due to the dynamic interaction between the PC sleeper and the ballast.

Figure 11 shows the relation between the train speed and the maximum bending moment of the PC sleeper during the train running. From the field measurement results, the maximum bending moment of the PC sleeper at the rail joint generated during the train running is almost 4 times larger than that in the plain section, and the maximum bending moment of the PC sleeper adjacent to the rail joint is also almost 2.7 times larger than that in the plain section. Furthermore, the bending moments of the type-6 PC sleeper are different depending on its installation section.

Regarding the comparison of the negative bending moments between “Joint 1” and “Joint 2” obtained by the numerical analyses, it can be seen that “Joint 2” is 1.5 times larger than “Joint 1”. This is due to the difference of the support condition between “Joint 1” and “Joint 2”. From the numerical analyses, it can be seen that regarding the dynamic response amplification ratio from 40km/h to 130km/h of the train speed, the rail joint PC sleeper is larger than

type-6 PC sleeper. Concretely, the ratio of the rail joint PC sleeper is 1.4 and that of the type-6 PC sleeper is 1.2.

In figure 11, the design limit values under the allowable stress design method in cases where the design wheel load is 80kN, the impact factor is 2.0, the load dispersion coefficient is 0.5, and the allowable tensile stress is 2.0N/mm^2 are indicated. The actual generated bending moments are under the design value.

(b) Negative bending moment

Figure 11: Relation between the train speed and the maximum bending moment of the PC sleeper during the train running.

3.3 Influence of various parameters

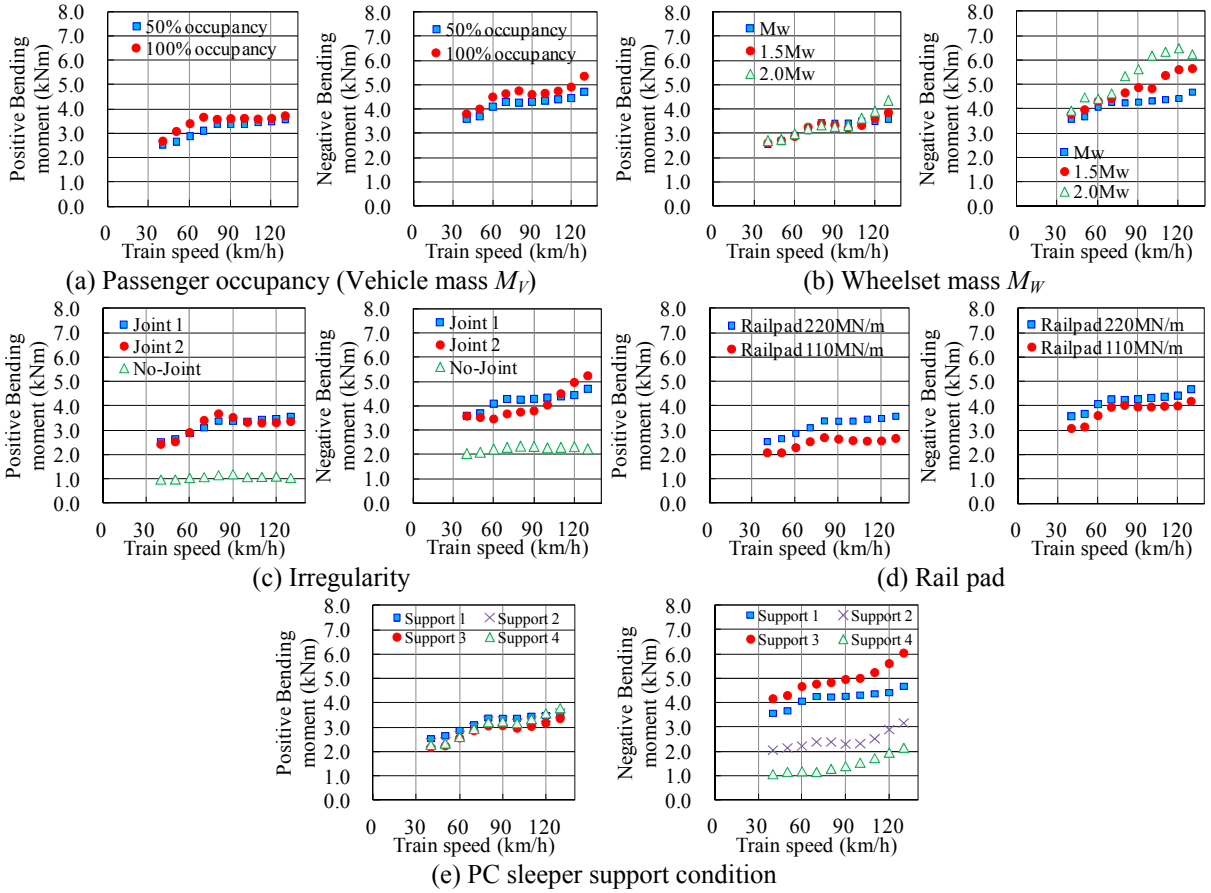
Figure 12 shows the effect of the various parameters on the bending moment of the PC sleeper during the train running. The knowledge and findings obtained by the numerical analyses in this research are shown below.

As for the passenger occupation variation, when the passenger occupation ratio increases from 50% to 100%, the bending moment increases by up to 1.2 times.

As for the wheelset mass variation, when the wheelset mass increases by 2 times, the bending moment increases by up to 1.5 times. It can be seen that negative bending moment especially is largely affected.

As for the irregularity variation, the bending moment of the PC sleeper at "Joint 1" or "Joint 2" is up to 3.4 times larger than that at "No-joint".

Concerning the rail pad stiffness, when the spring constant of the rail pad decreases by half, the bending moment decreases by up to 20%. Furthermore, it can be seen that the bending moment in the case of "Support 3" is up to 4 times larger than that in the case of "Support 4".



(a) Passenger occupancy (Vehicle mass M_V)

(b) Wheelset mass M_W

(c) Irregularity

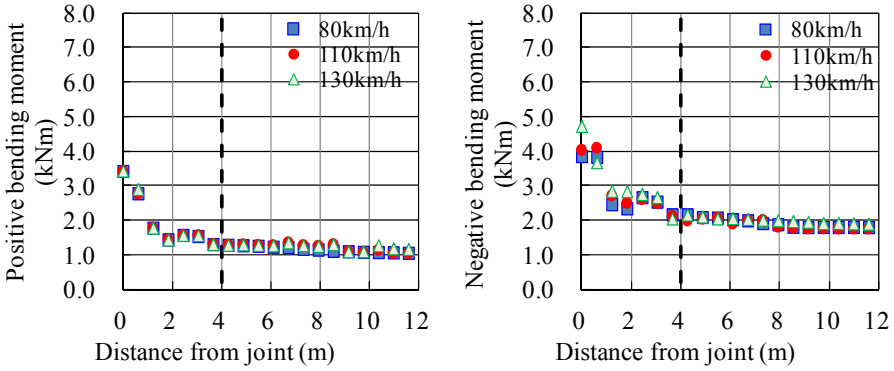
(d) Rail pad

(e) PC sleeper support condition

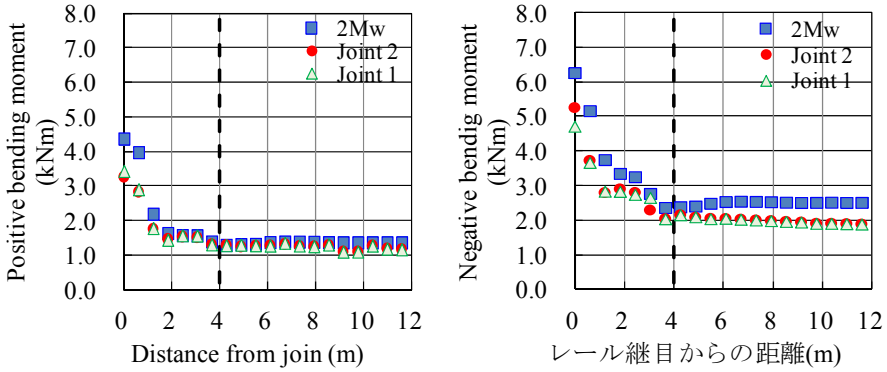
Figure 12: Effect of the various parameters on the bending moment of the PC sleeper during the train running.

3.4 Influence of the rail joint

Figure 13 shows the longitudinal span of the influence due to the impact wheel load at the rail joint. It can be seen that the longitudinal span of the influence is almost 4m, and there are not much difference between each case. Based on these results, the plain section, i.e. the section which is not affected by the rail joint, can be defined as a section more than a span of 4m away from the rail joint. Though length of this span absolutely depends on the given condition, this span is one of the reference values about the rail joint section. In the future, we must clarify the generality of the longitudinal span of the influence of the impact wheel load at the rail joint by increasing the sample of the irregularity and the analysis parameters.



(a) Basic case (80,110,130km/h)



(b) Effect of wheelset mass and PC sleeper support condition (130km/h)

Figure 13: Longitudinal span of the influence of the impact wheel load at rail joint.

4 CONCRUSIONS

This research focused on the impact wheel load at the rail joints. We carried out field measurement in an operating line and numerical analyses, in order to reveal the dynamic response characteristics of the PC sleeper. The knowledge and findings obtained in this research are summarized as below.

- The field measurement results shows that the maximum bending moment of the PC sleeper at the rail joint during the train passing is almost four times larger than that in the plain section, and the maximum bending moment of the PC sleeper adjacent to the rail joint is almost 2.7 times larger than that in the plain section. Furthermore, the bending moment of type-6 PC sleeper varies depending on the measurement section.
- The absolute value of negative bending moment at the center of the PC sleeper was larger than that of the positive bending moment at the rail seat of the PC sleeper.

- Results of the numerical analyses indicate that the dynamic amplification ratio of the rail joint PC sleeper at from 40km/h to 130km/h is larger than type-6 PC sleeper. Concretely, the rail joint PC sleeper was 1.4 times, type-6 PC sleeper was 1.2 times.
- The longitudinal span of the influence of the impact wheel load at the rail joint is almost 4m.

In the future, we will reflect the concept of these knowledge and findings in the design of the PC sleeper.

Abstract. *As a main background practical context of the present numerical investigation, the appropriate description of track vibrations induced by high-speed trains looks crucial in contemporary railway engineering. The present paper is concerned with the modelization of the transient dynamic response of a simply-supported Euler-Bernoulli beam resting on a homogeneous in space Winkler elastic foundation, under the action of a transverse concentrated load with harmonic-varying magnitude, moving at constant velocity along the beam. Two types of constitutive laws are considered for the foundation subgrade reaction: (a) a linear law and (b) a nonlinear, cubic law. The governing linear/non-linear partial differential equation of motion is first semi-discretized in space with a Finite Element Method approach, by using cubic Hermitian polynomials as interpolation functions for the unknown deflection. Then, the dynamic solution is obtained numerically by a direct integration method, with focus on determining several characteristic response features, such as the critical velocities of the moving load, leading to high transverse deflections. Extensive numerical analyses are finally performed, with the following two main goals: (1) to demonstrate the reliability, consistency and accuracy of the present implementation, specifically by the comparison of the obtained numerical critical velocities with previously-published analytical and numerical results; (2) to investigate how the frequency of the harmonic moving load as well as its velocity do influence the response of the whole beam-foundation system, with or without taking viscous damping into account. Results show that such goals have been consistently achieved and outline new interesting trends, like the appearance of two critical velocities also for the nonlinear foundation, the first of which gets close to zero as the frequency of the load approaches the first natural frequency of the beam. The present outcomes reveal potential implications in practical terms, especially in lowering the ranges of admissible train speeds, as for structural requirement or for preventing passenger discomfort.*

1 INTRODUCTION

The observed ground, beam and track vibrations, induced by rapidly-growing high-speed railway networks and the considerable evolution of train vehicles capable to travel at more than 500 km/h may degrade rolling equipment and track and raise questions about vehicle stability, maintenance costs and possible passenger discomfort. For these reasons many studies have been carried out in the last few decades towards the prediction of the dynamic behavior of railway beams and tracks. Amongst the prevailing models, the most diffused one considers the train vehicle as a single load traveling at constant velocity on a beam supported by an elastic foundation (see Kerr [13]). Comprehensive literature reviews about the problem of moving loads acting on beams may be found in Beskou and Theodorakopoulos [2], Frýba [11], Kerr [13] and Wang et al. [20].

The main scope of the elastic foundation model is that of providing a simplified description of the contact between the rail and the sleepers-ballast-ground system. Based on the well-known Winkler model, the foundation is represented as a uniform layer of infinitely closely-spaced springs, which, according to its original formulation, push up/pull down the beam with a force linearly-proportional to the beam deflection (see e.g. Froio and Rizzi [9] and wide state of the art review, with historical perspective, presented therein).

Concerning the analysis of beams lying on a damped or undamped Winkler elastic foundation, excited by a moving load, different approaches have been adopted so far. One of the most common modelizations is to consider the steady-state response of infinite beams subjected to a constant magnitude moving load (see e.g. Frýba [11]), as well as to a moving load with harmonically-varying amplitude, as reported by Bogacz et al. [3]. Similar results were also obtained by Chen et al. [6], by using the dynamic stiffness matrix method in the description of the influence of the structural parameters and of the load frequency on the critical velocities of the beam. A further extension of this work was then reported by Chen and Huang [7], for the case of a beam of finite length.

Besides analytical solutions and other numerical methods, in the past two decades the Finite Element Method (FEM) has been widely used for solving structural dynamic problems involving moving loads. Combined with the Finite Element Method, the numerical direct integration in time appears one of the most common approaches for the solution of the equations of motion in the time domain. For instance, FEM and Newmark method were applied successfully by Thambiratnam and Zhuge [19] for a constant amplitude moving load and by Kien and Hai [14] for a harmonic moving load. Following a FEM approach, Andersen et al. [1] treated the steady-state response of an infinite Euler-Bernoulli beam lying on a viscoelastic foundation, subjected to a harmonic point load moving with uniform velocity.

Regarding beams of finite length, simply-supported beams on nonlinear viscoelastic foundations were tackled by Castro et al. [4, 5]. Critical velocities were determined and the effects of load intensity and foundation stiffness on both beam displacements and critical velocity were investigated. The results they presented were in agreement to those shown earlier by Dimitrovová and Rodrigues [8] for a linear elastic foundation.

The present paper is concerned with the transient dynamic response of a simply-supported Euler-Bernoulli beam resting on a homogeneous in space Winkler elastic foundation under the action of a transverse concentrated load with harmonic-varying magnitude, moving at constant velocity along the beam. Two types of constitutive laws are considered for the foundation subgrade reaction: (a) a linear law and (b) a nonlinear, cubic law. The dynamic response is obtained numerically by using a FEM implementation and a HHT-α algorithm for the time

integration. Then, critical velocities are determined for both types of foundation, by considering different values of the frequency of the moving load.

The purpose of the present paper is two-fold. Firstly, this work aims at demonstrating the reliability, consistency and accuracy of the present implementation, by the comparison of the obtained numerical critical velocities to results reported by earlier Castro et al. [4] and by Chen et al. [6]. Secondly, extensive numerical analyses are performed to study the effects of the frequency of the moving load, of its velocity and of the foundation behavior, on the response of the whole beam-foundation system, with or without viscous damping, outlining here new results for the nonlinear foundation case.

The paper is organized as follows. Section 2 presents the governing boundary value problem for the linear/nonlinear partial differential equation of motion of a simply-supported beam on elastic foundation and its semi-discretization in space through a FEM formulation and implementation. In Section 3 the outcomes of a series of independent numerical analyses relative to the case of a constant amplitude moving load are presented and consistently compared to results reported in the literature. Section 4 provides the outcomes of a vast numerical investigation on the dynamic response of beams lying on visco-elastic foundations, subjected to a force which moves along the beam axis at constant velocity and simultaneously varies its amplitude in time on the basis of a harmonic law. In particular, the relationship between the amplitude frequency of the moving load and the critical velocity of the beam-foundation system is explicitly depicted in appropriate bifurcation curves, for both linear and nonlinear elastic foundations. Finally, main conclusions are outlined in closing Section 5.

2 MODEL EQUATION AND FINITE ELEMENT FORMULATION

Consider the idealized system shown in Fig. 1, consisting of a simply-supported finite beam lying on a Winkler elastic foundation under the action of a concentrated force of magnitude F (either constant or variable in time), moving with constant velocity v. The force is assumed positive if directed upward. The following assumptions are adopted throughout the formulation:

1. Euler-Bernoulli beam model with Young's modulus (E), cross section area (A), moment of inertia (I) and mass density (ρ), assumed constant along the beam axis;
2. Viscous damping smeared onto both the beam and the foundation, with constant damping coefficient (c);
3. Beam at rest with zero initial deflection and velocity at the instant when the force leaves from the left support of the beam.

From these assumptions, the equation of motion describing the transverse deflection of the beam is (see Frýba [11]):

$$EI\frac{\partial^4 w(x,t)}{\partial x^4}+\rho A\frac{\partial^2 w(x,t)}{\partial t^2}+c\frac{\partial w(x,t)}{\partial t}+r\big(w(x,t)\big)=F(t)\delta(x-vt);\ 0<x<l,\ t>0; \quad (1)$$

where x is the axial coordinate, with the origin fixed on the left end of the beam, t is the time coordinate, with the origin at the instant on which the force starts its motion from the left extreme of the beam ($x=0$), $w(x,t)$ is the vertical deflection of the beam (positive if upward), measured from the static equilibrium position of the beam subjected to its self-weight only, acting downward, and $r(w)$ is the reaction force per unit length supplied by the foundation. The right hand side of Eq. (1) represents, by means of the Dirac delta function δ, the unit

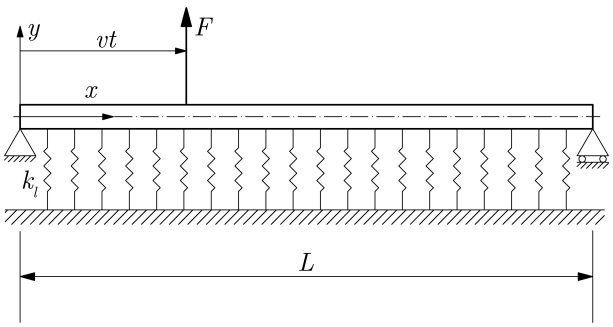

Figure 1: *Simply-supported finite beam lying on an elastic foundation subjected to a moving force.*

concentrated moving load acting at time t at relative position vt, with either constant $F(t) = F$ or variable amplitude $F(t) = F\cos(\Omega t)$, where F is its reference amplitude and Ω is the angular frequency of the harmonic amplitude variation in time.

According to Castro et al. [4] and many other authors the adopted force-displacement relation for the foundation may be described by the following polynomial cubic law:

$$r\big(w(x,t)\big) = k_l\, w(x) + k_{nl}\, w(x)^3; \tag{2}$$

where k_l is a classical linear Winkler coefficient and k_{nl} describes an additional nonlinear stiffness coefficient attached to the cubic term.

By means of cubic Hermitian polynomials as interpolation functions and by the application of Galerkin Finite Element Method, equation of motion (1) may be rewritten for an arbitrary finite element in semi-discretized form. Then, by assembling the contributions from all of the finite elements and imposing the boundary conditions of zero transverse displacements at the two extreme nodes of the beam, the global equations of motion are obtained as:

$$\mathbf{M}\ddot{\mathbf{q}} + \mathbf{C}\dot{\mathbf{q}} + \mathbf{K}\mathbf{q} + \mathbf{Q}_{nl}(\mathbf{q}) = F\boldsymbol{\Psi}(x_c); \tag{3}$$

where $\mathbf{M}$ and $\mathbf{K}$ are the global structural mass and stiffness matrices, $\mathbf{Q}_{nl}$ is the global vector of the nonlinear forces, $\boldsymbol{\Psi}(x_c)$ is the vector deriving from the assembly of the element-wise vectors of equivalent external forces produced by the Dirac delta function, $\mathbf{q}$, $\dot{\mathbf{q}}$ and $\ddot{\mathbf{q}}$ are the global vectors of the generalized displacements, velocities and accelerations, respectively. Both mass and stiffness matrices are symmetric and positive definite. The previously-defined matrices and vectors have been obtained according to the work of Castro et al. [4, 5].

The viscous damping term $\mathbf{C}\dot{\mathbf{q}}$ has been added to Eq. (3) to account for smeared damping. Rayleigh-type damping is assumed, e.g. the damping matrix $\mathbf{C}$ is defined as a linear combination of the mass and stiffness matrices:

$$\mathbf{C} = a_0\mathbf{M} + a_1\mathbf{K}. \tag{4}$$

The values of the coefficients a_0 and a_1 have been chosen accordingly to Dimitrovová and Rodrigues [8] as follows:

$$a_0 = 2\xi\sqrt{\frac{2k_l}{\rho A}}; \qquad a_1 = 0;$$

where ξ is the damping factor. Coefficient a_1 is taken null, meaning that a mass-proportional viscous damping is considered.

Hence, the semi-discrete equations of motion (3) represent a coupled system of linear second-order differential equations with constant coefficients, whose solution, given the initial conditions, represents the transient response of the beam. In this work, the following homogeneous initial conditions are assumed:

$$\mathbf{q}(0) = \mathbf{0}; \quad \dot{\mathbf{q}}(0) = \mathbf{0}. \tag{5}$$

The numerical solution of the initial-value problem satisfying Eqs. (3), (5) has been achieved through a HHT-α implementation (see Hilber et al. [12]). The main methodologies and computational details about the implementation will be reported elsewhere (Froio et al. [10]).

3 CONSTANT AMPLITUDE MOVING LOAD: VALIDATION OF THE FEM FORMULATION

In this section, a concentrated load of constant magnitude $F(t) = F$, namely $\Omega = 0$, moving along the beam axis with constant velocity v, is considered. A consistent validation comparison between the present numerical analyses, in terms of maximum upward and downward beam displacements versus load velocity, and analogous studies proposed in the literature is performed. In particular, results obtained by Castro et al. [4] for both linear and nonlinear foundation behaviors have been taken as reference outcomes, since their work has been lying at the basis of the present investigation.

The type of analyzed beam is a UIC60 rail (see Fig. 2a), one of the most diffused steel profiles in railway tracks. Its mechanical properties are reported in Fig. 2b. A beam length (L) of 200 m has been selected in order to reasonably represent the limit case of a beam of an infinite length. The assumed load magnitude is 83.4 kN, corresponding to a locomotive of the Thalys high-speed train (EU), which has a total axle mass of about 17000 kg (see Castro et al. [4]). The number of adopted finite elements is 200, i.e the spatial discretization consists of finite elements with a length of 1 m.

Computations are performed for velocities of the moving load varying between 50 m/s and 300 m/s with a step variation of 1 m/s. For each simulation performed at a certain value of the moving load velocity, the maximum upward (positive) and downward (negative) displace-

Figure 2: *UIC60 rail profile (taken from the internet), quotes in millimeters (a) and mechanical properties of UIC60 rail (b).*

ments of the beam have been recorded. Then, these values have been plotted as a function of the moving load velocity. From such curves the critical velocity for a finite beam may be detected as the velocity of the moving load at which maximum displacements are attained (see Dimitrovová and Rodrigues [8]).

Regarding aspects of numerical integration, the time span taken throughout the integration process corresponds to the amount of time along which the moving load is really acting along the beam, that is $\tau = L/v$. The adopted time step corresponds to the time taken by the load to travel a distance of 0.2 m, namely a fifth of the finite element length. The HHT-α parameter expressing the numerical dissipation rate is chosen equal to -0.1. The finite element program has been implemented within a MatLab environment [16].

3.1 Beams lying on a linear elastic foundation

A uniform linear elastic foundation is considered, with two different values of Winkler's elastic coefficient equal to $k_l = 250$ kN/m^2 and $k_l = 500$ kN/m^2, respectively. Both undamped and damped behaviors are taken into account, assuming the damping factor ζ in the amount of 2%. As already noticed by Dimitrovová and Rodrigues [8], both foundation stiffness values are actually not that realistic, but they may be adopted in order to achieve a more direct inspection of the critical behavior of the system. The results obtained for the case of a beam on an undamped foundation with the two linear Winkler stiffness coefficients are shown in Fig. 3a. The same results for the damped case are reported in Fig. 3b.

From the observation of these plots, the critical velocity may be clearly detected and the corresponding maximum and minimum displacements are indicated in Tables 1 and 2. It appears that the value of the critical velocity is weakly sensitive to the damping factor, while it affects more the magnitude of the maximum and minimum displacements. From Figs. 3a and 3b, it appears clear that increasing the stiffness of the foundation causes a shift in the position of the critical velocities towards higher values, in addition to the expected effect of decreasing the deflection amplitudes.

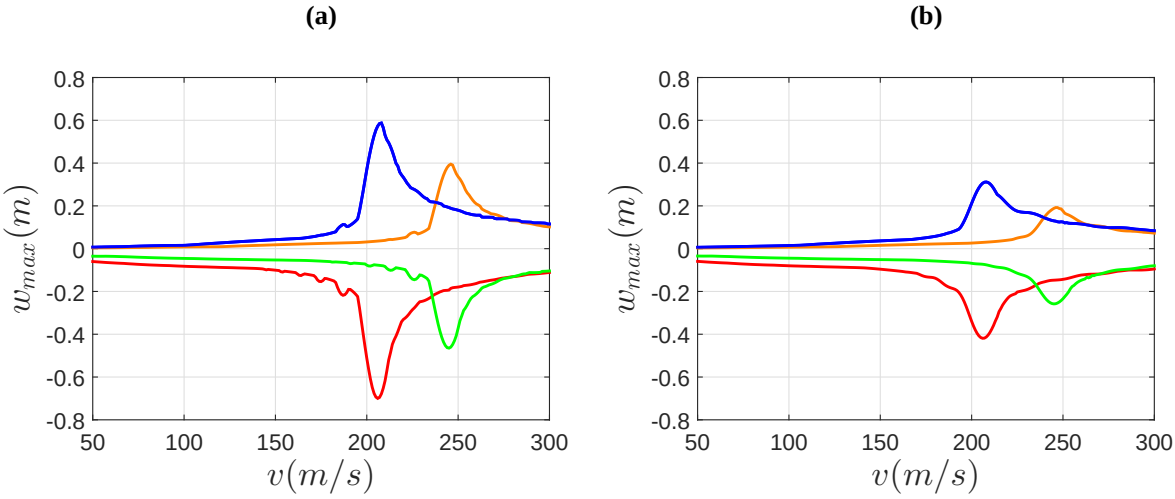

Figure 3: *Representation of beam maximum displacements as a function of load velocity for linear elastic foundations with stiffnesses of* $k_l = 250\,\text{kN/m}^2$ *(— upward and — downward displacements) and* $k_l = 500\,\text{kN/m}^2$ *(— upward and — downward displacements), undamped case* $\zeta = 0\%$ *(a) and damped case* $\zeta = 2\%$ *(b).*

Table 2: *Maximum displacements and critical velocities for a linear foundation with stiffness* $k_l = 500\,\text{kN/m}^2$. *Percentage relative error with respect to Castro et al. [4].*

The comparisons between the outcomes depicted in Figs. 3a and 3b and gathered in Tables 1 and 2, if compared to those reported in Castro et al. [4], reveal a very good agreement, for both damped and undamped cases. Furthermore, in view of the results above, it may be noticed that a good degree of consistency has been also achieved with respect to the analytical solution proposed by Dimitrovová and Rodrigues [8].

3.2 Beams lying on a nonlinear elastic foundation

Two examples of nonlinear foundations are examined in this section: one with a nonlinear component of foundation stiffness $k_{nl} = 2500\,\text{kN/m}^4$ and another with $k_{nl} = 25000\,\text{kN/m}^4$. The assumed linear component of foundation stiffness is $k_l = 250\,\text{kN/m}^2$ for both examples. The computed results are shown in Fig. 4a and 4b for both undamped and damped ($\zeta = 2\%$) cases.

Comparing these plots to those depicted for a linear foundation, it can be seen that the addition of the nonlinear contribution to the foundation stiffness results in an increment of the critical velocities. Moreover, a decrease of the maximum upward and downward displacements is detected. The inclusion of damping brings a further decrease of the maximum displacements entity, together with a small decrease of the critical velocities.

For the nonlinear type of foundation the values of the critical velocities are not explicitly indicated by Castro et al. [4]. Nonetheless, the results obtained with the implemented method are matching the deflection curves and the maximum values of displacements reported in that work. The values of critical velocities, maximum displacements and percentage relative errors upon the latter are reported in Table 3, for a foundation with nonlinear stiffness $k_{nl} = 2500\,\text{kN/m}^4$, and in Table 4, for a foundation with nonlinear stiffness $k_{nl} = 25000\,\text{kN/m}^4$.

The results reported in this section are preliminary to the analysis with a harmonic moving load, which represents the core of this work and will be presented in Section 4. In fact, first the concept of critical velocity of a constant amplitude moving load for a finite simply-supported beam has been again outlined and its dependence on the mechanical parameters of the systems,

already reported in the literature, has been confirmed. Second, thanks to the previously-reported results, the present finite element implementation reveals to be fully reliable with respect to the outcomes presented by Castro et al. [4] and by Dimitrovová and Rodrigues [8], proving its correctness.

4 HARMONIC MOVING LOAD

In the present section the main effects of the load frequency of the harmonic-varying magnitude of the moving load on the displacements of the beam and on the critical velocities are outlined. In order to obtain values of beam displacements and critical velocities representative of real railway supports, more realistic values of foundation stiffness have been adopted for the numerical simulations presented herein, with respect to those reported in Section 3.

Regarding the load frequency range, according to Chen et al. [6] the frequency (Ω) shall be always lower than 420 rad/s in nowadays engineering problems. Consequently, the computations have been performed in the range from 0 rad/s to 440 rad/s, with intervals of 40 rad/s. For each of these frequencies, the maximum upward and downward beam displacements have been computed, for velocities of the moving load starting from 10 m/s to 600 m/s, at speed intervals of 10 m/s. Then, when the neighborhood of the position of the critical velocity has been approximately recognized, the velocity step is further refined to 1 m/s, for reaching locally a better accuracy. Although the upper bound of the selected range of moving load velocity is clearly unattainable by today railway transports, its adoption looks necessary in order to properly capture more than one critical velocity.

The number of adopted finite elements is 400 (twice as in the previous analyses), each one with a length of 0.5 m. It is worth to point out that for some of the simulations presented in this section, the results retrieved with a time step chosen accordingly to the criterion given by Castro et al. [4], namely choosing the time step as the time taken by the load to travel a fifth of a finite element length, are actually characterized by a low accuracy. Therefore, a lower time step, equal to 10^{-4} s, has been adopted for all the numerical analyses presented in this section. Further information and data are extensively reported in Moioli [17].

4.1 Beams lying on a linear elastic foundation

First, a uniform linear elastic foundation is considered, with a value of Winkler linear elastic coefficient (k_l) equal to 10^4 kN/m^2. The relationship between beam maximum upward and downward displacements and load velocities, retrieved for an undamped and a damped foundation, is shown in Fig. 5.

It is noticeable that, as the amplitude of the moving load starts oscillating with frequency Ω, the critical velocities might be either one or two within the displayed range of velocities. In particular, the higher critical velocity (v_{cr2}) increases and quickly moves towards the upper limit of the plot as the load frequency increases. Conversely, the lower critical velocity (v_{cr1}) decreases until reaching zero at a very high load frequency. Such value corresponds to the lowest natural frequency of a simply-supported beam lying on a linear elastic foundation, which is defined as (see Frýba [11]):

$$\omega_1 = \sqrt{\frac{\pi^4}{L^4}\frac{EI}{m} + \frac{k_l}{m}} = 408.5\,\text{m/s}.$$

The interpretation of this result is straightforward: in fact, it is well known that a fixed load oscillating at the same natural frequency of the beam causes the resonance of the system.

A comparison between the results for the undamped foundation and those for the damped foundation reveals that, as for the case of a moving load with constant magnitude, the maximum beam displacements of the damped foundation are much smaller and much more difficult to be defined, with respect to those computed for the undamped foundation. The latter observation may be clearly visualized in Fig. 5, where multiple little peaks appear in the neighborhood of

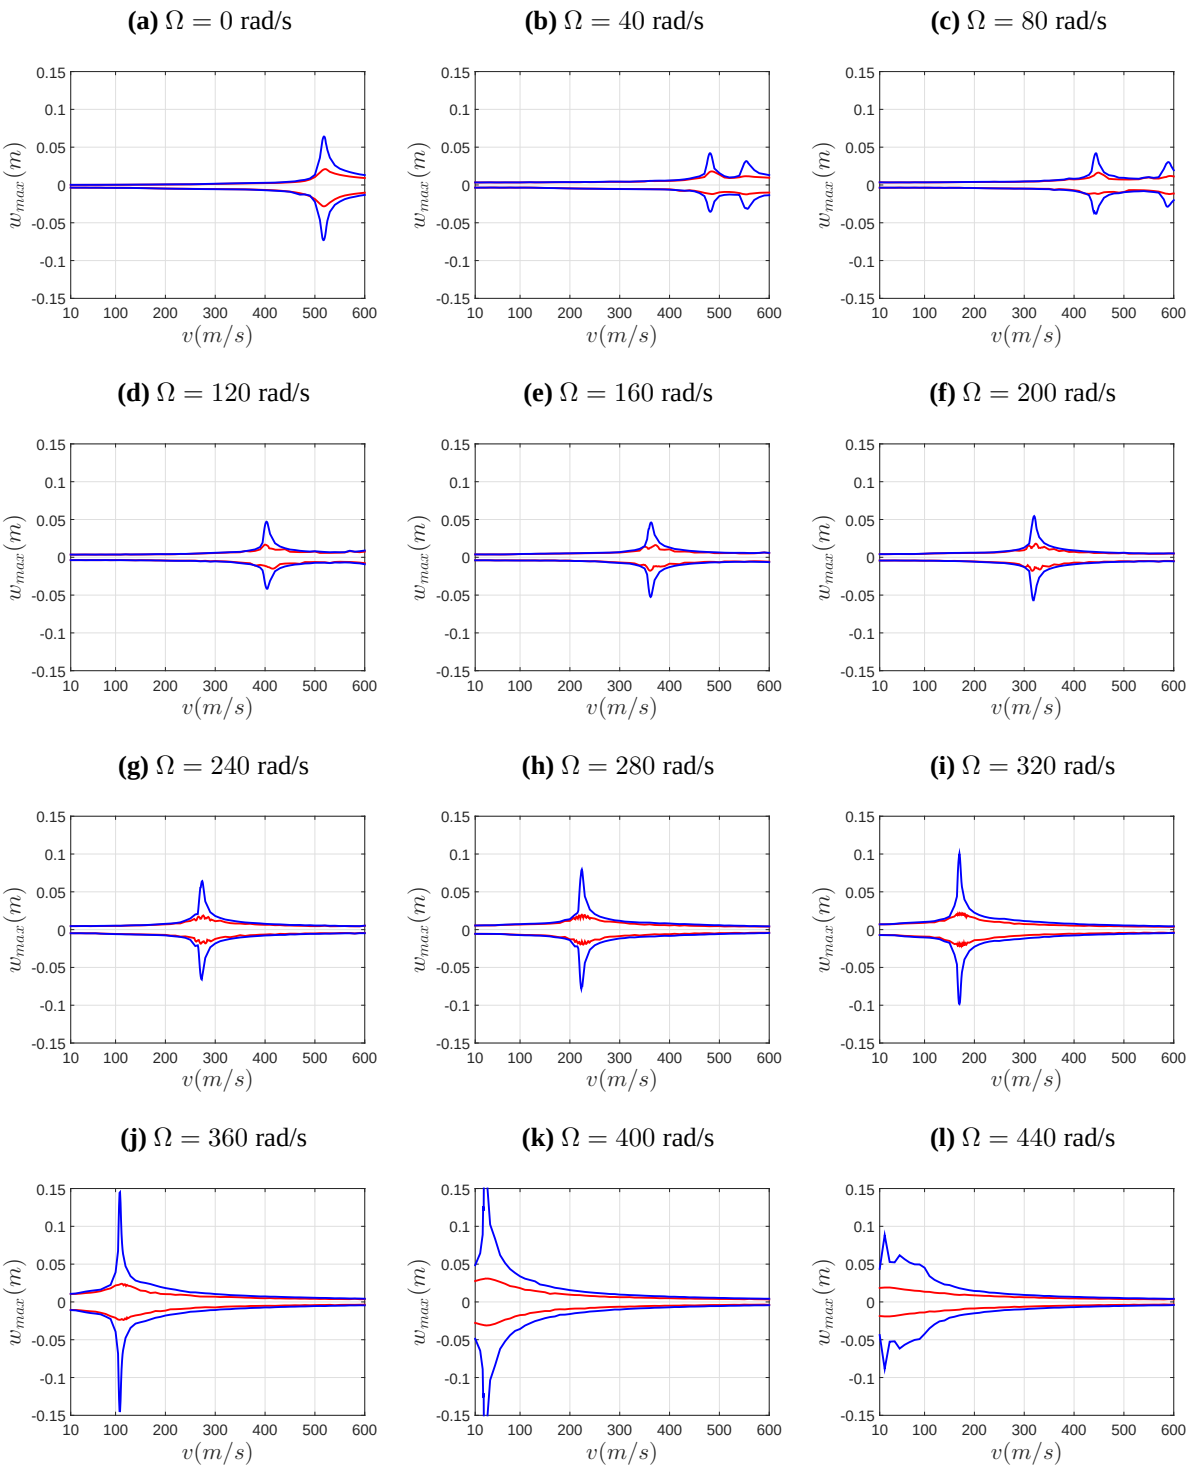

Figure 5: *Representation of beam maximum displacements as a function of load velocity and frequency for undamped (—) and damped (—) linear elastic foundations with stiffness of* $k_l = 10^4\,\mathrm{kN/m^2}$.

the critical velocity. These oscillations point out that an even more refined time step is needed for obtaining a better accuracy in the local definition of the peaks. Critical velocities are instead much less affected by damping.

The relationship between the frequency of oscillation of the moving load and the critical

velocity is explicitly depicted in Figs. 6a and 6b. These bifurcation curves have been established by fitting the values of the critical velocity computed at the different frequencies of the load. The fitting is performed by adopting the following proposed models for the lower and higher critical velocities, respectively:

$$v_{cr1} = a_1 + a_2\,\Omega + a_3\,e^{a_4\Omega}; \tag{6}$$

$$v_{cr2} = b_1 + b_2\,\Omega + b_3\,\Omega^2. \tag{7}$$

The four coefficients of the first expression are retrieved with a nonlinear least squares regression method, while the three of the second expression are achieved with a linear least squares regression method, performed by using the curve fitting built-in function in MatLab. The computed values of the coefficients in Eq. (6) and Eq. (7) for the undamped system are:

$$a_1 = 521.8 \text{ m/s}, \quad a_2 = -0.9206 \text{ m/rad}, \quad a_3 = -2.694 \text{ m/s}, \quad a_4 = 9.559 \times 10^{-3} \text{ s/rad};$$
$$b_1 = 516.9 \text{ m/s}, \quad b_2 = \quad 0.9750 \text{ m/rad}, \quad b_3 = -1.250 \times 10^{-3} \text{ ms/rad}^2.$$

The fitted curves for the undamped linear elastic foundation are plotted in Fig. 6a. This figure shows also bifurcation curves computed in accordance with the analytical solution developed by Chen et al. [6]. The comparison between the fitted curves and the analytical result reveals a very good agreement, providing a further verification of the reliability of the present finite element implementation, even for the case of a variable load.

Even though the determination of the coefficients in Eqs. (6), (7) require a significant amount of computational time, they show explicitly the critical velocities as a function of the load frequency, differently from the implicit formulation developed by Chen et al. [6]. Furthermore, the obtained models for the critical velocity/load frequency pairs are much simpler than their analytical counterparts proposed by Chen et al. [6], which involve cumbersome complex irrational fractions of polynomials containing the mechanical parameters of the system.

It is important to notice that the solution by Chen et al. [6] presents a third branch, on the right of the first natural frequency of the beam (408 rad/s). Nevertheless, as already proven by

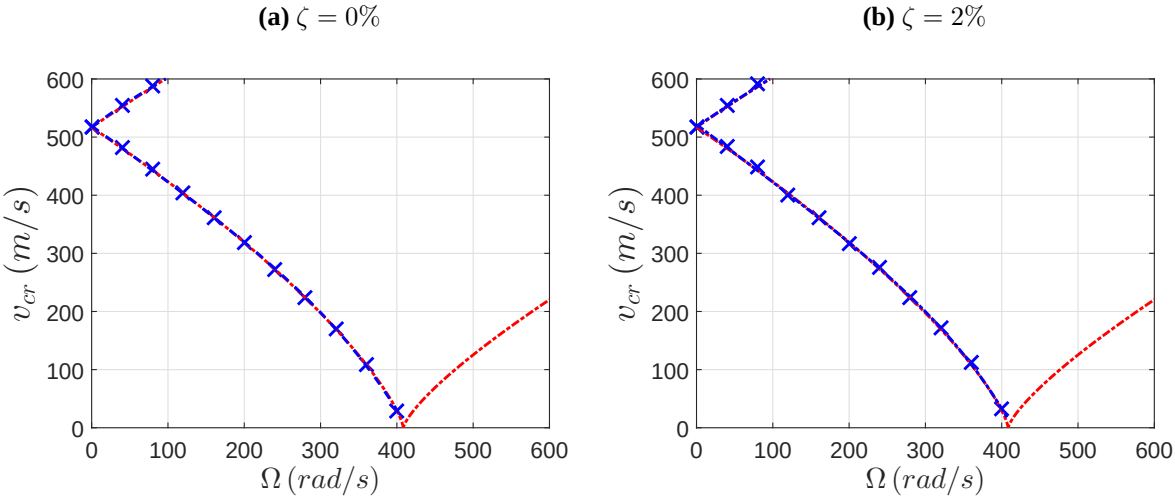

Figure 6: *Critical velocity and load frequency pairs for undamped and damped linear elastic foundations with stiffness of* $k_l = 10000\,kN/m^2$. *Results computed with: (*$\times$*) finite element implementation; (-·-) fitted curves; (-·-) analytical solution by Chen et al. [6].*

Kim [15], the critical velocities represented by such a branch cannot be detected from the plots of the maximum displacements versus load velocity, because no peak of displacement corresponds to these velocities in a finite beam. Therefore, it is not necessary to perform numerical simulations for load frequencies higher than the first natural frequency of the beam.

Bifurcation curves for critical velocity and frequency pairs have also been obtained for the case of a damped ($\zeta = 2\%$) linear elastic foundation. The adopted fitting models have been the same as those employed for the undamped foundation, i.e. those defined by Eq. (6) and Eq. (7). The coefficients computed for the damped foundation are:

$$a_1 = 522.6 \text{ m/s}, \quad a_2 = -0.9698 \text{ m/rad}, \quad a_3 = -0.9883 \text{ m/s}, \quad a_4 = 1.116 \times 10^{-2} \text{ s/rad};$$
$$b_1 = 517.9 \text{ m/s}, \quad b_2 = \quad 0.8875 \text{ m/rad}, \quad b_3 = -3.125 \times 10^{-3} \text{ ms/rad}^2.$$

The corresponding curves are plotted in Fig. 6b. In this case the critical velocity has not been reported by Chen et al. [6]. Nonetheless, comparing the curves obtained in accordance to Chen et al. [6] for the undamped case to those fitted from the numerical results, it can be seen that the level of damping is almost ineffective on the value of the critical velocity.

4.2 Beams lying on a nonlinear elastic foundation

For the nonlinear foundation model the assumed linear and nonlinear parameters defining the foundation stiffness are $k_l = 5 \times 10^3$ kN/m^2 and $k_{nl} = 2 \times 10^6$ kN/m^4, respectively. These values are selected in such a way that to provide a foundation model that is more compliant with respect to that of the linear elastic foundation for small beam displacements and, at the same time, stiffer for large displacements, as proposed by many authors (see e.g. Nguyen and Duhamel [18]).

Fig. 7 shows the retrieved results for damped and undamped nonlinear elastic foundations. It can be seen that, as in the case of a linear foundation, a second critical velocity appears for a harmonic variation of the moving load amplitude. A comparison between the graphs in Fig. 7 and their counterparts in Fig. 5 for the linear foundation, reveals that lower critical velocities and associated smaller maximum deflections are retrieved for the case of a nonlinear elastic foundation. For a foundation with viscous damping, a decrease of the maximum displacements can be observed, together with a small decrease of the critical velocities.

Bifurcation curves describing the relationship between critical velocities and load frequency are established in an analogous way as for the case of a linear elastic foundation. The adopted models for the higher and the lower critical velocity curves are the same as those employed for the linear foundation, in Eqs. (6)-(7). The coefficients computed for the undamped nonlinear elastic foundation are:

$$a_1 = 459.6 \text{ m/s}, \quad a_2 = -1.139 \text{ m/rad}, \quad a_3 = -4.5089 \text{ m/s}, \quad a_4 = 8.007 \times^{-3} \text{ s/rad};$$
$$b_1 = 456.9 \text{ m/s}, \quad b_2 = \quad 0.8082 \text{ m/rad}, \quad b_3 = \quad 4.018 \times 10^{-4} \text{ ms/rad}^2;$$

and, for the damped ($\zeta = 2\%$) nonlinear elastic foundation are:

$$a_1 = 452.1 \text{ m/s}, \quad a_2 = -1.084 \text{ m/rad}, \quad a_3 = -4.991 \text{ m/s}, \quad a_4 = 0.089 \text{ s/rad};$$
$$b_1 = 443.9 \text{ m/s}, \quad b_2 = \quad 1.078 \text{ m/rad}, \quad b_3 = -8.929 \times 10^{-4} \text{ ms/rad}^2.$$

Fig. 8 shows the curves retrieved for the undamped and the damped nonlinear foundation. Comparing these plots to those reported previously in Fig. 6, it is clear that the relationship between the critical velocities and the load frequency for linear and nonlinear elastic foundations displays similar features. Nonetheless, in contrast with the case of a linear foundation, the curves for the damped nonlinear foundation are slightly shifted downward, with respect to the undamped ones.

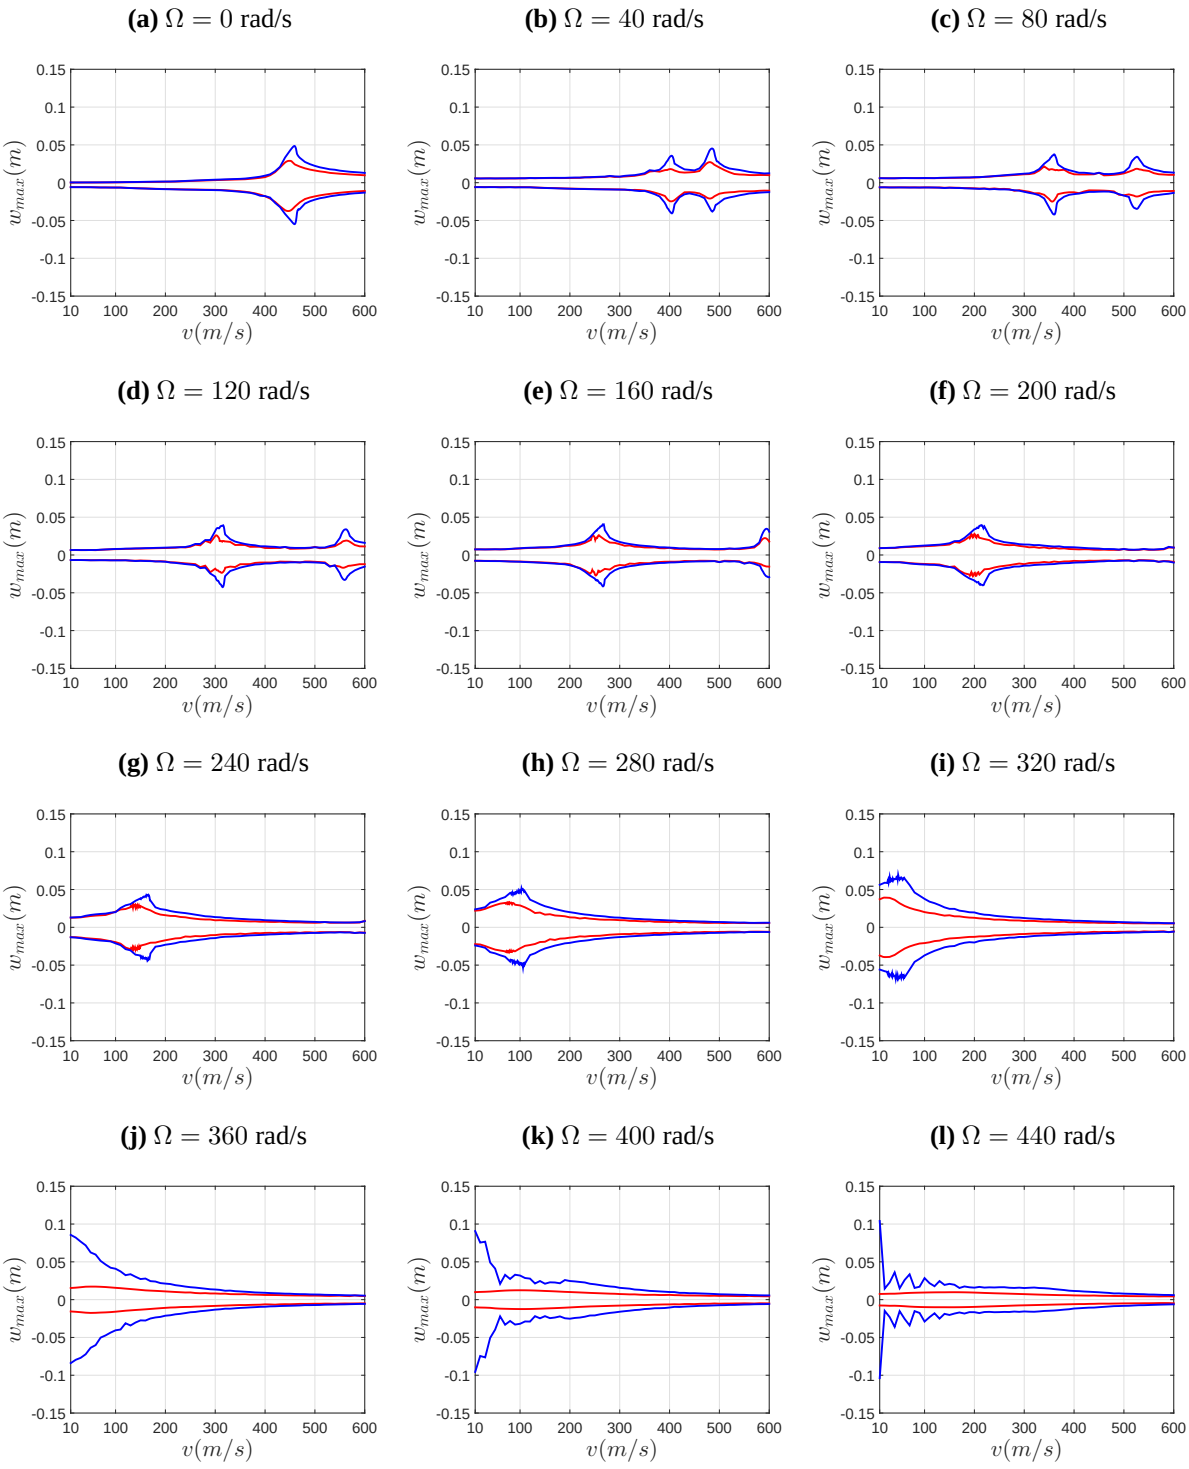

Figure 7: *Representation of beam maximum displacements as a function of load velocity and frequency for undamped (—) and damped (—) nonlinear elastic foundations with stiffnesses of* $k_l = 5 \times 10^3\,\mathrm{kN/m^2}$ *and* $k_{nl} = 2 \times 10^6\,\mathrm{kN/m^4}$.

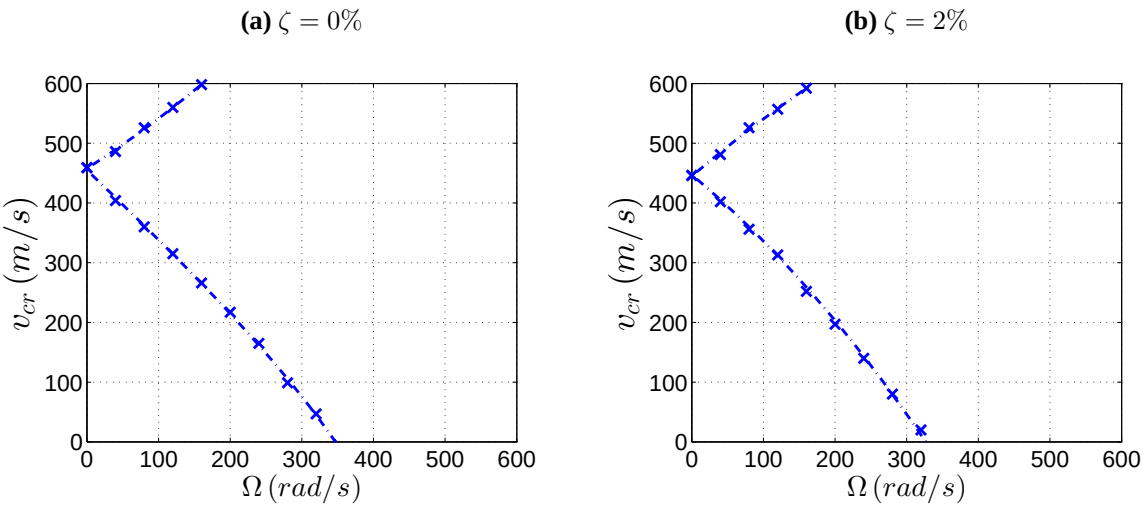

Figure 8: *Critical velocity and load frequency pairs for undamped and damped nonlinear elastic foundations with stiffnesses of* $k_l = 5 \times 10^3$ kN/m^2 *and* $k_{nl} = 2 \times 10^6$ kN/m^4. *Results computed with: (*$\times$*) finite element implementation; (- - -) fitted curves.*

5 CONCLUSIONS

In this work a finite element approach has been developed within a MatLab environment to analyze the dynamic transient response of a simply-supported beam lying on linear or nonlinear Winkler elastic foundation, subjected to a concentrated load moving at constant velocity with either constant or harmonically-varying amplitude.

The extensive performed campaign of numerical simulations provided several interesting findings and new outcomes about the behavior of high-speed rail tracks. The most significant results may be summarized in the following itemized list:

- When the amplitude of the moving load is constant, the present finite element implementation has been proven to provide results that appear fully consistent to those reported by Castro et al. [4].

- For all types of foundation, the beam maximum displacements at the critical velocities initially decrease with the load amplitude frequency, before increasing sharply near the natural frequency of the beam. Furthermore, when damping is included in the analysis, no significant effects on the critical velocities are detected, while the amplitude of displacements is lowered.

- When the beam is subjected to a moving harmonic load, two critical velocities are detected, independently from the considered type of foundation behavior, either linear or nonlinear. The two critical velocities tend to separate as the loading frequency increases. The higher critical velocity v_{cr2} increases, starting from the value of the critical velocity obtained for a constant magnitude load. On the contrary, the lower critical velocity v_{cr1} decreases, until it reaches zero for a frequency of the load equal to the first natural frequency of the beam. This behavior may reveal potential implications in practical terms, especially in lowering down the ranges of admissible train speeds, when the frequency of oscillation of the moving load amplitude becomes high.

- The relationship between the moving load amplitude frequency and the critical velocity of

the beam is portrayed in appropriate analytical bifurcation curves. These curves have been achieved by fitting the values of the critical velocity computed at different frequencies of the load variation, according to proposed variations with the amplitude frequency, with calibrated best-fitted coefficients.

- For the case of a linear foundation, the obtained bifurcation curves show a very good agreement to those available from the analytical approaches by Chen et al. [6]. In addition, the employed models for the description of the analytical bifurcation curves are explicit and much simpler than those exact proposed by Chen et al. [6].

- The employed models for the description of the bifurcation curves are also appropriate for the nonlinear case, with or without damping. The derived formulas are simple and possibly workable in practice; they may supply a guideline for the design of railway tracks when the magnitude of the moving load is oscillating in time.

It must be recognized that, in order to obtain a more realistic dynamic response of the system, some further improvements of the modelization could be made. Real applications usually require extensions to infinite beams; it is then necessary to eliminate the effect of the supports, to mitigate the perturbation induced by the boundary conditions and to prevent the reflection of the traveling waves. This could be achieved by using appropriate absorbing boundaries. Furthermore, a real vehicle spring-mass-damper system interacting with the rail should be considered, instead of a simple moving force. Finally, the assumption of symmetric behavior in tension and compression for the foundation stiffness should also be relaxed, leading to the analysis of a bilinear foundation. These issues will be the subject of on-going (Froio et al. [10]) and future investigations.

Abstract. *In this contribution, a homogenized beam finite element of double symmetric cross-section made of a Functionally Graded Material (FGM) is presented, which can be used for static, modal and buckling analysis of single beams and beam structures with three directional variation of material properties. The material properties in a real beam can vary continuously in longitudinal direction while the variation with respect the transversal and lateral directions is assumed to be symmetric in a continuous or discontinuous manner. The shear force deformation effect and the effect of inertia and rotary inertia are taken into account. Additionally, the longitudinally varying Winkler elastic foundation and the effect of axial force are included by the finite element equations as well. Homogenization of spatially varying material properties to effective quantities with a longitudinal variation is done by the extended mixture rules and multilayer method (MLM). For the homogenized beam the 12×12 finite element effective matrix, consisting of the linearized stiffness and consistent mass inertia terms, is established. Numerical experiments are made concerning static, modal and buckling analyses of single FGM beam and beam structures to show the accuracy and effectiveness of the proposed FGM beam finite element.*

1 INTRODUCTION

Important classes of structural components, where FGM is used, are beams and beam structures. FGM beams play an important role not only in classical structural applications, but we can find many applications in thermal, electric-thermal or electric-thermal-structural systems (e.g. micro-electro-mechanical systems (MEMS) as sensors and actuators and other mechatronic devices). In all these applications, using new materials like FGM can greatly improve the efficiency of the systems. FGM is built as a mixture of two or more constituents whose particles have almost the similar form and dimensions (powder, plasma particles, etc.). The continuous or multilayered variation of macroscopic material properties can be caused by varying the volume fraction of the constituents or by varying the constituent's material properties (e.g. by a non-homogeneous temperature field). In the literature a huge amount of papers can be found which deal with modeling and simulation of static and dynamic problems of FGM beams.

The latest results of theoretical research on statics and vibration and loss of stability of FGM and composite beams are presented for example in the articles [1-13].The first significant feature of the references [1-8] (and also of those published in the previous period) is that variation of material properties is considered only in one direction, usually along the beam thickness, and exceptionally in the longitudinal direction of the beam. The second feature of these works is that they are analyzed only a simple planar beams with rectangular cross-section. The third feature of most of these works is that their fundamental equations are based on the equations of plane stress state in a continuum with varying material properties which are simplified for the solution of the beams. In [9-12], general formulations for non-uniform shear warping are presented and an advanced 20×20 stiffness matrix and the corresponding nodal load vector of a member of arbitrary composite cross section is developed, taking shear lag effects into account due to both flexure and torsion. In [13], a static analysis of three-dimensional FGM beams by hierarchical modeling and a collocation meshless solution method is presented.

With regard to our work in the past period in the field, we presented in [14-16] a solution of free vibration of a single 2D FGM beam with continuous planar polynomial variation of material properties (in axial and transversal direction) by a fourth-order differential equation of second order beam theory. The focus of these publications is laid on a new concept for expanding the second order bending beam theory considering the shear deformation according to Timoshenko beam theory. There, the shear deformation effect in FGM beams with planar continuous variations of material properties is originally included by means of the average shear correction factor that has been obtained by an integration of the shear correction function [17]. A continuous polynomial variation of the effective elastic modulus and the mass density is considered by continuous polynomial planar variation of both the volume fraction and material properties of the FGM constituents. The choice of a polynomial gradation of material properties enables an easier integration of the derived differential equation and allows to model practically realizable variations of material properties. The effect of consistent inertia and rotary inertia, and the effect of axial forces are taken into account as well.

As mentioned above, many time published papers registered e.g. in the Web of Science database, deal with static and dynamic and buckling analysis of the FGM single planar beam with transverse variation of material properties only. Less attention is paid on both the longitudinal and lateral variations of material properties. The authors failed in finding more papers which deal with analysis of single beams or spatial beam structures made of FGM with spatial variation of material properties (in three directions).

The proposed contribution is a continuation of our previous papers [14-18]. The derivation of the FGM beam finite element equations suitable for static, modal and buckling analyses of single beams or spatial beam structures made of spatially varying FGM (in longitudinal and transversal and lateral direction) is presented. From the differential equations of axial, flexural and torsional deformation of the FGM beam with longitudinally varying material properties the transfer relations and following the local and global finite beam element matrices are established. Effects of axial and shear forces are included as well as the longitudinally varying Winkler elastic foundation and inertia loads. Homogenization of the spatially varying material properties in the real FGM beam and calculation of their effective values are done by extended mixture rules and by the multilayer method (MLM) [18,25]. This method can also be used in the homogenization of multilayer beams with symmetrically discontinuous (multilayered) variation of material properties in transversal and lateral direction. In the modal and buckling analysis an eigenvalue problem is solved. Numerical experiments are performed to calculate the elastostatic and modal response and the critical buckling force of chosen FGM beams and beam structures with rectangular and hollow cross-sections with spatial variations of material properties. The solution results are discussed and compared to those obtained by means of very fine 3D – solid and beam finite element meshes of the software ANSYS Workbench [34].

The novel aspects of the current paper are:

- extension of the MLM to homogenization of the spatially (polynomial) varying material properties (continuously in longitudinal and symmetrically in transversal and lateral direction (continuously or multilayered)) for calculation of the effective longitudinally varying elasticity modules for axial and flexural and torsional loading, and the competent effective mass-densities;
- extension of the second order beam theory and the uniform torsion theory on static, modal and buckling analysis of FGM beams with spatial variation of material properties (in three directions);
- including the effects of the shear and axial forces, as well as the longitudinally varying Winkler elastic foundations;
- derivation of the transfer relations for the 3D straight FGM beam (with homogenized longitudinal variation of the effective material properties) of doubly symmetric cross-section;
- establishing of the 12×12 effective finite element matrix of the 3D FGM beam (with homogenized longitudinal variation of the effective material properties) consisting of the linear and linearized geometric stiffness and consistent mass inertia terms;
- performing of the numerical experiments concerning the static and modal and buckling analysis of the FGM beams and beam structures with spatially varying material properties.

2 FINITE ELEMENT EQUATIONS OF THE 3D FGM BEAM

Let us consider a straight beam element of doubly symmetric cross-section – Figure 1. The degrees of freedom at node *i* are: the displacements u_i, v_i, w_i in the local directions *x*, *y*, *z*, and the cross-sectional area rotations about the *x*, *y*, *z* directions - $\varphi_{x,i}, \varphi_{y,i}, \varphi_{z,i}$. The degrees of freedom at the node *j* are denoted in a similar manner. The internal forces at node *i* are: the axial force N_i, the transversal forces $R_{y,i}$ and $R_{z,i}$, the bending moments $M_{y,i}$ and, the torsion moment $M_{x,i}$.

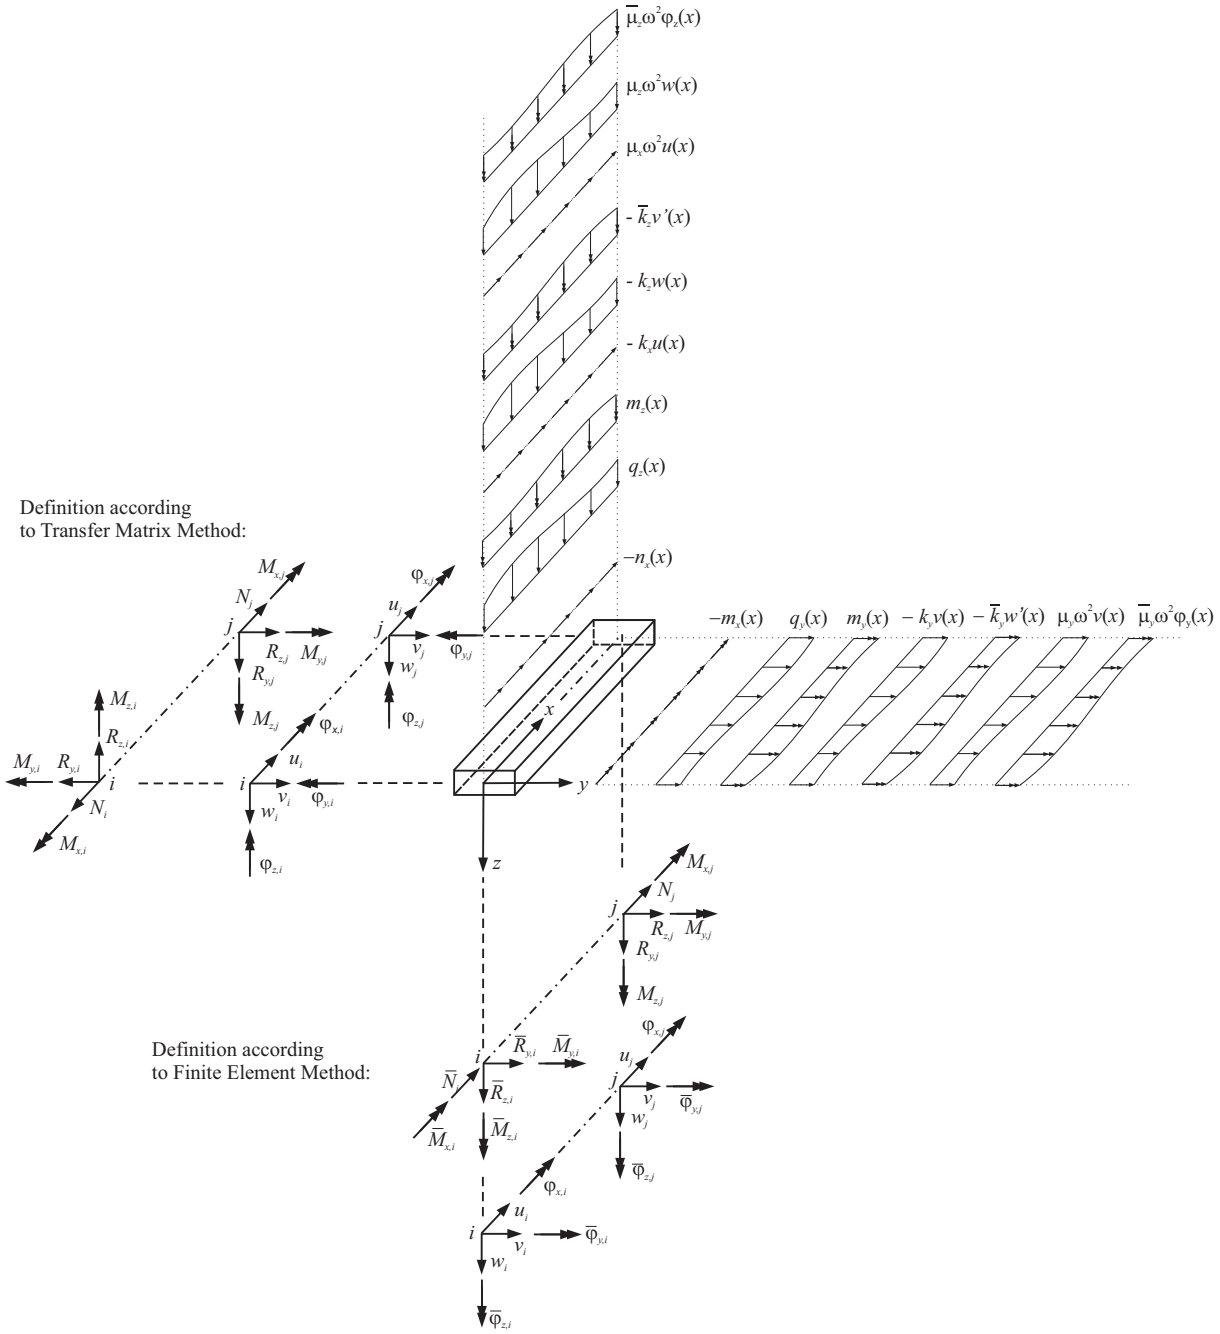

Figure 1: The local internal variables, static and inertia and loads for transfer matrix and finite element methods.

Furthermore, $n_x = n_x(x)$ denotes the axial force distribution, $q_z = q_z(x)$ and $q_y = q_y(x)$ are the transversal and lateral force distributions, $m_x = m_x(x)$, $m_y = m_y(x)$ and $m_z = m_z(x)$ are the distributed moments, $\mu_x = \rho A = \mu_y = \mu_z = \mu$ denote the mass distribution, $\overline{\mu}_y = \rho I_y$, $\overline{\mu}_z = \rho I_z$ and $\overline{\mu}_{xT} = \rho I_p$ refer to the distributions of mass moments of inertia, $\rho = \rho_L^H(x) \equiv \rho_L^H$ is the homogenized effective mass density distribution, A is the cross-sectional area, I_y and I_z are the second moments of area, $I_p = I_y + I_z$ denotes the polar moment of area, $k_x = k_x(x)$, $k_y = k_y(x)$, $k_z = k_z(x)$, $\overline{k}_y = \overline{k}_y(x)$, $\overline{k}_z = \overline{k}_z(x)$ are the elastic foundation modules

(the torsional elastic foundation is not considered), and ω is the circular frequency. The effective homogenized and longitudinally varying stiffness reads as follows: $EA = E_L^{NH}(x)A$ is the axial stiffness ($E_L^{NH}(x) \equiv E_L^{NH}$ is the effective elastic modulus for axial loading), $EI_y = E_L^{M_yH}(x)I_y$ is the flexural stiffness about the *y*-axis ($E_L^{M_yH}(x) \equiv E_L^{M_yH}$ is the effective elastic modulus for bending about axis *y*), $EI_z = E_L^{M_zH}(x)I_z$ is the flexural stiffness in axis *z*, ($E_L^{M_zH}(x) \equiv E_L^{M_zH}$ is the effective elastic modulus for bending about axis *z*), $G\bar{A}_y = G_{Ly}^{H}(x)k_y^{sm}A$ is the reduced shear stiffness in *y*-direction ($G_{Ly}^{H}(x) \equiv G_{Ly}^{H}$ is the effective shear modulus and k_y^{sm} is the average shear correction factor in *y*-direction), $G\bar{A}_z = G_{Lz}^{H}(x)k_z^{sm}A$ is the reduced shear stiffness in *z* – direction ($G_{Lz}^{H}(x) \equiv G_{Lz}^{H}$ is the effective shear modulus and k_z^{sm} is the average shear correction factor in *z* - direction), $G_L^{M_xH}(x)I_T$ is the effective torsional stiffness, $G_L^{M_xH}(x) = G_L^{M_xH}$ is the torsional elastic modulus and I_T is the torsion constant – $I_p = I_T$ for the circular and ring cross-section). The derivatives with respect to *x* of the relevant variable is denoted with an apostrophe " ′ " throughout the article.

The differential equations for axial, transversal, lateral and torsional deformation and their solution are established according the Figure 1: Definition according the Transfer Matrix Method. The finite element equations of the 3D FGM beam are established from the transfer matrix relations according Figure 1: Definition according the Finite Element Method.

2.1 Axial deformation

Equation (1) results from the axial deformation problem of the FGM beam, including the specific case of harmonic oscillations ($u = u(x)$ is the axial displacement distribution, $u' = u'(x)$ is its first derivative and $u'' = u''(x)$ is its second derivative):

$$N' = n_x + \left(k_x - \mu_x \omega^2\right)u\,, \tag{1}$$

$$u' = \frac{N}{EA}, \tag{2}$$

By combination of (1) and (2) we get the differential equation with non-constant polynomial coefficients

$$\eta_{2u}u'' + \eta_{1u}u' + \eta_{0u}u = n_x\,, \tag{3}$$

with $\eta_{2u} = EA,\ \eta_{1u} = E'A,\ \eta_{0u} = \mu\omega^2 - k_x$, and $E \equiv E_L^{NH}(x)$. The polynomial distributed axial force is: $n_x = \sum_{k=0}^{p_n} n_{x,k}x^k = n_{x,0}x^0 + n_{x,1}x^1 + n_{x,2}x^2 + \ldots + n_{x,p_n}x^{p_n}$, where $n_{x,k}$ are the values of the *k*-th derivative of the axial force n_x at the beam node *i*. For the modal analysis of axial vibration the right hand side of (3) vanishes.

The solution of (3) can be expressed by the polynomial transfer functions $\bar{b}_{kN} = \bar{b}_{kN}(x)$, ($k \in \langle 0, p_n + 2\rangle$) for axial loading [19, 20]:

$$\begin{bmatrix} u(x) \\ u'(x) \end{bmatrix} = \begin{bmatrix} \bar{b}_{0N} & \bar{b}_{1N} \\ \bar{b}'_{0N} & \bar{b}'_{1N} \end{bmatrix} \cdot \begin{bmatrix} u_i \\ u'_i \end{bmatrix} + \begin{bmatrix} \sum_{k=0}^{p_n} n_{x,k} \bar{b}_{k+2N} \\ \sum_{k=0}^{p_n} n_{x,k} \bar{b}'_{k+2N} \end{bmatrix}. \tag{4}$$

Here, u_i is the axial displacement and u'_i is the value of first derivative of $u(x)$ at node *i*.

If the $u'(x)$ and u'_i are replaced with the constitutive equation of the FGM beam (2), we get

$$\begin{bmatrix} u(x) \\ N(x) \end{bmatrix} = \begin{bmatrix} A_{1,1} = \bar{b}_{0N} & A_{1,2} = \dfrac{\bar{b}_{1N}}{E_i A} \\ A_{2,1} = EA\bar{b}'_{0N} & A_{2,2} = \dfrac{EA}{E_i A}\bar{b}'_{1N} \end{bmatrix} \cdot \begin{bmatrix} u_i \\ N_i \end{bmatrix} + \begin{bmatrix} A_{1,3} = \sum_{k=0}^{p_n} n_{x,k} \bar{b}_{k+2N} \\ A_{2,3} = EA \sum_{k=0}^{p_n} n_{x,k} \bar{b}'_{k+2N} \end{bmatrix}, \tag{5}$$

where E_i is the initial value of the homogenized elastic modulus $E_L^{NH}(x)$ at node *i*.

By setting $x = L$ in (5), the dependence of the nodal variables at node *j* on the nodal variables at node *i* are obtained. By appropriated mathematical operations and by considering the altered orientation of the local internal variables in FEM formulation (see Fig. 1), the local finite element equation for the axial loading (including the particular case of axial harmonic vibrations) are obtained (with $\bar{N}_i = -N_i$):

$$\begin{bmatrix} \bar{N}_i \\ N_j \end{bmatrix} = \begin{bmatrix} B_{1,1} = \dfrac{A_{1,1}}{A_{1,2}} & B_{1,7} = -\dfrac{1}{A_{1,2}} \\ B_{7,1} = A_{2,1} - \dfrac{A_{1,1}A_{2,2}}{A_{12}} & B_{7,7} = \dfrac{A_{2,2}}{A_{1,2}} \end{bmatrix} \cdot \begin{bmatrix} u_i \\ u_j \end{bmatrix} + \begin{bmatrix} F_1 = \dfrac{A_{1,3}}{A_{1,2}} \\ F_7 = A_{2,3} - \dfrac{A_{1,3}A_{2,2}}{A_{1,2}} \end{bmatrix}. \tag{6}$$

It can be easy shown that the matrix *B* is symmetric. The terms of the matrix *B*and the loads vector *F* are calculated numerically using MATHEMATICA [21]. Their indices are deliberately numbered in order to indicate the position of the components in the local matrix and loads vector of the 3D beam finite element, which is established later.

2.2 Flexural deformation about the *y* and *z* axis

The differential equation of 4th order with non-constant coefficients of the homogenized FGM beam flexural transversal deformation (including the particular case of flexural harmonic vibrations) in the *x*-*z* plane (Figure 1) has the form [15]:

$$\eta_{4w} w'''' + \eta_{3w} w''' + \eta_{2w} w'' + \eta_{1w} w' + \eta_{0w} w = \eta_{Lxz}(x) \tag{7}$$

with polynomial loads acting in the *x*-*z* plane

$$\eta_{Lxz}(x) = \sum_{s=0}^{\max s} \eta_{Lxz,s} x^s = \sum_{k=0}^{p_{qz}} q_{z,k} x^k + \sum_{k=1}^{p_{qz}} k q_{z,k} x^{k-1} + \sum_{k=2}^{p_{qz}} k(k-1) q_{z,k} x^{k-2} + \sum_{k=0}^{p_{my}} m_{y,k} x^k + \sum_{k=1}^{p_{my}} k m_{y,k} x^{k-1}, \tag{8}$$

where: $\eta_{Lxz,s}$ are the values of the *k*-th derivative of load polynomial (8) at the beam node *i* (*s* is the maximum degree of the polynomial); $q_{z,k}$ are the values of the *k*-th derivative of the

polynomial transversal force $q_z = q_z(x)$, and $m_{y,k}$ are the values of the *k*-th derivative of the polynomial moment $m_y = m_y(x)$ at the beam node *i* (p_{qz} and p_{my} is the maximum degree of the polynomials).For the modal analysis of flexural vibration the right hand side of (7) vanishes. Again, $w = w(x)$ refers to the deflection curve in the $x-z$ plane. The derivation of the non-constant coefficients η_{0w} to η_{4w} and appropriated parameters of the differential equation (7) from the main coupled equations (9) and (10) of the 2nd order beam theory (including the inertia forces, shear and axial force) using the relation between the transversal and shear force (11) is described in [15, 17].

$$R_z' = -q_z + k_z w - \mu\omega^2 w \qquad M_y' = Q_z + m_y + \overline{\mu_y}\omega^2\varphi_y \tag{9}$$

$$\varphi_y' = -\frac{M_y}{EI_y} \Rightarrow M_y = -EI_y\varphi_y'^{\,e} \quad w' = \varphi_y + \frac{Q_z}{G\overline{A}_z} \Rightarrow Q_z = G\overline{A}_z w' - G\overline{A}_z\varphi_y \tag{10}$$

$$Q_z = -\left(\overline{k_z} + N^{II}\right)w' + R_z \tag{11}$$

Here, Q_z is the shear force and $N^{II} \equiv N$ is the resultant axial force of the 2nd order beam theory (it has a system character and has to be known). In our case, $E \equiv E_L^{M_y H}$ is the homogenized elastic modulus for bending about *y* and $G \equiv G_{Lz}^{H}$ is the shear modulus in *z*-direction. Further, $\varphi_y = \varphi_y(x)$ denotes the angle of cross-section rotation about the*y*-axis.

If the variation of the beam parameters is polynomial, the solution of the differential equation (7) based on the transfer functions [20] can be written as,

$$\begin{bmatrix} w(x) \\ w'(x) \\ w''(x) \\ w'''(x) \end{bmatrix} = \begin{bmatrix} b_{0w} & b_{1w} & b_{2w} & b_{3w} \\ b_{0w}' & b_{1w}' & b_{2w}' & b_{3w}' \\ b_{0w}'' & b_{w1}'' & b_{2w}'' & b_{3w}'' \\ b_{0w}''' & b_{1w}''' & b_{2w}''' & b_{3w}''' \end{bmatrix} \cdot \begin{bmatrix} w_i \\ w_i' \\ w_i'' \\ w_i''' \end{bmatrix} + \begin{bmatrix} \sum_{s=0}^{max\,s} \eta_{Lxz,s} b_{s+4w} \\ \sum_{s=0}^{max\,s} \eta_{Lxz,s} b_{s+4w}' \\ \sum_{s=0}^{max\,s} \eta_{Lxz,s} b_{s+4w}'' \\ \sum_{s=0}^{max\,s} \eta_{Lxz,s} b_{s+4w}''' \end{bmatrix}. \tag{12}$$

There, b_{jw}, b_{jw}', b_{jw}'' and b_{jw}''' with ($j \in \langle 0,3 \rangle$),and b_{s+4w}, b_{s+4w}', b_{s+4w}'' and b_{s+4w}''' are the solution functions (so called the transfer functions for bending) of the differential equation (7). The dependence of the $w' = w'(x)$, $w'' = w''(x)$ and $w''' = w'''(x)$ on the $\varphi_y = \varphi_y(x)$, $M_y = M_y(x)$ and $R_z = R_z(x)$ is described in [648], from which the transfer matrix expression is obtained

$$\begin{bmatrix} w(x) \\ \varphi_y(x) \\ M_y(x) \\ R_z(x) \end{bmatrix} = \begin{bmatrix} A_{1,1} & A_{1,2} & A_{1,3} & A_{1,4} \\ A_{2,1} & A_{2,2} & A_{2,3} & A_{2,4} \\ A_{3,1} & A_{3,2} & A_{3,3} & A_{3,4} \\ A_{4,1} & A_{4,2} & A_{4,3} & A_{4,4} \end{bmatrix} \cdot \begin{bmatrix} w_i \\ \varphi_{y,i} \\ M_{y,i} \\ R_{z,i} \end{bmatrix} + \begin{bmatrix} A_{1,5} \\ A_{2,5} \\ A_{3,5} \\ A_{4,5} \end{bmatrix}. \tag{13}$$

The kinematical and kinetic variables at node *I* are denoted by index *i* in (12). The terms *A* in (12) are established semi analytically using MATHEMATICA [21].

By setting $x = L$ in (13) the dependence of the nodal variables at node *j* on the nodal variables at node *i* are obtained. Then, using appropriate mathematical operations and by considering the altered orientation of the local internal variables in FEM formulation (see Fig. 1), the local finite element equations for the deflection (in particular case for the flexural free vibration) about the *y*-axis read (with $\bar{R}_{z,i} = -R_{z,i}$, $\bar{M}_{y,i} = -M_{y,i}$, $\bar{\varphi}_{y,i} = -\varphi_{y,i}$ and $\bar{\varphi}_{y,j} = -\varphi_{y,j}$),

$$\begin{bmatrix} \bar{R}_{z,i} \\ \bar{M}_{y,i} \\ R_{z,j} \\ M_{y,j} \end{bmatrix} = \begin{bmatrix} B_{3,3} & B_{3,6} & B_{3,9} & B_{3,12} \\ B_{5,2} & B_{5,5} & B_{5,8} & B_{5,11} \\ B_{9,3} & B_{9,6} & B_{9,9} & B_{9,12} \\ B_{11,2} & B_{11,5} & B_{11,8} & B_{11,11} \end{bmatrix} . \begin{bmatrix} w_i \\ \bar{\varphi}_{y,i} \\ w_j \\ \bar{\varphi}_{y,j} \end{bmatrix} + \begin{bmatrix} F_3 \\ F_5 \\ F_9 \\ F_{11} \end{bmatrix} . \tag{14}$$

Indices in matrix B and $F$are deliberately numbered to indicate the position of members of the components in the local matrix of 3D beam finite element, which is shown later. The terms of matrix B and F have to be evaluated numerically. It can be easy shown that the matrix *B* is symmetric.

The differential equation of 4th order with non-constant coefficients for the homogenized FGM beam flexural deformation (including the particular case of lateral flexural harmonic vibrations) in the *x*-*y* plane (Figure 1), can be derived similarly to the previous case:

$$\eta_{4v} v'''' + \eta_{3v} v''' + \eta_{2v} v'' + \eta_{1v} v' + \eta_{0v} v = \eta_{Lxy}(x), \tag{15}$$

with polynomial loads acting in the *x*-*y* plane

$$\eta_{Lxy}(x) = \sum_{s=0}^{\max s} \eta_{Lxy,s} x^s = \sum_{k=0}^{p_{qz}} q_{y,k} x^k + \sum_{k=1}^{p_{qz}} k q_{y,k} x^{k-1} + \sum_{k=2}^{p_{qz}} k(k-1) q_{y,k} x^{k-2} + \sum_{k=0}^{p_m} m_{z,k} x^k + \sum_{k=1}^{p_m} k m_{z,k} x^{k-1}, \tag{16}$$

where: $\eta_{Lxy,s}$ are the values of the *k*-th derivative of load polynomial (16) at the beam node *i* (*s* is the maximum degree of the polynomial); $q_{y,k}$ are the values of the *k*-th derivative of the polynomial transversal force $q_y = q_y(x)$ and $m_{z,k}$ are the values of the *k*-th derivative of the polynomial moment $m_z = m_z(x)$ at the beam node *i* (p_{qy} and p_{mz} is the maximum degree of the polynomials).). For the modal analysis of flexural vibration the right hand side of (15) vanishes.

Again, $v = v(x)$ is the deflection curve in $x - y$ plane. Its derivatives with respect to *x* are denoted by an apostrophe.

By appropriated mathematical operations (similarly to the previous case) the local finite element equations for the flexural lateral deflection (in *x*-*y* plane) are obtained,

$$\begin{bmatrix} \bar{R}_{y,i} \\ \bar{M}_{z,i} \\ R_{y,j} \\ M_{z,j} \end{bmatrix} = \begin{bmatrix} B_{2,2} & B_{2,6} & B_{2,8} & B_{2,12} \\ B_{6,2} & B_{6,6} & B_{6,8} & B_{6,12} \\ B_{8,2} & B_{8,6} & B_{8,8} & B_{8,12} \\ B_{12,2} & B_{12,6} & B_{12,8} & B_{12,12} \end{bmatrix} . \begin{bmatrix} v_i \\ \bar{\varphi}_{z,i} \\ v_j \\ \bar{\varphi}_{z,j} \end{bmatrix} + \begin{bmatrix} F_2 \\ F_6 \\ F_8 \\ F_{12} \end{bmatrix} . \tag{17}$$

It can be easy shown that the matrix *B* is symmetric.

2.3 Uniform torsional deformation

The differential equations of uniform torsion of a beam are formulated according the Figure 1 and have a form,

$$M_x' = m_x - \rho_L^H I_p \omega^2 \varphi_x, \tag{18}$$

$$\varphi_x' = \frac{M_x}{GI_T}. \tag{19}$$

Here, $\varphi_x = \varphi_x(x)$ is the angle of twist about x - axis and $\varphi_x' = \varphi_x'(x)$ is its first derivative.

By a combination of equations (18) and (19) and after some mathematical manipulations the differential equation for uniform torsion (including the particular case of torsional harmonic vibrations) has been obtained

$$\eta_{2T}\varphi_x'' + \eta_{1T}\varphi_x' + \eta_{0T}\varphi_x = m_x, \tag{20}$$

with non-constant parameters $\eta_{1T} = GI_T$, $\eta_{2T} = G'I_T$, $\eta_{0T} = \rho_L^H I_p \omega^2$ and $G \equiv G_L^{M_x H}$. Further, $\varphi_x'' = \varphi_x''(x)$ is the second derivative of the angle of twist. The polynomial distributed axial force is: $m_x = \sum_{k=0}^{p_n} m_{x,k} x^k = m_{x,0}x^0 + m_{x,1}x^1 + m_{x,2}x^2 + ... + m_{x,p_n} x^{p_{mx}}$, where $m_{x,k}$ are the values of the k-th derivative of the distributed torsional moment m_x at the beam node i. For the modal analysis of axial vibration the right hand side of (3) vanishes. According to [19], the solution of the differential equation (20) reads:

$$\begin{bmatrix} \varphi_x(x) \\ \varphi_x'(x) \end{bmatrix} = \begin{bmatrix} \bar{b}_{0T} & \bar{b}_{1T} \\ \bar{b}_{0T}' & \bar{b}_{1T}' \end{bmatrix} \cdot \begin{bmatrix} \phi_{x,i} \\ \phi_{x,i}' \end{bmatrix} + \begin{bmatrix} \sum_{k=0}^{p_{mx}} m_{x,k} \bar{b}_{k+2T} \\ \sum_{k=0}^{p_{mx}} m_{x,k} \bar{b}_{k+2T}' \end{bmatrix}. \tag{21}$$

In equation (21), the $\bar{b}_{kT}$ and $\bar{b}_{kT}'$, $(k \in \langle 0, p_{mx} + 2 \rangle)$, are the transfer functions for torsion and their first derivatives, respectively and represent the solution functions of the differential equation (20). The transfer functions depend on the longitudinal variation of the torsional shear modulus, the natural frequency, the polar moment of inertia, the torsion constant and the consistent mass density. They are calculated in a similar way as is shown in the previous loading cases. By inserting (18) and (19) into (21) and after some mathematical manipulations the transfer matrix relations (22) for the particular case of uniform torsion harmonic free vibration are obtained,

$$\begin{bmatrix} \varphi_x(x) \\ M_x(x) \end{bmatrix} = \begin{bmatrix} \bar{b}_{0T} & \dfrac{\bar{b}_{1T}}{G_i I_T} \\ GI_T \bar{b}_{0T}' & \dfrac{GI_T}{G_i I_T} \bar{b}_{1T}' \end{bmatrix} \cdot \begin{bmatrix} \phi_{x,i} \\ M_{x,i} \end{bmatrix} + \begin{bmatrix} A_{1,3} = \sum_{k=0}^{p_{mx}} m_{x,k} \bar{b}_{k+2T} \\ A_{2,3} = GI \sum_{k=0}^{p_{mx}} m_{x,k} \bar{b}_{k+2T}' \end{bmatrix}. \tag{22}$$

By setting $x = L$ in (22) a dependence of the state variables at point j on the state variables at initial point i for modal analysis reads

$$\begin{bmatrix} \varphi_{x,j} \\ M_{x,j} \end{bmatrix} = \begin{bmatrix} \left[\bar{b}_{0T}\right]_{x=L} & \dfrac{\left[\bar{b}_{1T}\right]_{x=L}}{G_i I_T} \\ G_j I_T \left[\bar{b}'_{0T}\right]_{x=L} & \dfrac{G_j I_T}{G_i I_T}\left[\bar{b}'_{1T}\right]_{x=L} \end{bmatrix} \cdot \begin{bmatrix} \varphi_{x,i} \\ M_{x,i} \end{bmatrix} + \begin{bmatrix} \sum_{k=0}^{p_{mx}} m_{x,k}\, \bar{b}_{k+2T}\big|_{x=L} \\ GI \sum_{k=0}^{p_{mx}} m_{x,k}\, \bar{b}'_{k+2T}\big|_{x=L} \end{bmatrix}. \tag{23}$$

By simple mathematical manipulations we get the local finite element equation for uniform torsion (with $\bar{M}_{x,i} = -M_{x,i}$):

$$\begin{bmatrix} \bar{M}_{x,i} \\ M_{x,j} \end{bmatrix} = \begin{bmatrix} B_{4,4} & B_{4,10} \\ B_{10,4} & B_{10,10} \end{bmatrix} \cdot \begin{bmatrix} \varphi_{x,i} \\ \varphi_{x,j} \end{bmatrix} + \begin{bmatrix} F_4 = \dfrac{A_{1,3}}{A_{1,2}} \\ F_{10} = A_{2,3} - \dfrac{A_{1,3}A_{2,2}}{A_{1,2}} \end{bmatrix}. \tag{24}$$

The transfer constants $\left[\bar{b}_{kT}\right]_{x=L}$ and $\left[\bar{b}'_{kT}\right]_{x=L}$, $\left(k \in \langle 0, p_{mx}+2\rangle\right)$, can be calculated with a simple numerical algorithm [20] which we programmed using software[21]. The variables G_i and G_j correspond to the values of the homogenized torsional shear modulus at point *i*and*j*. It can be easy shown that the matrix *B* is symmetric. The case of non-uniform torsion will be considered in our future work.

2.4 Local FGM beam finite element equation

The local equation of the FGM finite beam element is obtained by superposition of the equations for axial, flexural, lateral and torsional deformation, and it reads,

$$\begin{bmatrix} \bar{N}_i \\ \bar{R}_{y,i} \\ \bar{R}_{z,i} \\ \bar{M}_{x,i} \\ \bar{M}_{y,i} \\ \bar{M}_{z,i} \\ N_j \\ R_{y,j} \\ R_{z,j} \\ M_{x,j} \\ M_{y,j} \\ M_{z,j} \end{bmatrix} = \begin{bmatrix} B_{1,1} & 0 & 0 & 0 & 0 & 0 & B_{1,7} & 0 & 0 & 0 & 0 & 0 \\ & B_{2,2} & 0 & 0 & 0 & B_{2,6} & 0 & B_{2,8} & 0 & 0 & 0 & B_{2,12} \\ & & B_{3,3} & 0 & B_{3,5} & 0 & 0 & 0 & B_{3,9} & 0 & B_{3,11} & 0 \\ & & & B_{4,4} & 0 & 0 & 0 & 0 & 0 & B_{4,10} & 0 & 0 \\ & S & & & B_{5,5} & 0 & 0 & 0 & B_{5,9} & 0 & B_{5,11} & 0 \\ & & Y & & & B_{6,6} & 0 & B_{6,8} & 0 & 0 & 0 & B_{6,12} \\ & & & M & & & B_{7,7} & 0 & 0 & 0 & 0 & 0 \\ & & & & M & & & B_{8,8} & 0 & 0 & 0 & B_{8,12} \\ & & & & & E & & & B_{9,9} & 0 & B_{9,11} & 0 \\ & & & & & & T & & & B_{10,10} & 0 & 0 \\ & & & & & & & R & & & B_{11,11} & 0 \\ & & & & & & & & Y & & & B_{12,12} \end{bmatrix} \cdot \begin{bmatrix} u_i \\ v_i \\ w_i \\ \varphi_{x,i} \\ \bar{\varphi}_{y,i} \\ \bar{\varphi}_{z,i} \\ u_j \\ v_j \\ w_j \\ \varphi_{x,j} \\ \bar{\varphi}_{y,j} \\ \bar{\varphi}_{z,j} \end{bmatrix} + \begin{bmatrix} F_1 \\ F_2 \\ F_3 \\ F_4 \\ F_5 \\ F_6 \\ F_7 \\ F_8 \\ F_9 \\ F_{10} \\ F_{11} \\ F_{12} \end{bmatrix}. \tag{25}$$

The local finite element matrix *B* in (25) consists formally of the linear stiffness matrix K_L and the linearized geometric stiffness matrix K_N (containing the terms with second order axial force N^{II} that has to be known or has to be evaluated by a linear elastic-static calculation) and the consistent mass matrix *M*:

$$[B] = \left[K_L + K_N - \omega^2 M\right]. \tag{26}$$

The terms B and F correspond to the previously derived terms of the local beam element matrices and load vectors in (6), (14), (17) and (24). In the modal analysis of a single straight beam the global finite element matrix coincides with the local matrix. For a general case, the global matrix of the beam and the beam structure are established in the usual finite element method way. In the modal and buckling analysis the eigenvalue problem is solved. In modal analysis, for given or calculated axial forces N^{II} and defined geometrical parameters and homogenized material properties and the global boundary conditions, the circular frequency ω is increased until the determinant of the global beam structure matrix tends to zero. This circular frequency is the natural circular frequency from which the natural frequency (eigenfrequency) can be calculated. In buckling analysis, the circular frequency ω is set to zero, and the second order beam theory axial force N^{II} is increased until the determinant of the global beam structure matrix tends to zero. Then, the axial force represents the buckling force N_{Ki}^{II}.Further, the mode or buckling shapes can be calculated by the transfer relations (5), (13), and (22). In static analysis, the circular frequency ω is set to zero and the load vector hast be established. The global and local displacements and rotations at the nodes are calculated from those the local internal forces and moments in the homogenized beam elements cross-sections are evaluated. After that the normal and shear stress is calculated in the beam cross sections with real distribution of material properties. The solution approach we have implemented into the software MATHEMATICA [21] by which the numerical calculations presented in the chapter 4 were done.

3 HOMOGENIZATION OF IN THREE DIRECTIONS VARYING MATERIAL PROPERTIES

One important goal of mechanics of heterogeneous materials is to derive their effective properties from the knowledge of the constitutive laws and complex micro-structural behavior of their components. Microscopic modeling expresses the relation between the characteristics of the components and the average (effective) properties of composites. In the case of FGM it is the relation between the characteristics of the components and the effective properties of FGM.

The methods based on homogenization theories (e.g. the mixture rules [22,23]; self-consistent methods [24]) have been designed and successfully applied to determine the effective material properties of heterogeneous materials from the corresponding material behavior of the constituents (and of the interfaces between them) and from the geometrical arrangement of the phases. In this context, the microstructure of the material under consideration is basically taken into account by a representative volume element (RVE).

Mixture rules are one of the methods for micromechanical modeling of heterogeneous materials. Extended mixture rules [25] are based on the assumption that the constituents volume fractions, formally denoted as fibers – f and matrix – m (the notation is very often used in the literature also for the FGM constituents, although this material is point wise isotropic and the reinforcing constituents are not of several forms and dimensions) vary continuously as polynomial functions, $v_f(x,y,z)$ and $v_m(x,y,z)$. The condition $v_f(x,y,z)+v_m(x,y,z)=1$ has to be fulfilled. The appropriated material property distribution in the real FGM beam (Figure 2a) then reads

$$p(x,y,z)=v_f(x,y,z)\,p_f(x,y,z)+v_m(x,y,z)\,p_m(x,y,z). \tag{27}$$

Here, $p_f(x,y,z)$ and $p_m(x,y,z)$ are the spatial distribution of material properties of the FGM constituents. The extended mixture rule (27) can be analogically used for FGM made of more than two constituents. The assumption of a polynomial variation of the constituent's volume fractions and material properties enables an easier establishing of the main field equations and allows the modeling of many common realizable variations.

In the research studies and in practical applications, the one directional variation of the FGM properties is mostly considered. For the FGM beams and shells the transversal variation (continuously or discontinuously, symmetrically or asymmetrically) has been mainly considered. There, an exponential law for variation of the constituents volume fractions through the beam's height is often presented, e.g. in [26-28] and in references therein. The homogenization of such variations is relatively simple. If the material properties vary only with respect to the longitudinal direction, the homogenization is frequently not needed since there are the FGM beam and link finite elements established that consider such variations in a very accurate and effective way [29-31]. The more complicated case is, when the material properties vary in three directions - namely in transversal, lateral and longitudinal directions of the FGM beam.

In this contribution, the homogenization techniques of spatially varying (continuously or discontinuously and symmetrically in transversal and lateral direction, and continuously in longitudinal direction) material properties of FGM beams of selected doubly-symmetric cross-sections are presented. The expressions are proposed for the evaluation of effective elastic modules for axial loading and for transversal and lateral bending complemented with the shear modules for transversal and lateral shear and uniform torsion and for themass density by the extended mixture rules (EMR) and the multilayer method (MLM).

Let us consider a two node straight beam element with predominantly rectangular cross-sectional area *A* (Figure 2). The composite material of this beam arises from mixing two constituents. The continuous polynomial spatial variation of the elastic modules and mass density can be caused by continuous polynomial spatial variation of both the volume fractions ($v_f(x,y,z)$ and $v_m(x,y,z)$) and the material properties ($p_f(x,y,z)$ and $p_m(x,y,z)$) of the FGM constituents.

In our case the elastic modulus $E(x,y,z)$, the Poisson ratio $\nu(x,y,z)$, and mass density $\rho(x,y,z)$ are calculated by expression (27). The FGM shear modulus is calculated by expression:

$$G(x,y,z)=\frac{E(x,y,z)}{2(1+\nu(x,y,z))} \tag{28}$$

If the Poisson's ratio of the constituents is approximately of the same value and the constituents volume fraction variation is not strong, then the FGM shear modulus can by calculated using a simplification

$$G(x,y,z)=\frac{E(x,y,z)}{\xi}, \tag{29}$$

where ξ is an average value of the function $\xi(x,y,z)=2(1+\nu(x,y,z))$

$$\xi=\frac{1}{L}\int_0^L\left(\frac{1}{A}\int_{(A)}\xi(x,y,z)dA\right)dx. \tag{30}$$

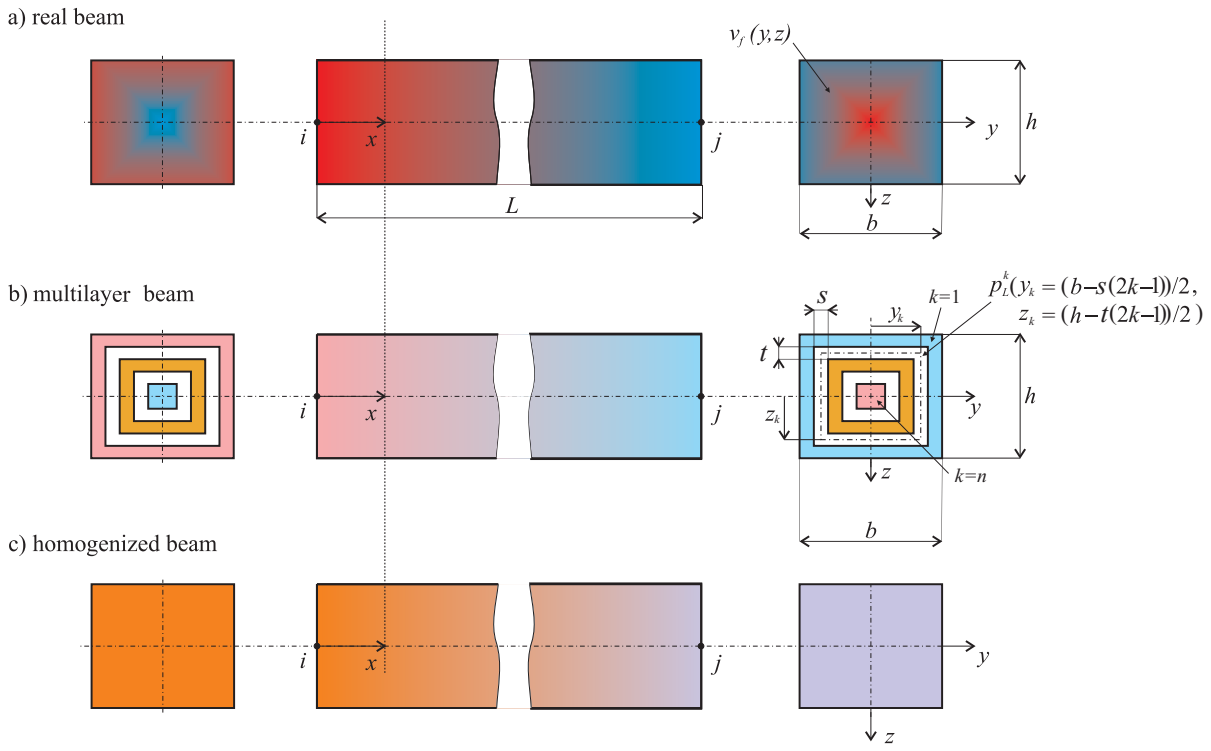

Figure 2: FGM beam with rectangular cross-section.

Homogenization of the spatially varying material properties (the reference volume is the volume of the whole beam) is done in two steps. In the first step, the real beam (Figure 2a) is transformed into a multilayer beam (Figure 2b). Homogenized material properties of the layers are calculated with the EMR [30]. Competent homogenized layer *k* at position *x* has a constant volume fractions and the material properties of the constituents in the *y* and *z* direction. They are calculated as an average value from their values at the boundaries of the respective layer. Polynomial variation of these parameters appears with respect to the longitudinal direction of the layer. Sufficient accuracy of the proposed substitution of the continuous transversal and lateral variation of material properties by the layer-wise constant distribution of material properties is reached if the division to layers is fine enough. In the second step, the effective longitudinal material properties of the homogenized beam are derived using the MLM. These homogenized material properties are constant through the beam's height and depth but they vary continuously along the longitudinal beam axis. Accordingly, the beam finite element equations are established for the homogenized beam (Figure 2c) in order to calculate the primary effective beam unknowns (the displacements, temperatures, electric potential, eigenfrequency, buckling force, etc…). The secondary variables, for example the mechanical stress, have to be calculated from the internal local forces and moments on the real beam [29].

The homogenized elastic modules for tension-compression - $E_L^{NH}(x)$, bending about axis *y* - $E_L^{M_yH}(x)$, bending about axis *z* - $E_L^{M_zH}(x)$, shear in *y* direction - $G_{Ly}^{H}(x)$, shear in *z* direction - $G_{Lz}^{H}(x)$, torsion $G_L^{M_xH}(x)$, and the homogenized mass density for axial loading $\rho_L^{NH}(x)$ and torsion $\rho_L^{M_xH}(x)$ can be calculated using the following expressions:

$$E_L^{NH}(x)=\frac{\sum_{k=1}^{n}E_k(x)A_k}{A},\quad E_L^{M_yH}(x)=\frac{\sum_{k=1}^{n}E_k(x)I_{y,k}}{I_y},\quad E_L^{M_zH}(x)=\frac{\sum_{k=1}^{n}E_k(x)I_{z,k}}{I_z},\tag{31}$$

$$G_{Ly}^{H}(x)=\frac{\sum_{k=1}^{n}k_{y,k}^{sm}G_k(x)A_k}{k_y^{sm}A},\quad G_{Lz}^{H}(x)=\frac{\sum_{k=1}^{n}k_{z,k}^{sm}G_k(x)A_k}{k_z^{sm}A},\tag{32}$$

$$G_L^{M_xH}(x)=\frac{\sum_{k=1}^{n}G_k(x)I_{T,k}}{I_T},\quad \rho_L^{NH}(x)=\frac{\sum_{k=1}^{n}\rho_k(x)A_k}{A},\ \rho_L^{M_xH}(x)=\frac{\sum_{k=1}^{n}\rho_k(x)I_{p,k}}{I_p}.\tag{33}$$

Here, A_k denotes the cross-sections area, $E_k(x)$is the elastic modulus, $I_{y,k}$ and $I_{z,k}$ are the second moments of area, $G_k(x)$ is the shear modulus, $I_{T,k}$ is the torsion constant and $\rho_k(x)$ is the mass density, $I_{p,k}$ is the polar moment of area of the kth layer. The exact expressions for homogenization of spatial varying (continuously or discontinuously and symmetrically in transversal and lateral direction, and continuously in longitudinal direction) material properties for the FGM beams depend on the form of the cross-section. For rectangular hollow cross-sections we present the corresponding expressions in the following chapters.

3.1 Hollow cross-section

A straight beam of hollow cross-sectional area $A=b_1h_1-b_nh_n$(Figure 3) is made of a FGM whose properties vary in the y and z direction continuously and symmetrically according the main inertial planes, $x-y$ and $x-z$, and continuously in longitudinal beam direction x. Further, $I_y=\frac{b_1h_1^3}{12}-\frac{b_nh_n^3}{12}$ and $I_z=\frac{h_1b_1^3}{12}-\frac{h_nb_n^3}{12}$ are the second moments of area, $I_p=I_y+I_z$ is the polar moment of area, $\overline{A}_y=k_y^{sm}A$ and $\overline{A}_z=k_z^{sm}A$ refer to the reduced cross-sectional areas – by the average shear correction factors k_y^{sm} and k_z^{sm} [17,32,75], and $I_T=\frac{2(h_1-t)^2(b_1-s)^2}{\frac{h_1-t}{s}+\frac{b_1-s}{t}}$ is the torsion constant. Here, s and t refer to the thicknesses of the cross-section walls.

For the homogenization of spatially varying material properties the hollow cross-sectional area is divided into n hollow parts, where $t_k=(h_1-h_n)/2n$ is the flange thickness and $s_k=(b_1-b_n)/2n$ is the web thickness (Figure 3), respectively. The hollow area of the kth part $(k\in\langle 1,\ n\rangle)$ is: $A_k=2t_k(b_1-s_k(2k-1))+2s_k(h_1-t_k(2k-1))$. The second moments of area of the kth part are: $I_{y,k}=(b_1-s_k(2k-2))(h_1-t_k(2k-2))^3/12-(b_1-2ks_k)(h-2kt_k)^3/12$, $I_{z,k}=(b_1-s_k(2k-2))^3(h_1-t_k(2k-2))/12-(b_1-2ks_k)^3(h_1-2kt_k)/12$ .The polar moment of area of kth part is $I_{p,k}=I_{y,k}+I_{z,k}$.

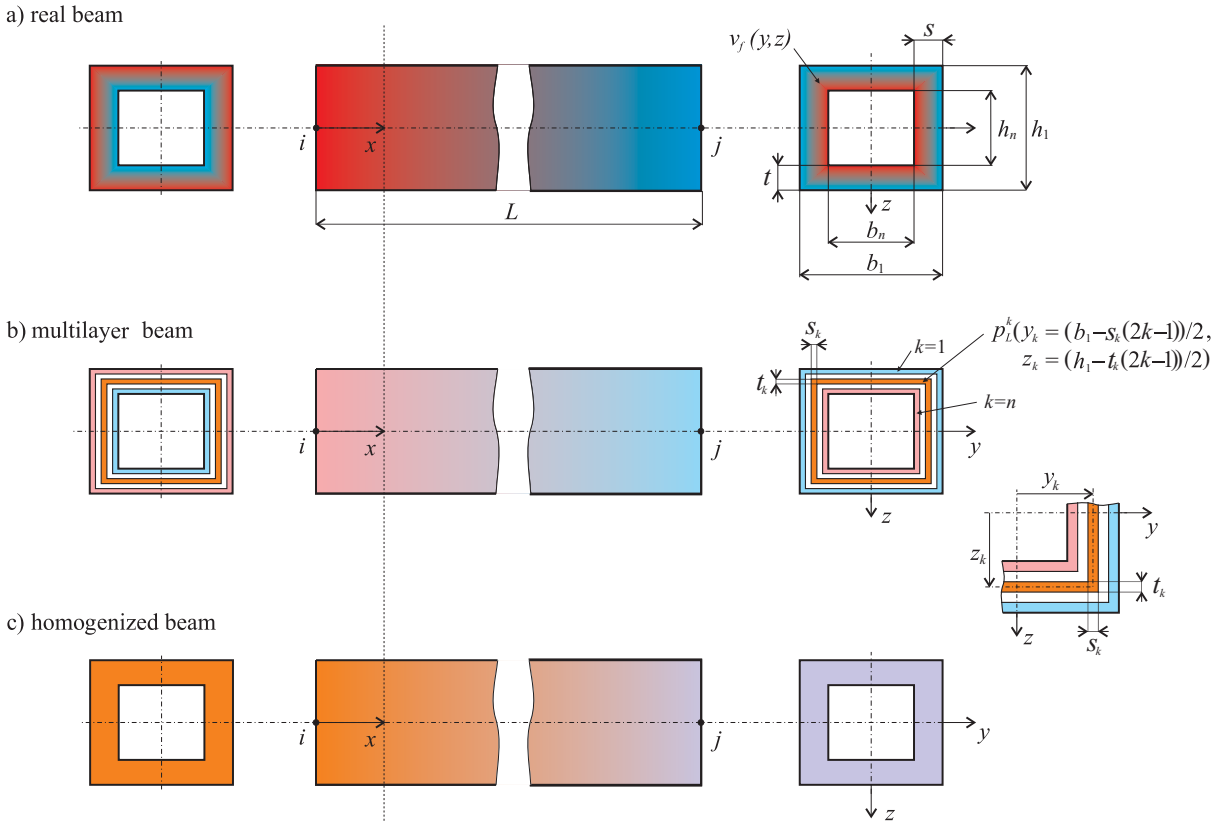

Figure 3: A straight FGM beam of hollow cross-section.

According to (27) and (28) the real material properties are: $E(x,y,z)$ is the elastic modulus, $\nu(x,y,z)$ is the Poisson's ratio, $G(x,y,z)=E(x,y,z)/(2(1+\nu(x,y,z)))$ is the shear modulus and $\rho(x,y,z)$ is the mass density: $(x\in<0,L>, y\in<\pm h_n/2, \pm h_1/2>, z\in<\pm b_n/2, \pm b_1/2>)$. The effective homogenized material properties, like the elastic modules, are calculated under assumption, that the relevant stiffness of the homogenized beam is equal to the stiffness of the real beam virtually divided on the hollow parts. Thus, we get the effective elastic modulus for axial loading

$$E_L^{NH}(x)=\frac{\sum_{k=1}^{n-1}E_k(x)A_k}{A}, \tag{34}$$

with $E_k(x)=\left[E(x,y,z)\right]_{\substack{y=y_k\\z=z_k}}$ and the effective elastic modules for bending about the y and z axis,

$$E_L^{M_yH}(x)=\frac{\sum_{k=1}^{n}E_k(x)I_{y,k}}{I_y},\quad E_L^{M_zH}(x)=\frac{\sum_{k=1}^{n}E_k(x)I_{z,k}}{I_z}. \tag{35}$$

The effective elastic modulus for uniform torsion reads,

$$G_L^{M_xH}(x)=\frac{\sum_{k=1}^{n}G_k(x)I_{T,k}}{I_T}, \tag{36}$$

with $G_k(x) = \left[G(x,y,z)\right]_{\substack{y=y_k \\ z=z_k}}$. The torsion constant of the kth hollow part $\left(k \in \langle 1,\ n\rangle\right)$ can be evaluated as

$$I_{T,k} = \frac{2\left(b_1 - s_k(2k-1)\right)^2 \left(h_1 - t_k(2k-1)\right)^2}{\dfrac{\left(b_1 - s_k(2k-1)\right)}{t_k} + \dfrac{\left(h_1 - t_k(2k-1)\right)}{s_k}}. \tag{37}$$

The effective shear modulus in y direction is given by,

$$G_{Ly}^H(x) = \frac{\sum_{i=1}^{n} k_{y,k}^{sm} G_k(x) A_k}{k_y^{sm} A}, \tag{38}$$

with the average shear correction factors: k_y^{sm} for whole rectangular cross-section and $k_{y,k}^{sm}$ for kth part.
The shear modulus in z direction then reads,

$$G_{Lz}^H(x) = \frac{\sum_{k=1}^{n} k_{z,k}^{sm} G_k(x) A_k}{k_z^{sm} A}, \tag{39}$$

with the average shear correction factors: k_z^{sm} for whole rectangular cross-section and $k_{z,k}^{sm}$ for kth part.
The effective mass density for tension - $\rho_L^{NH}(x)$ and torsion $\rho_L^{M_xH}(x)$ is

$$\rho_L^H(x) = \frac{\sum_{k=1}^{n} \rho_k(x) A_k}{A}, \qquad \rho_L^{M_xH}(x) = \frac{\sum_{k=1}^{n} \rho_k(x) I_{p,k}}{I_p}, \tag{40}$$

with $\rho_k(x) = \left[\rho(x,y,z)\right]_{\substack{y=y_k \\ z=z_k}}$.It should be noted, that the effective mass density for tension has been taken also for the lateral and transversal bending.

4 NUMERICAL INVESTIGATIONS

4.1 Example 1: FGM beam structure - hollow cross-section

The FGM beam structure with a constant rectangular hollow cross-section is considered (Figure 4), which consists of two parts – Beam1 and Beam2. Its geometry is given byh_1 = 0.005 m, h_n = 0.00375 m, b_1 = 0.01 m, b_n = 0.0075 m and L = 0.1 m. The angle between the beams is $\theta = 150°$. The cross-sectional area is $A = 2.1875\times10^{-5}$ m^2, the second moments of area are $I_{y'} = 7.12077\times10^{-11}$ m^4 and $I_{z'} = 2.84831\times10^{-10}$ m^4, the polar moment of area is $I_p = I_{y'} + I_{z'} = 3.56038\times10^{-10}$ m^4 and the torsion constant is $I_T = 1.6748\times10^{-10}$ m^4.

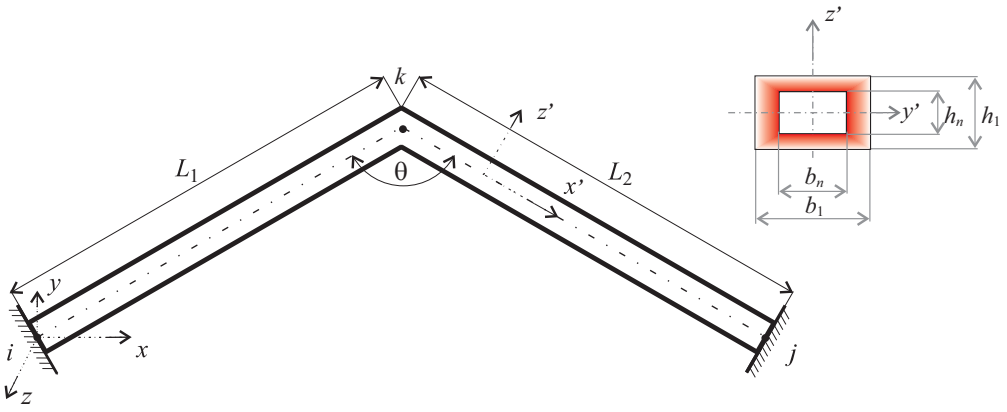

Figure 4: FGM beam structure in global (*x*, *y*, *z*) coordinate system.

The material of the beam consists of two components: Aluminum Al6061-TO – denoted with index *m* and Titanium carbide TiC – denoted with index *f*. The material properties of the components are assumed to be constant and their values are: Aluminum Al6061-TO – the elasticity modulus $E_m = 69.0\,\text{GPa}$, the mass density $\rho_m = 2700$ kgm^{-3}, the Poisson's ratio $\nu_m = 0.33$; Titanium carbide TiC – the elasticity modulus $E_f = 480.0\,\text{GPa}$, the mass density $\rho_f = 4920$ kgm^{-3}, the Poisson's ratio $\nu_f = 0.20$.

The TiC volume fraction varies in the local y' and z' direction linearly and symmetrically according to the $x'-y'$ and $x'-z'$ planes: $\left[v_f\left(y',z'\right)\right]_{\substack{y'=\pm h_n/2\\ z'=\pm b_n/2}} = 0$, $\left[v_f\left(y',z'\right)\right]_{\substack{y'=\pm h_1/2\\ z'=\pm b_1/2}} = 1$ - the inner edges of the cross-sectional area are made of pure Al6061-TO –and the outer cross-section edges are made of pure TiC. Constant effective material properties are considered in the local x' – direction of both beams. Using EMR and MLM the effective elastic modulus (in [GPa]) for axial loading E_L^{NH}, for bending about axis y' - $E_L^{M_yH}$ and about axis z' - $E_L^{M_zH}$ the shear moduli G_{Ly}^{H} and G_{Lz}^{H}, the torsional shear modulus $G_L^{M_xH}$, and the mass density ρ_L^{NH} [kgm^{-3}] for tension and $\rho_L^{M_xH}$ [kgm^{-3}] for torsion have been calculated by equations (34 - 40). The influence of the number of divisions *n* to the layers on the homogenized material properties [32, 33] is shown in Table 1. The average shear correction factors k_y^{sm} and k_z^{sm} for $n = 20$ layers are $k_y^{sm} = 0.4712$ and $k_z^{sm} = 0.2910$ [32, 33]. For homogeneous hollow cross-section, following shear correction factors are obtained: $k_y = 0.5081$ and $k_z = 0.3291$ (calculated e.g. with ANSYS [34], for rectangular hollow beam-section).

layers *n*	E_L^{NH}	$E_L^{M_yH} = E_L^{M_zH}$	$G_{Ly}^{H} = G_{Lz}^{H}$	$G_L^{M_xH}$	ρ_L^{NH}	$\rho_L^{M_xH}$
2	281.839	296.151	112.716	120.614	3849.643	3926.946

Modal analysis

The FGM beam structure, clamped at the node *i* and *j*, is studied by modal analysis. The effect of axial force is not considered by this example. The first six eigenfrequencies *f* [Hz] are given in Table 2 using the new FGM beam finite element (NFE) and homogenized material properties for $n = 20$. Only two of our proposed FGM finite element are used – one for each part. For comparison purposes, the same problem is solved using a very fine mesh – 21600 of SOLID186 elements of the FEM program ANSYS [34]. The average relative difference Δ[%] between eigenfrequencies calculated by our method (NFE) and the ANSYS solution is evaluated.

eigenfrequencies *f* [Hz]		NFE without shear	NFE with shear	ANSYS	Δ[%] without shear	Δ[%] with shear
1st	flexural – *xz* plane	2392.0	2361.1	2343.6	2.07	0.75
2nd	flexural – *xy* plane	3859.1	3765.4	3798.8	1.65	0.82
3rd	flexural – *xy* plane	4444.0	4384.0	4341.1	2.37	0.99
4th	flexural – *xz* plane	7391.0	7123.3	7182.5	2.96	0.77
5th	flexural – *xy* plane	9147.1	9027.1	8928.4	2.57	1.23
6th	torsional	10051.1	10013.4	9896.8	1.56	1.18

Table 2: Eigenfrequencies of the FGM beam structure.

A comparison of 1st,2nd and 3rd eigenforms of the FGM beam structure evaluated by the new FGM beam finite element and FEM program ANSYS is shown in Figures 5 - 7.

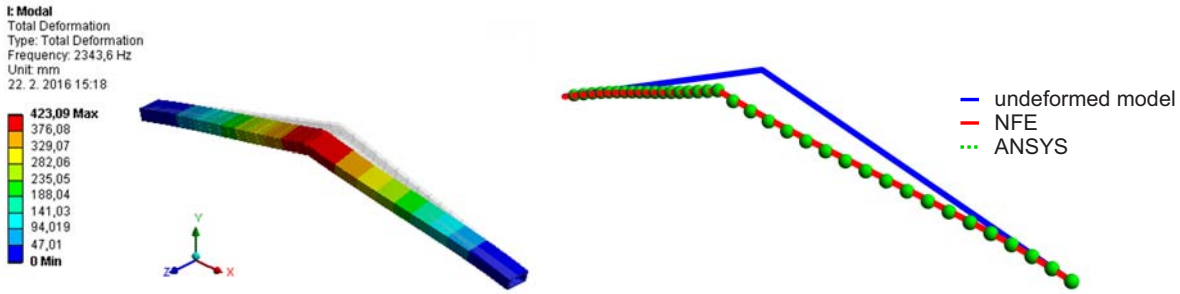

Figure 5: The 1st eigenform of the FGM beam structure displayed by the ANSYS postprocessor and comparison of NFE and ANSYS.

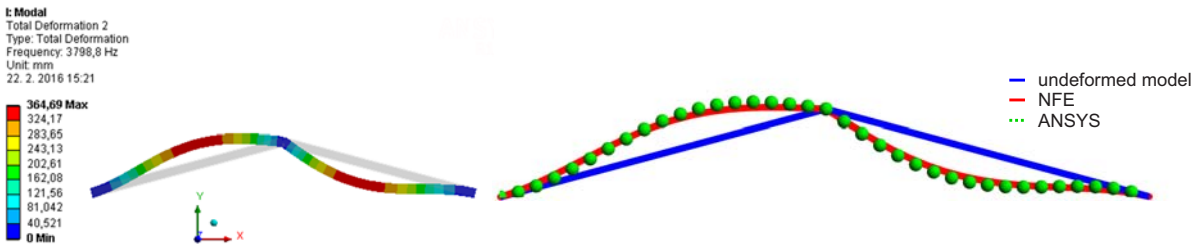

Figure 6: The 2nd eigenform of the FGM beam structure displayed by the ANSYS postprocessor and comparison of NFE and ANSYS.

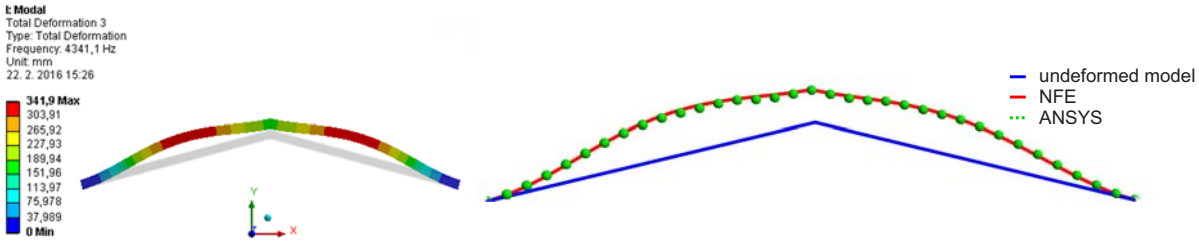

Figure 7: The 3rd eigenforms of the FGM beam structure displayed by the ANSYS postprocessor and comparison of NFE and ANSYS.

Elasto-static analysis

The FGM beam structure, clamped at the node *i* and *j*, loaded by the vertical force $F_{ky} = 100$ N in the global negative *y* direction and the torsion moment $M_{kx} = 100$ Nm about global *x*-axis at point *k*, is studied by elasto-static analysis. The effects of axial forces is not considered by this example. The displacements according the global coordinate system at the point *k* are given in Table 3 using the new FGM beam finite element (NFE) and homogenized material properties for *n* = 20. Only two of the herein proposed new FGM finite elements were used – one for each part. For comparison purposes, the same problem is solved using a very fine mesh – 21600 of SOLID186 elements of the FEM program ANSYS [34]. The average relative difference Δ[%] between displacements calculated by our method and the ANSYS solution is evaluated.

Displacements [mm], [rad]	NFE without shear correction	NFE with shear correction	ANSYS	Δ[%] without shear correction	Δ[%] with shear correction
v_k	-0.01135	-0.01137	-0.01140	0.39	0.27
w_k	-2.56285	-2.56285	-2.58651	0.91	0.91
φ_{xk}	0.19804	0.19804	0.20030	1.13	1.13

Table 3: Global displacements at point *k*.

The total deformation of the FGM beam structure is shown in Figure 8.

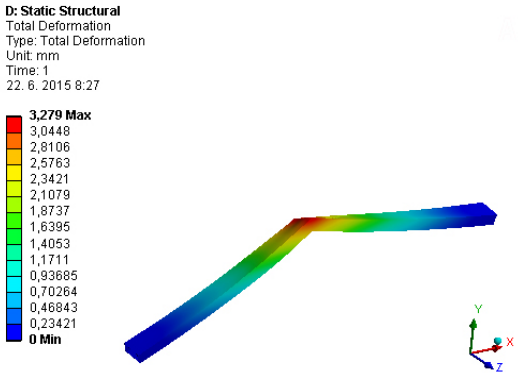

Figure 8: Total deformation of the FGM beam structure.

As can be seen in Table 4, a very good agreement of our results is obtained.

4.2 Example 2: FGM beam – spatial variation of material properties

The cantilever FGM beam on varying horizontal and vertical Winkler foundation is considered (as shown in Figure 9). Its rectangular cross-section is constant with height h = 0.005 m and width b = 0.01 m. The length of the beam is L = 0.1 m.

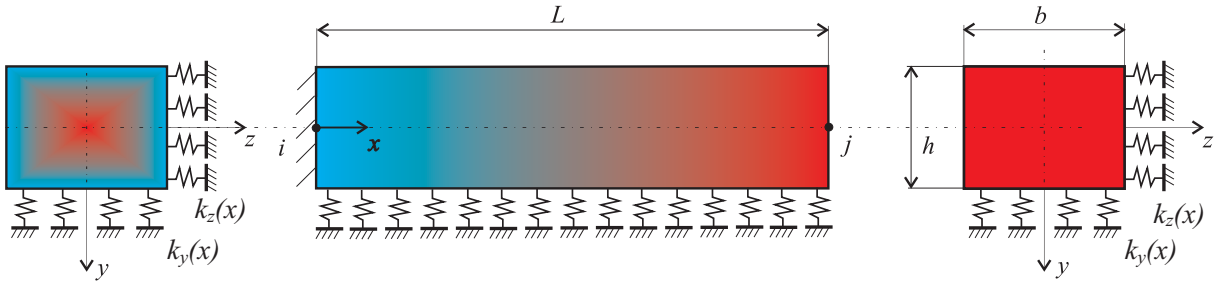

Figure 9: Clamped beam on elastic foundation with spatially varying material properties.

The beam is made of a mixture of two components: Aluminum Al6061-TO and Titanium Carbide TiC, their constant constituent's material properties are given in Case I. The Aluminum volume fraction, in this case, varies linearly and symmetrically according to the $x-y$ and $x-z$ planes: At node i is $\left\lfloor v_{fi}(y,z)\right\rfloor_{\substack{y=0\\z=0}}=1, \left\lfloor v_{fi}(y,z)\right\rfloor_{\substack{y=\pm h/2\\z=\pm b/2}}=0$ and then vary continuous linearly in the longitudinal direction to the constant value at node j ($v_{fj}=1$).

Using EMR and MLM with n = 20 layers the effective elastic modulus for axial loading E_L^{NH}, for bending about axis y - $E_L^{M_yH}$ and about axis z - $E_L^{M_zH}$, shear modules G_{Ly}^{H} and G_{Lz}^{H}, torsional shear modulus $G_L^{M_xH}$, and mass density ρ_L^{NH} for tension and $\rho_L^{M_xH}$ for torsion are evaluated as:

$$E_L^{NH}=342.109-2731.095x\ \text{GPa};$$

$$E_L^{M_yH}=E_L^{M_zH}=396.429-3274.293x\ \text{GPa};$$

$$G_{Ly}^{H}=G_{Lz}^{H}=138.581-1129.418x\ \text{GPa};$$

$$G_L^{M_xH}=162.233-1362.936x\ \text{GPa};$$

$$\rho_L^{NH}=4175.19-14751.9x\ \text{kgm}^{-3};$$

$$\rho_L^{M_xH}=4468.34-17683.43x\ \text{kgm}^{-3}.$$

Modal analysis

The FGM cantilever beam, clamped at the node i, and resting on varying Winkler elastic foundation $k_y(x)$=5000-30000x+60000x^2 kN/m^2 and $k_z(x)$=5000-1000x+6000x^2 kN/m^2 is studied by modal analysis. The average shear correction factors in y' – direction $k_y^{sm}=5/6$ and in z' – direction $k_z^{sm}=5/6$ are used [35]. The first nine eigenfrequencies f [Hz] are evaluated as shown in Table 4. It is use only one of our proposed finite element. The effect of axial force was not considered in this example. The same problem is solved using a very fine mesh – 32000 of SOLID186 elements of the FEM program ANSYS [34]. The results of ANSYS as

well as the results of the NFE are presented in Table 4. The average relative difference $\Delta[\%]$ between eigenfrequencies calculated by our method and the ANSYS solution is evaluated.

eigenfrequencies f [Hz]		NFE without foundation	ANSYS without foundation	$\Delta[\%]$	NFE with foundation	ANSYS with foundation	$\Delta[\%]$
1st	flexural - axis y	838.9	844.9	0.71	1356.1	1365.3	0.67
2nd	flexural - axis z	1660.0	1674.4	0.86	1896.3	1911.3	0.78
3rd	flexural - axis y	4329.5	4301.7	0.65	4433.4	4413.5	0.45
4th	flexural - axis z	8288.5	8228.8	0.73	8332.2	8275.1	0.69
5th	flexural - axis y	11046.0	10920.0	1.15	11125.8	10961.0	1.50
6th	torsional	11182.0	10926.0	2.34	11048.0	10969.0	0.72
7th	flexural - axis z	20023.0	19907.0	0.58	20051.0	19925.0	0.63
8th	flexural - axis y	20379.0	20312.0	0.33	20397.1	20333.0	0.32
9th	axial	22212.6	22213.0	0.01	22212.7	22213.0	0.01

Table 4: Eigenfrequencies of the FGM beam with and without elastic foundation.

Again, a very good agreement of our results compared to ANSYS is indicated in Table 4. For instance, the 1st, 6th and 9th mode of the FGM beam structure displayed by ANSYS is shown in Figure 10.

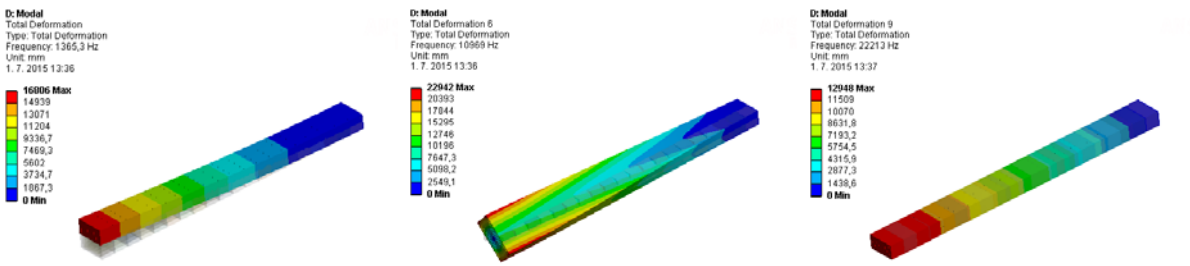

Figure 10: The 1th and 6th and 9th eigenforms of the beam (with Winkler elastic foundations).

Buckling and elastic-static analysis

The FGM cantilever beam, clamped at the node i, has been studied by buckling and elastic-static analysis. All the calculations were done with our 3D FGM beam finite element (NFE) which we have implemented into the code MATHEMATICA [21]. Additionally, the effect of axial force was considered. It has to be pointed out that the entire structure is discretized using only one herein proposed finite element.

The critical buckling force calculated by our 3D FGM beam finite element is $N_{Ki}^{II} = 7.171$ kN and calculated by ANSYS (with 50 of BEAM188 elements) is $N_{Ki}^{II} = 7.081$kN. The first buckling form is shown in Figure 11. In the elasto-static analysis the axial force $N^{II} \equiv N$ have been chosen as a part of the critical buckling force N_{Ki}^{II}.

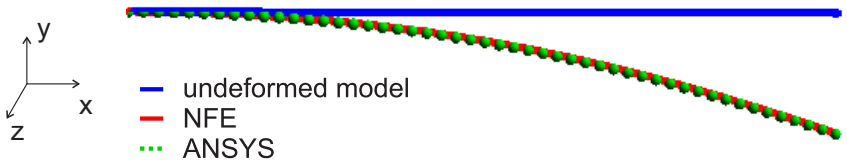

Figure 11: The first buckling form.

In the elastic-static analysis, the cantilever FGM beam resting on varying vertical Winkler elastic foundation $k_y = 5000 - 30000x + 600000x^2$ kN/m^2 is loaded by forces $F_y = F_z = 50$ N and $F_x = -2$ kN at node j (Figure 12). The average shear correction factors in y' – direction $k_y^{sm} = 5/6$ and in z' – direction $k_z^{sm} = 5/6$ are used [35]. The displacements at node j are evaluated using the only one new FGM beam finite element (NFE). The same problem is solved using a very fine mesh – 23015 of SOLID186 elements of the FEM program ANSYS [34]. The results of ANSYS as well as the results of the NFE are presented in Table 5. The average relative difference Δ[%] between displacements calculated by our method and the ANSYS solution is evaluated.

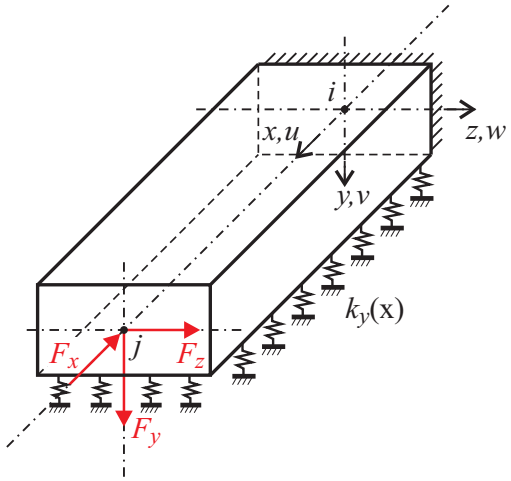

Figure 12: Loaded FGM beam.

Displacements at node j [mm], [rad]	NFE with foundation	ANSYS with foundation	NFE without foundation	ANSYS without foundation
u_j	-0.02445	-0.02507	-0.02445	0.02507
v_j	0.24641	0.24933	0.74414	0.75348
w_j	0.14452	0.14791	0.14452	0.14791

φ_{zj}	0.00503	0.00527	0.1304	0.01321

Table 5: Displacements at node j with and without elastic foundation.

The comparison of the vertical beam deflection curve with and without elastic foundation is shown in Figure 13.

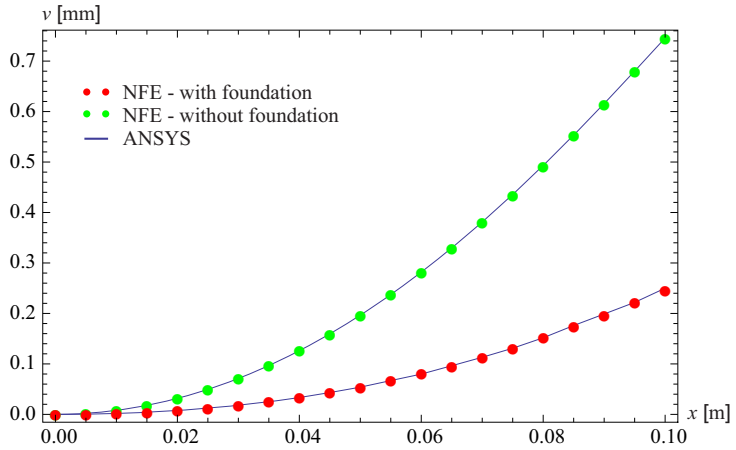

Figure 13: Vertical beam deflection curve with and without elastic foundation.

The bending moments about the *y* and *z* – axis for case without elastic foundation are shown in Figures 14 and 15, respectively. The Figures 16 and 17 show the transversal force in *y* and *z* – axis. The comparison of the bending moments $M_y(x=0)$, $M_z(x=0)$ and transversal forces $R_y(x=L)$, $R_{yz}(x=L)$ for the case F_x = -2 kN calculated by our approach and by ANSYS are compared in Table 6.

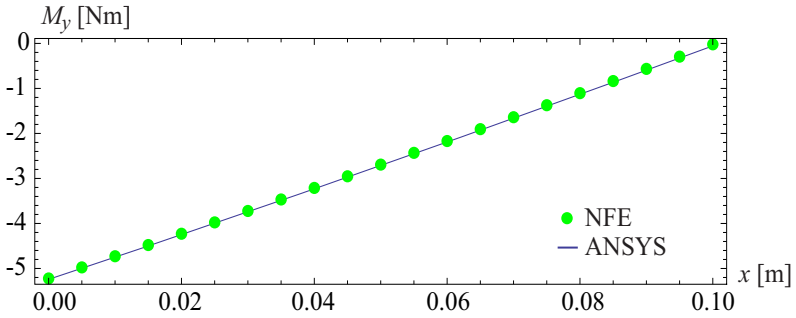

Figure 14: Bending moment about the *y* – axis (without elastic foundation).

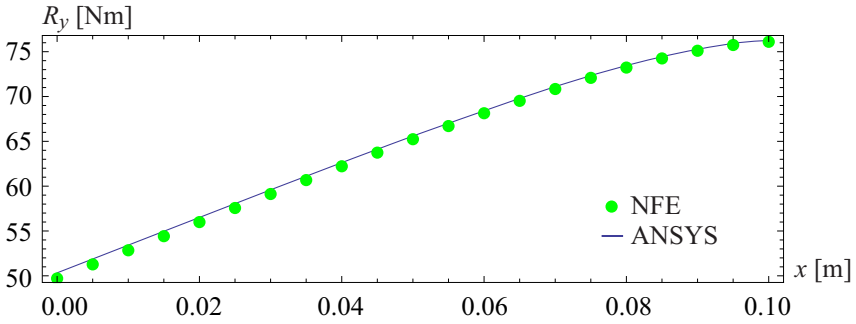

Figure 16: Transversal force in y – axis (without elastic foundation).

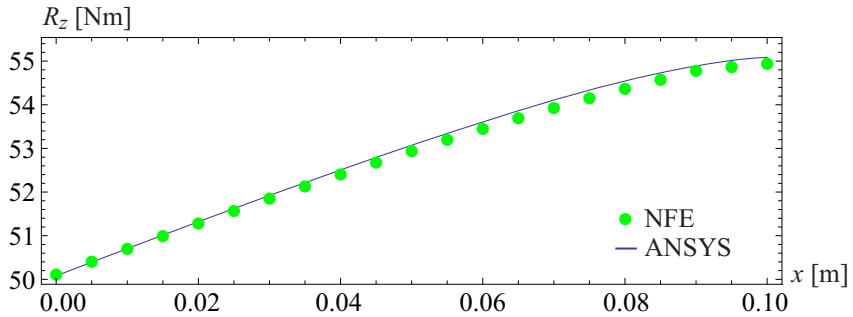

Figure 17: Transversal force in z – axis (without elastic foundation).

	NFE Fx = -2 kN	ANSYS Fx = -2 kN	Δ[%]
$M_y(x=0)$ [Nm]	-5.2182	-5.2416	0.45
$M_z(x=0)$ [Nm]	6.4691	6.4404	0.45
$R_y(x=L)$ [N]	54.9472	55.0873	0.25
$R_z(x=L)$ [N]	76.2088	76.2251	0.02

Table 6: Bending moments and transversal forces.

In Figure 18, the resultant normal stress, caused by axial, transversal and lateral forces, in the clamped cross-section is shown that was calculated by our approach [18] extended here for variation of material properties in three directions.

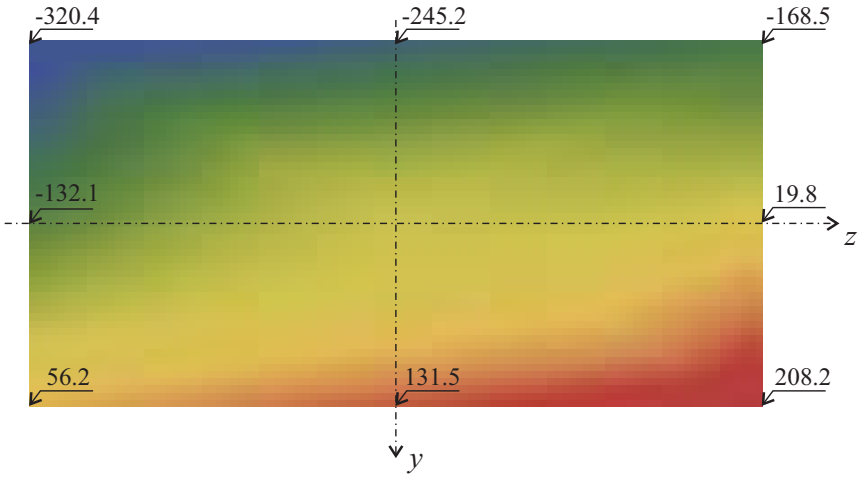

Figure 18: Resultant normal stress $\sigma(x, y, z)$ [MPa] at position $x = 0$ calculated by our approach [18].

In Figure 19, the resultant normal stress, caused by axial, transversal and lateral forces, in the clamped cross-section is shown that was calculated by ANSYS (using a very fine mesh – 23015 of SOLID186). As can be seen, a very good agreement of both solution method has been obtained at all marked points excluding the corners. As is well known, the solutions with 3D solid finite elements produce in the sharp corners incorrect stress first of all by the very fine meshes. In the nearby points of the sharp corners is the match of the results very good (see the details in Figure 19). More detailed description of the stress calculation for the FGM beam with spatial variation of material properties will be given in our newly prepared paper.

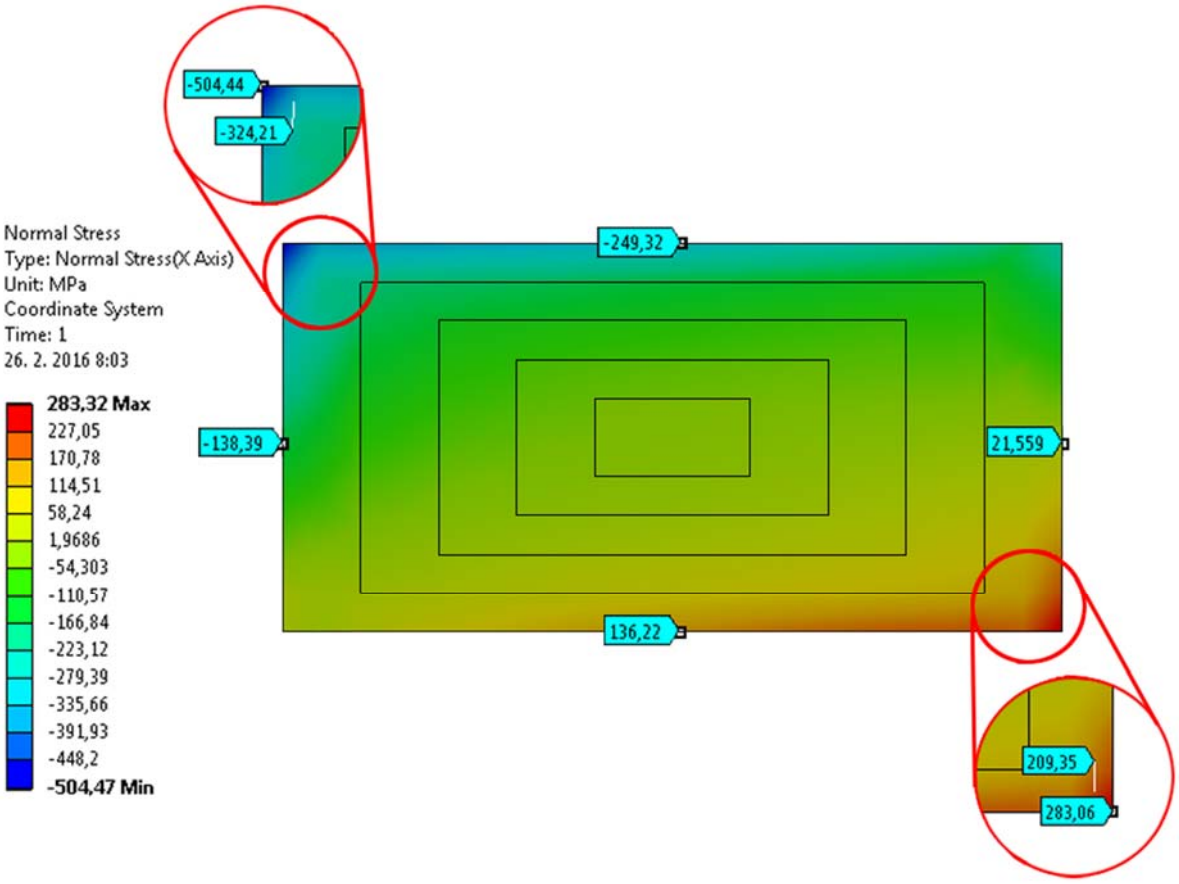

Figure 19: Normal stress $\sigma(x, y, z)$ [MPa] at position $x = 0$ calculated by ANSYS (SOLID186)

5 CONCLUSION

On base of the transfer relations for the 3D straight FGM beam of doubly symmetric cross-section with longitudinal polynomial variation of the effective material properties, the effective matrix of the 3D beam finite element for static, modal and buckling analysis of the FGM single beams and beam structures is established in this contribution. Symmetrically transversal and lateral, and continuously longitudinal variation of material properties is considered in the real beam. Homogenization of the spatially varying material properties in the real FGM beam and the calculation of effective parameters of the homogenized beam are done by the extended mixture rules and the multilayer method (MLM). Effects of the varying planar Winkler elastic foundations and the shear force deformation (by means of the average shear correction factors) and the consistent mass and mass moment of inertia distribution are

taken into account. The effect of axial force is included for the flexural deformations as well that allows performing of analysis within the 2nd order beam theory. All the derived equations were programmed through the software MATHEMATICA [21] and the numerical calculations were carried out. In modal and buckling analysis, the eigenvalue problem is solved. In buckling analysis, the circular frequency ω is set to zero and axial force N is increased the determinant of the global matrix of the beam structure tends to zero. This axial force corresponds to the critical buckling force. In modal analysis, for given internal axial forces N in the competent beams and geometrical parameters and material and boundary conditions, the circular frequency ω is increased until the determinant of the global matrix of the beam structure tends to zero. This circular frequency corresponds to the natural circular frequency from which the natural frequency (eigenfrequency) is calculated. In linearized elastostatic analysis (according the second order beam theory), the internal axial forces have to be evaluated that input in the linearized geometric stiffness matrix. By the linear beam theory only linear stiffness matrix is established. The load vector is established and the local and global displacements and internal forces are calculated. After that, as usually, the secondary variables like eigen- and buckling- forms, and the stress are calculated. The main issue of numerical investigations is the modal, buckling and elastostatic analysis of FGM beam structures (single beams and spatial beam structures) with spatial variation of material properties. By selected numerical examples the effect of axial and shear forces is evaluated. The results carried out by our approach are compared with results obtained using very fine beam and continuum meshes in the FEM program ANSYS [34]. An excellent agreement of our solution results is obtained, which confirms respectable accuracy and effectiveness of our approach.

The main advantage of the new beam finite element is that the individual beams of the beam structure with spatial variation of material properties (continuous or layered but symmetrically in transversal and lateral direction, and continuous polynomial in longitudinal direction) can be modeled with only one beam finite element, because the variation of the material properties is relatively accurately included into the finite element matrix. Another advantage is that the beam finite element can be very effectively used also for the modeling of spatial beam structures.

Disadvantage of this approach is that by more complicated variation of material properties some problems arise by the transfer constants calculation. This problem can be solved by the dividing of the definition domain of the transfer functions [20]. Another problems comparing to continuum approach can arise by the beams with complex cross-sectional area.

Keywords: Thermo-Elasticity, FGM-Shell-Structures, Drilling degrees of freedom, Two-Step-Algorithm.

Abstract. *An efficient low order finite shell element is derived for the thermo-elastic analysis of shell structures made of functionally graded materials or multilayer composites. It is based on a one-way coupling between the thermal and the mechanical analysis. The thermal quantities are evaluated using a new iterative scheme that properly accounts for convection boundary conditions and large gradients of the thermal conductivity. The resulting non-constant temperature field with respect to the thickness direction gives nodal forces and couples, which are applied on a shear weak six parameter shell formulation. Here, drill rotations are included, supplemented with a proper method for calculating effective elastic properties. Numerical results indicate efficiency and accuracy of the proposed approach.*

1 Introduction

This paper focuses on the analysis of thermo-elastic effects in shell structures of functionally graded materials (FGM) or multilayer composites (MLC). The constitutive model is characterized by a variation of material properties, which is continuous in FGMs and discontinuous in MLCs. We focus only on arbitrary variations in transverse direction. Variations with respect to the membrane directions can be modeled easily using a discretization scheme with elements each showing constant transverse variations. FGM and MLC structures play an important role in the development of sensors and actuators (see [1] and references therein) and accurate virtual analysis procedures are required.

Many papers deal with the static and dynamic analysis of FGM beams with transverse variations of material properties. In [2] elasticity solutions for simply supported FGM beams are given using the Euler-Bernoulli beam theory. Chakraborty et al. [3] discuss thermo-elastic beam problems based on the first order shear theory. Mahi et al. [4] consider free vibrations of symmetric FGM beams subjected to an initial thermal stress. In case of combined variations of material properties in transverse and longitudinal directions, many achievements are due to Murin et al. [5, 6, 7]. The amount of literature dealing with FGM shells is also overwhelming. In Shen [8] special attention is put onto the nonlinear response of FGM plates. In [9, 10] electro-mechanical analyses of FGM shells with piezo-electric layers are proposed. Thermo-elastic analysis procedures of FGM plate and shell structures are discussed in [11]. There, a higher order shell formulation is used. However, only little literature is found if drill rotations (i.e. the rotation about the shell's normal) are to be included. This frequently missing sixth nodal degree of freedom gets important if shell structures are combined with beam structures. There, any torsional moment within the beam directly activates drill rotations if the beam axis is perpendicular to the shell's membrane. In that field many achievements are due to Kugler et al. [12, 13], where references to earlier procedures [14] can be found. A generalization of those procedures to FGMs and MLCs are given in [15, 16] where elasticity is described using effective elastic properties derived in [15].

In this paper we discuss a numerical framework to analyze thermo-elastic effects in FGM and MLC shells. Frequently, the variation of Poisson's ratio in FGMs and MLCs does not show large gradients - therefore, we assume Poisson's ratio to be constant. As boundary conditions we consider the following cases:

- Nodal temperatures (Dirichlet-type): The mean temperature at any node is prescribed.
- Convection on top- and bottom-surface (von Neumann-type): Convection is applied independently onto the top- and bottom-surface prescribing the gradient of the non-constant transverse temperature distribution.
- Nodal displacements and rotations (Dirichlet-type): Displacements and rotations are prescribed.
- Mechanical loads (von Neumann-type): Any transverse and in-plane mechanical loads can be applied onto the finite element model.

The present paper is organized as follows: In Sect. 2 the details of the proposed numerical framework is discussed. We start with describing the thermal analyses in Sect. 2.1. The temperature field in FGM and MLC shells is found for an arbitrary variation of thermal conductivity and convection conditions. Non-constant temperature distributions with respect to the thickness

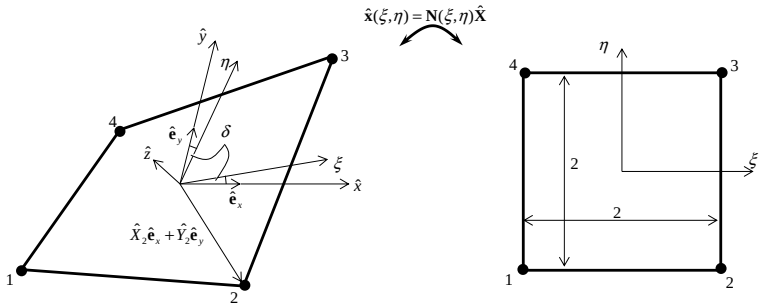

Figure 1: Plane quadrilateral with skew angled element coordinates ξ and η

direction require an iterative solution scheme. The mechanical analysis is discussed in Sect. 2.2. There, a quadrilateral six parameter shell element is described, where drilling rotations are included within the membrane part of the stiffness matrix. The bending part of the stiffness matrix incorporates a shear elastic behavior with an exact thin plate limit. A projection procedure for arbitrarily warped element geometries is included. Arbitrary variations of the Young's modulus require four effective elastic properties, i.e. the offset of a mechanical neutral surface from the discretized mid-surface, effective moduli for membrane and bending properties and a shear correction factor. In Sect. 2.3 an efficient one-way coupling scheme between the thermal and the mechanical field is proposed. Based on the evaluated temperature distributions internal nodal forces and couples are calculated, which are applied onto the mechanical model. The numerical accuracy and the effectiveness of the proposed formulation is discussed in Sect. 3. There, solutions based on the proposed framework are compared to continuum solutions found with ANSYS an to reference solutions found in literature. Finally, in Sect. 4 conclusions are drawn.

2 Numerical procedure

Consider a curved FGM or MLC shell geometry of thickness h, where the geometrical mid-surface is discretized by four noded shell elements. Thus, the element configuration could possibly be warped. Any warped surface geometries do not pose a problem if scalar fields like temperature distributions are analyzed (see Sect. 2.1). However, in mechanical analyses warped shell elements lead to a coupling between membrane and bending properties, which can be circumvented by special projection schemes (see Sect. 2.2). Within each element we assume material properties to be constant in membrane directions $\hat{x}$ - $\hat{y}$ and variable in transverse direction $\hat{z}$.

Since both the thermal analysis and the mechanical analysis is based on a four noded finite element, we introduce a two dimensional element kinematics. The nodal coordinates of the i-th node ($i = 1, 2, 3, 4$) read $\hat{\mathbf{r}}_i = \hat{X}_i\hat{\mathbf{e}}_x + \hat{Y}_i\hat{\mathbf{e}}_y$ and the mapping (Fig. 1) between the Cartesian and the parameter coordinates is carried out using the classical bilinear shape functions [17],

$$\begin{bmatrix} \hat{x} \\ \hat{y} \end{bmatrix} = \begin{bmatrix} \mathbf{N} & \mathbf{0} \\ \mathbf{0} & \mathbf{N} \end{bmatrix} \begin{bmatrix} \hat{\mathbf{X}} \\ \hat{\mathbf{Y}} \end{bmatrix} \tag{1}$$

with

$$\mathbf{N} = \begin{bmatrix} N_1 & N_2 & N_3 & N_4 \end{bmatrix}$$

$$N_1 = \frac{1}{4}(1-\xi)(1-\eta) \quad , \quad N_2 = \frac{1}{4}(1+\xi)(1-\eta) \ ,$$

$$N_3 = \frac{1}{4}(1+\xi)(1+\eta) \quad , \quad N_4 = \frac{1}{4}(1-\xi)(1+\eta) \ . \tag{2}$$

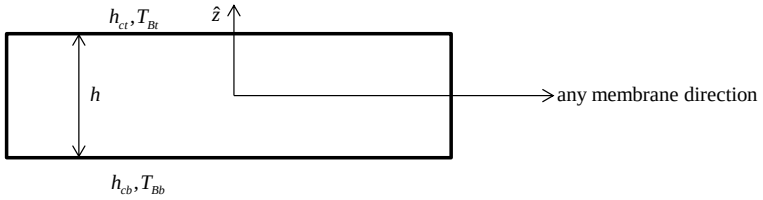

Figure 2: Description of the thermal field problem

In (1) the nodal coordinates are arranged as $\hat{\mathbf{X}} = \left[\begin{array}{cccc} \hat{X}_1 & \hat{X}_2 & \hat{X}_3 & \hat{X}_4 \end{array} \right]^T$ and $\hat{\mathbf{Y}} = \left[\begin{array}{cccc} \hat{Y}_1 & \hat{Y}_2 & \hat{Y}_3 & \hat{Y}_4 \end{array} \right]^T$. An alternative formulation [18] of the shape functions (2) is

$$\mathbf{N} = \boldsymbol{\Delta} + \mathbf{b}_x \hat{x} + \mathbf{b}_y \hat{y} + \boldsymbol{\gamma} \xi \eta, \tag{3}$$

with

$$\mathbf{b}_x = \frac{1}{2A_e} \left[\begin{array}{cccc} \hat{y}_{24} & \hat{y}_{31} & \hat{y}_{42} & \hat{y}_{13} \end{array} \right], \; \mathbf{b}_y = \frac{1}{2A_e} \left[\begin{array}{cccc} \hat{x}_{42} & \hat{x}_{13} & \hat{x}_{24} & \hat{x}_{31} \end{array} \right], \tag{4}$$

$$\boldsymbol{\gamma} = \frac{1}{4A_e} \left[\begin{array}{c} \hat{X}_2 \hat{y}_{34} + \hat{X}_3 \hat{y}_{42} + \hat{X}_4 \hat{y}_{23} \\ \hat{X}_1 \hat{y}_{43} + \hat{X}_3 \hat{y}_{14} + \hat{X}_4 \hat{y}_{31} \\ \hat{X}_1 \hat{y}_{24} + \hat{X}_2 \hat{y}_{41} + \hat{X}_4 \hat{y}_{12} \\ \hat{X}_1 \hat{y}_{32} + \hat{X}_2 \hat{y}_{13} + \hat{X}_3 \hat{y}_{21} \end{array} \right]^T, \tag{5}$$

$$\boldsymbol{\Delta} = \frac{1}{4} \left[\mathbf{t} - \left(\sum_{i=1}^{4} \hat{X}_i \right) \mathbf{b}_x - \left(\sum_{i=1}^{4} \hat{Y}_i \right) \mathbf{b}_y \right], \tag{6}$$

$$\mathbf{t} = \left[\begin{array}{cccc} 1 & 1 & 1 & 1 \end{array} \right], \tag{7}$$

$$\hat{x}_{IJ} = \hat{X}_I - \hat{X}_J \,, \; \hat{y}_{IJ} = \hat{Y}_I - \hat{Y}_J \,, \; A_e = \frac{1}{2} \left(\hat{x}_{24} \hat{y}_{31} + \hat{x}_{31} \hat{y}_{42} \right). \tag{8}$$

2.1 Thermal analysis

In this section we evaluate the temperature field $T(\hat{x}, \hat{y}, \hat{z})$ within the shell's volume. Consider a FGM or MLC shell structure of thickness h with a transversely varying thermal conductivity k, where convection is applied onto the outer surfaces. Figure 2 shows a cut through the shell structure, where convection is applied independently onto the top- and bottom-surface, i.e.

$$\hat{z} = -h/2: \;\; q_n^b = h_{cb}(T(\hat{z} = -h/2) - T_{Bb}), \tag{9}$$

$$\hat{z} = h/2: \;\; q_n^t = h_{ct}(T(\hat{z} = h/2) - T_{Bt}). \tag{10}$$

In (9) and (10) h_{ct} and h_{cb} denote the convection coefficient on the top and bottom surface, while T_{Bt} and T_{Bb} are the temperatures of the adjacent fluid. We decompose $T(\hat{x}, \hat{y}, \hat{z})$ according to

$$T(\hat{x}, \hat{y}, \hat{z}) = \bar{T}(\hat{x}, \hat{y}) + \widetilde{T}(\hat{z}), \tag{11}$$

where

$$\bar{T}(\hat{x}, \hat{y}) = 1/h \int_h T(\hat{x}, \hat{y}, \hat{z}) \, d\hat{z}, \tag{12}$$

is the mean temperature, while $\widetilde{T}(\hat{z})$ describes the unknown temperature distribution in transverse direction. The iterative solution strategy consists of two steps:

1. Evaluation of the mean temperature $\bar{T}(\hat{x},\hat{y}) = {}^1\!/_h \int_h T(\hat{x},\hat{y},\hat{z})\, d\hat{z}$ in membrane direction.
2. Estimate $\widetilde{T}(\hat{z})$ based on a mean temperature $\bar{T}$.

An iterative procedure with iteration number I is required since the shell's surface temperatures are initially unknown. Hence, (9) and (10) cannot be satisfied exactly, and we rewrite (9) and (10) according to

$$\hat{z} = -{}^h\!/_2 : \quad q_n^{b\,I+1} = h_{cb}(\bar{T}^{I+1} - T_{Bb}^{*I}),$$

$$\hat{z} = {}^h\!/_2 : \quad q_n^{t\,I+1} = h_{ct}(\bar{T}^{I+1} - T_{Bt}^{*I}), \tag{13}$$

with

$$T_{Bb}^{*I} = T_{Bb} - \widetilde{T}^I(\hat{z} = -{}^h\!/_2),$$

$$T_{Bt}^{*I} = T_{Bt} - \widetilde{T}^I(\hat{z} = {}^h\!/_2). \tag{14}$$

The **global iterative algorithm** can be summarized as follows:

1. $I = 0$
2. $\widetilde{T}^{I=0}(\hat{z} = \pm {}^h\!/_2) = 0$
3. WHILE $\frac{\bar{T}^{I+1} - \bar{T}^I}{\bar{T}^{I+1}} <$ tol (tol = tolerance limit)
   (a) $T_{Bb}^{*I} = T_{Bb} - \widetilde{T}^I(\hat{z} = -{}^h\!/_2)$ and $T_{Bt}^{*I} = T_{Bt} - \widetilde{T}^I(\hat{z} = {}^h\!/_2)$
   (b) FIND $\bar{T}^{I+1}$ according to Sect. 2.1.1 using convection boundary condition (13) and (14).
   (c) FIND $\widetilde{T}^{I+1}$ according to Sect. 2.1.2
   (d) $I = I + 1$

2.1.1 Evaluation of mean temperature

In this section we discuss a suitable procedure to evaluate the mean temperature $\bar{T}$. The strong form of the corresponding boundary value problem [19] reads

$$\bar{k}\bar{T}_{,ii} = 0, \tag{15}$$

$$\bar{T} = T_0 \ \text{ at } \ \Gamma_T, \tag{16}$$

$$q_0 = q_n = -\bar{k}\bar{T}_{,i} n_i \ \text{ at } \ \Gamma_q. \tag{17}$$

where a comma within an index denotes a partial derivative and Einstein's summation convention is understood ($i = \hat{x},\hat{y}$). The Dirichlet boundary condition (16) prescribes a given value T_0 at the boundary Γ_T, while the von Neumann boundary condition prescribes the heat flux $q_i n_i$

along Γ_q. In (17) $-\bar{k}\bar{T}_{,i} = \bar{q}_i$ is the mean heat flux, while $\bar{k}$ denotes the mean value of thermal conductivity,

$$\bar{k} = \frac{1}{h}\int_h k(\hat{z})d\hat{z}. \tag{18}$$

The weak form of (15)-(17) is given by,

$$\int_V \bar{k}\bar{T}_{,ii}\delta\bar{T}dV - \int_{\Gamma_q}(q_0 - q_n)\delta\bar{T}d\Gamma = 0, \tag{19}$$

where the weighting function $\delta\bar{T}$ is a virtual temperature distribution that has to satisfy the Dirichlet boundary condition $\delta\bar{T} = 0$ at Γ_T. Applying the Gaussian theorem to the first integral leads to

$$\int_V \bar{k}\bar{T}_{,i}\delta\bar{T}_{,i}dV + \int_{\Gamma_q} q_0\delta\bar{T}d\Gamma = 0. \tag{20}$$

We use bilinear interpolations (2) for the mean temperature fields

$$\bar{T} = \mathbf{N}\bar{\mathbf{T}}^e \;\text{ and }\; \delta\bar{T} = \mathbf{N}\delta\bar{\mathbf{T}}^e\ , \tag{21}$$

where $\bar{\mathbf{T}}^e$ and $\delta\bar{\mathbf{T}}^e$ denote the corresponding nodal values. Introducing this into (20) yields

$$\begin{aligned}\left(\delta\bar{\mathbf{T}}^e\right)^T \Bigg[&\underbrace{\bar{k}h\int_{-1}^{1}\int_{-1}^{1}\mathbf{B}^T\mathbf{B}\det\mathbf{J}\,d\xi d\eta}_{\mathbf{K}_T^e}\bar{\mathbf{T}}^e + \\ &+\underbrace{\int_{-1}^{1}\int_{-1}^{1}\left(h_{ct}+h_{cb}\right)\mathbf{N}^T\mathbf{N}\det\mathbf{J}\,d\xi d\eta}_{\mathbf{K}_{Tc}^e}\bar{\mathbf{T}}^e - \\ &-\underbrace{\int_{-1}^{1}\int_{-1}^{1}\left(h_{ct}T^*_{Bt}+h_{cb}T^*_{Bb}\right)\mathbf{N}^T\det\mathbf{J}\,d\xi d\eta}_{\mathbf{F}_{Tc}^e}\Bigg] = 0,\end{aligned} \tag{22}$$

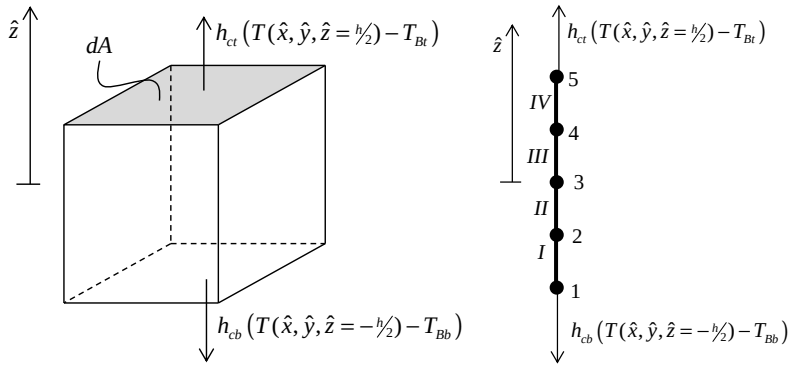
with $\mathbf{B}$ referring to the gradient of the shape functions,

$$\mathbf{B} = \begin{bmatrix}\mathbf{B}_{\hat{x}}\\ \mathbf{B}_{\hat{y}}\end{bmatrix} = \begin{bmatrix} N_{1,\hat{x}} & N_{2,\hat{x}} & N_{3,\hat{x}} & N_{4,\hat{x}} \\ N_{1,\hat{y}} & N_{2,\hat{y}} & N_{3,\hat{y}} & N_{4,\hat{y}}\end{bmatrix}. \tag{23}$$

We assume that $\widetilde{T}(\hat{z})$ is constant within one element, thus, T^*_{Bt} and T^*_{Bb} from (14) is also elementwise constant and is evaluated at each element's center. The differential volume of a shell structure is given by $dV = hdA = h\det\mathbf{J}\,d\xi d\eta$, where $\det\mathbf{J}$ denotes the determinant of the element Jacobian. With (22) we finally obtain

$$\left(\mathbf{K}_T^e + \mathbf{K}_{Tc}^e\right)\bar{\mathbf{T}}^e = \mathbf{F}_{Tc}^e, \tag{24}$$

Equations (24) have to be assembled to a global system in a standard manner [20]. All integrations over the element domain are carried out numerically by a 2×2 Gauss integration.



(a) Problem of transverse temperature distribution

(b) Discretized problem of transverse temperature distribution ($n = 4$)

Figure 3: Transverse temperature distribution

2.1.2 Evaluation of transverse temperature distribution

Once the mean temperature $\bar{T}(\hat{x},\hat{y})$ is evaluated at every point of the shell's structure, the temperature distribution with respect to the thickness direction is calculated. Thereby, we analyze the problem depicted in Fig. 3(a) showing an infinitesimal volume portion of cross section dA and a height of h where a convection boundary condition on the top and bottom surface is applied. In what follows we discuss a procedure where the temperature distribution with respect to the thickness direction is found from a thermal conduction problem with two Neumann conditions. At every location $\hat{x}$ and $\hat{y}$ the following system of equations holds[1]

$$\frac{d}{d\hat{z}}\left(k(\hat{x},\hat{y},\hat{z})\frac{d}{d\hat{z}}T(\hat{x},\hat{y},\hat{z})\right)+K^*=0\ , \tag{25}$$

$$\hat{z}=h/2:\ -k(\hat{x},\hat{y},\hat{z}=h/2)\left.\frac{dT(\hat{x},\hat{y},\hat{z})}{d\hat{z}}\right|_{\hat{z}=h/2}-h_{ct}\left(T(\hat{x},\hat{y},\hat{z}=h/2)-T_{Bt}\right)=0\ , \tag{26}$$

$$\hat{z}=-h/2:\ -k(\hat{x},\hat{y},\hat{z}=-h/2)\left.\frac{dT(\hat{x},\hat{y},\hat{z})}{d\hat{z}}\right|_{\hat{z}=-h/2}-h_{ct}\left(T(\hat{x},\hat{y},\hat{z}=-h/2)-T_{Bb}\right)=0\ . \tag{27}$$

In (25) K^* is given by

$$K^*=Kk(\hat{z}), \tag{28}$$

where K represents an unknown constant. The inclusion of (28) in (25) is mandatory for accurate results and is in contrast to [11] where a similar strong form is used without K^*. The inclusion of K^* can be motivated by the following thought experiment: Within a shell's section of constant conductivity the transverse temperature distribution is expected to be parabolic with prescribed gradients at the top and bottom surface. In absence of K^* the solution of (25) leads to a linear distribution and (26) and (27) cannot be satisfied exactly. The introduction of a non-vanishing constant K^* avoids such a deficiency. The unknown constant K is found from the

[1] Within one element the thermal conduction coefficient k is assumed to be constant, however, k can be discontinuous from element to element.

constraint that the mean value of $T(\hat{x},\hat{y},\hat{z})$ must equal $\bar{T}(\hat{x},\hat{y})$ from (12). Rewriting (25)-(27) with $T(\hat{x},\hat{y},\hat{z}) = \bar{T}(\hat{x},\hat{y}) + \widetilde{T}(\hat{z})$ leads to

$$\frac{d}{d\hat{z}}\left(k(\hat{x},\hat{y},\hat{z})\frac{d}{d\hat{z}}\widetilde{T}(\hat{z})\right) + Kk(\hat{z}) = 0\ , \tag{29}$$

$$\hat{z} = {}^{h}/_{2}:\ -k(\hat{x},\hat{y},\hat{z}={}^{h}/_{2})\left.\frac{d\widetilde{T}(\hat{z})}{d\hat{z}}\right|_{\hat{z}={}^{h}/_{2}} - h_{ct}\left(\bar{T}(\hat{x},\hat{y}) + \widetilde{T}(\hat{z}=-{}^{h}/_{2}) - T_{Bt}\right) = 0\ , \tag{30}$$

$$\hat{z} = -{}^{h}/_{2}:\ -k(\hat{x},\hat{y},\hat{z}=-{}^{h}/_{2})\left.\frac{d\widetilde{T}(\hat{z})}{d\hat{z}}\right|_{\hat{z}=-{}^{h}/_{2}} - h_{ct}\left(\bar{T}(\hat{x},\hat{y}) + \widetilde{T}(\hat{z}=-{}^{h}/_{2}) - T_{Bb}\right) = 0\ , \tag{31}$$

$$\int_{h}\widetilde{T}(\hat{z})\,d\hat{z} = 0\ . \tag{32}$$

An analytical solution of (29)-(32) can be given in case of a constant conductivity, i.e. $k(\hat{z}) = k$, however, for arbitrary variations of $k(\hat{z})$ we propose a FEM like solution procedure using a discretization with n linear elements of length $l_e = {}^{h}/_{n}$, see Fig. 3(b). Hence, we find for interior elements

$$dA\int_{l_e} k(\hat{z})\widetilde{T}_{,\hat{z}}\delta\widetilde{T}_{,\hat{z}}\,d\hat{z} = dAK\int_{l_e} k(\hat{z})\delta\widetilde{T}\,d\hat{z}, \tag{33}$$

and for the top and bottom elements

$$\text{bottom}\ (\hat{z}=-{}^{h}/_{2}):\ dA\int_{l_e} k(\hat{z})\widetilde{T}_{,\hat{z}}\delta\widetilde{T}_{,\hat{z}}\,d\hat{z} = dA\int_{l_e} K^{*}\delta\widetilde{T}\,d\hat{z} - \left(h_{cb}dA\left(\bar{T}+\widetilde{T}-T_{Bb}\right)\delta\widetilde{T}\right)\Big|_{\hat{z}=-{}^{h}/_{2}}, \tag{34}$$

$$\text{top}\ (\hat{z}={}^{h}/_{2}):\ dA\int_{l_e} k(\hat{z})\widetilde{T}_{,\hat{z}}\delta\widetilde{T}_{,\hat{z}}\,d\hat{z} = dA\int_{l_e} K^{*}\delta\widetilde{T}\,d\hat{z} - \left(h_{ct}dA\left(\bar{T}+\widetilde{T}-T_{Bt}\right)\delta\widetilde{T}\right)\Big|_{\hat{z}={}^{h}/_{2}}, \tag{35}$$

where $k(\hat{z})$ is assumed to the be the value of thermal conductivity at each element's center, being constant throughout each element. This finally leads to the following system of equations

$$\left\{\frac{n}{h}\begin{bmatrix} k_1 & \cdots & 0 & 0\\ \vdots & \ddots & \vdots & \vdots\\ 0 & \cdots & k_{n-1} & -k_n\\ 0 & \cdots & -k_n & k_n\end{bmatrix} + \begin{bmatrix} h_{cb} & \cdots & 0 & 0\\ \vdots & \ddots & \vdots & \vdots\\ 0 & \cdots & 0 & 0\\ 0 & \cdots & 0 & h_{ct}\end{bmatrix}\right\}\begin{bmatrix}\vartheta_1\\ \vdots\\ \vartheta_n\\ \vartheta_{n+1}\end{bmatrix} =$$

$$= \frac{K\,h}{2n}\begin{bmatrix} k_1\\ \vdots\\ k_{n-1}\\ k_n\end{bmatrix} + \begin{bmatrix} h_{cb}\left(T_{Bb}-\bar{T}\right)\\ \vdots\\ 0\\ h_{ct}\left(T_{Bt}-\bar{T}\right)\end{bmatrix}, \tag{36}$$

where ϑ_i for $i = 1...n+1$ denotes the nodal value of $\widetilde{T}$ and k_i for $i = 1...n$ refers to the thermal conductivity at the i-th element's center. Equation (36) can be rewritten according to

$$\mathbf{K}\boldsymbol{\vartheta} = K\mathbf{F} + \mathbf{F}_c, \tag{37}$$

and represents a linear algebraic system of equations approximating (29)-(31). Equation (32) is modeled as

$$\frac{1}{2}\left(\vartheta_1 + \vartheta_{n+1}\right) + \sum_{i=2}^{n} \vartheta_i = \left[\begin{array}{cccc} 1/2 & \cdots & 1 & 1/2 \end{array}\right] \left[\begin{array}{c} \vartheta_1 \\ \vdots \\ \vartheta_n \\ \vartheta_{n+1} \end{array}\right] = \mathbf{L}\boldsymbol{\vartheta} = 0, \tag{38}$$

and can be used to evaluate the unknown constant K,

$$K = -\frac{\mathbf{L}\mathbf{K}^{-1}\mathbf{F}_c}{\mathbf{L}\mathbf{K}^{-1}\mathbf{F}}, \tag{39}$$

consequently, the nodal values $\boldsymbol{\vartheta}$ read

$$\boldsymbol{\vartheta} = -\frac{\mathbf{L}\mathbf{K}^{-1}\mathbf{F}_c}{\mathbf{L}\mathbf{K}^{-1}\mathbf{F}}\mathbf{K}^{-1}\mathbf{F} + \mathbf{K}^{-1}\mathbf{F}_c. \tag{40}$$

2.2 Mechanical analysis

The derivation of a six parameter shell element is based on four steps. In Sect. 2.2.1 we present useful equations for evaluating effective elastic quantities. Arbitrary warped element geometries show a computationally expensive coupling between membrane and bending properties. In order to avoid the derivation of those coupling matrices, we describe in Sect. 2.2.2 a projection scheme, which extracts a plane element configuration. Using that projection the derivation of the stiffness matrix can be separated into a membrane (Sect. 2.2.3) and a bending part (Sect. 2.2.4).

2.2.1 Effective elastic quantities

The element formulation requires four effective quantities that are directly related to the distribution of Young's modulus $E(\hat{z})$. We present here only the main results and refer to [15] for details. In case of unsymmetrical variations of E the offset $\overline{z}$ of a neutral surface from the discretized mid-plane is evaluated as

$$\overline{z} = \frac{\int_{-h/2}^{h/2} E(\hat{z})\hat{z}d\hat{z}}{\int_{-h/2}^{h/2} E(\hat{z})d\hat{z}}. \tag{41}$$

With respect to this plane, membrane and bending deformations are decoupled and an arbitrary normal strain reads

$$\varepsilon_{ij}(\hat{z}') = \varkappa_{ij}\hat{z}' + \varepsilon_{ij}^{(0)}, \tag{42}$$

with $\hat{z}' = \hat{z} - \overline{z}$. In (42) $\varepsilon_{ij}^{(0)}$ denotes the strain in the neutral surface and $\varkappa_{ij}$ refers to a curvature. The effective moduli for membrane (E_m) and bending (E_b) read

$$E_m = \frac{1}{h}\int_{-h/2-\overline{z}}^{h/2-\overline{z}} E(\hat{z}')d\hat{z}', \tag{43}$$

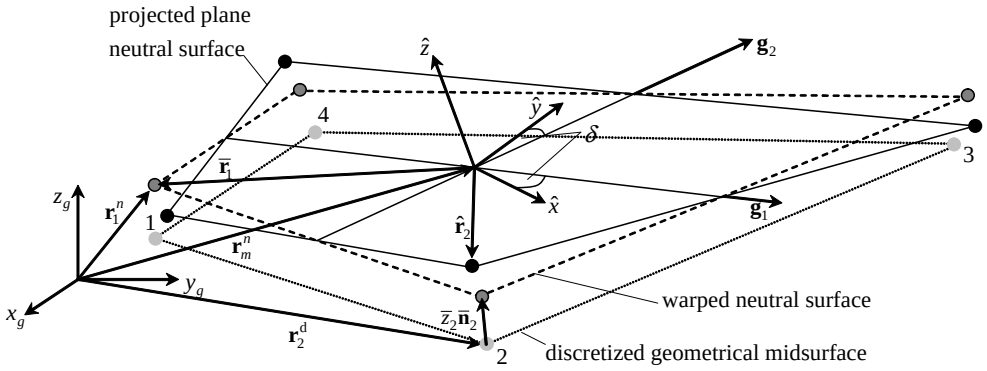


Figure 4: Discretized mid-surface, warped neutral surface, projected plane neutral surface

$$E_b = \frac{12}{h^3} \int_{-h/2-\overline{z}}^{h/2-\overline{z}} E(\hat{z}')\hat{z}'^2 d\hat{z}'. \tag{44}$$

Since shear deformations are accounted for, a shear correction factor α_s is to be introduced. For homogenous shells $\alpha_s = 5/6$, while in case of varying $E(\hat{z})$ one finds [15]

$$\frac{1}{\alpha_s} = \frac{144}{E_b h^5} \int_{-h/2-\overline{z}}^{h/2-\overline{z}} \frac{1}{E(\hat{z}')} \left[\int_{\hat{z}'}^{h/2-\overline{z}} E(\zeta)\zeta d\zeta \right]^2 d\hat{z}'. \tag{45}$$

2.2.2 A projection scheme

We decouple the membrane and bending properties in two steps. Firstly, we shift the element configuration, which is discretizing the geometrical mid-plane to the mechanical neutral surface (41). According to Fig. 4 this is done via

$$\mathbf{r}_i^n = \mathbf{r}_i^d + \overline{z}_i \overline{\mathbf{n}}_i \quad \text{no sum on } i, \tag{46}$$

where $\mathbf{r}_i^d$ and $\mathbf{r}_i^n$ denote the coordinates of the i-th node ($i = 1, 2, 3, 4$) of the discretized and the neutral surface. The projection is carried out along a nodal fiber direction $\overline{\mathbf{n}}_i$, which can be extracted from the preprocessor or can be found with the aid of an algorithm discussed in [15]. Since the element configuration discretizing the neutral surface may be warped, we extract a plane element configuration as shown in Fig. 4. A local Cartesian coordinate system $\hat{x} - \hat{y} - \hat{z}$ is placed at the element's center point with $\mathbf{r}_m^n = \frac{1}{4}\sum_{i=1}^4 \mathbf{r}_i^n$. The base vectors $\mathbf{e}_{\hat{x}}$ and $\mathbf{e}_{\hat{y}}$ share an equal angle δ to $\mathbf{g}_1$ and $\mathbf{g}_2$, which join the center and the mid-side points (Fig. 4). Finally, the nodes are projected onto the $\hat{\mathbf{e}}_x - \hat{\mathbf{e}}_y$ plane giving a plane element with local nodal vectors $\hat{\mathbf{r}}_i = \begin{bmatrix} \hat{X}_i & \hat{Y}_i & 0 \end{bmatrix}^T$ as depicted in Fig. 1. The proposed projection scheme may introduce some rigid body error. This problem is indicated by many authors, e.g. [21, 22] and can easily be corrected by a method proposed by Rankin and Nour-Omid [23]. The details of this procedure are discussed in [12, 24], we only give the final result

$$\hat{\mathbf{K}}_{proj} = \hat{\mathbf{P}}_R^T \hat{\mathbf{K}} \hat{\mathbf{P}}_R, \tag{47}$$

with $\hat{\mathbf{P}}_R = \left[\mathbf{I}_{(24\times24)} - \hat{\mathfrak{R}}\left(\hat{\mathfrak{R}}^T\hat{\mathfrak{R}}\right)^{-1}\hat{\mathfrak{R}}^T\right]$ denoting the projection with

$$\hat{\mathfrak{R}} = \begin{bmatrix} \hat{\mathfrak{R}}_1 \\ \hat{\mathfrak{R}}_2 \\ \hat{\mathfrak{R}}_3 \\ \hat{\mathfrak{R}}_4 \end{bmatrix} \quad \text{with} \quad \hat{\mathfrak{R}}_i = \begin{bmatrix} 1 & 0 & 0 & 0 & \hat{Z}_i & -\hat{Y}_i \\ 0 & 1 & 0 & -\hat{Z}_i & 0 & \bar{X}_i \\ 0 & 0 & 1 & \hat{Y}_i & -\bar{X}_i & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix}. \tag{48}$$

The parts of the element stiffness matrix

$$\hat{\mathbf{K}} = \begin{bmatrix} \hat{\mathbf{K}}_{membrane} & \mathbf{0} \\ \mathbf{0} & \hat{\mathbf{K}}_{plate} \end{bmatrix} \tag{49}$$

are derived in Sect. 2.2.3 and Sect. 2.2.4, while the global stiffness matrix $\widetilde{\mathbf{K}}$ is assembled after a transformation of $\hat{\mathbf{K}}_{proj}$ to the global Cartesian coordinate system. Note that $\widetilde{\mathbf{K}}$ refers to the mechanical neutral surface (41), while the load vector is usually applied onto the discretized mid-plane. Therefore, an element load vector applied onto the mid-surface $\left[\begin{array}{cc}\mathbf{F}^d & \mathbf{M}^d\end{array}\right]^T$ has to be reduced to a force vector, which refers the neutral surface $\left[\begin{array}{cc}\mathbf{F}^n & \mathbf{M}^n\end{array}\right]^T$ via

$$\mathbf{F}^n = \mathbf{F}^d \quad \text{and} \quad \mathbf{M}^n = \mathbf{M}^d - \overline{z}_i\overline{\mathbf{n}}_i \times \mathbf{F}^d. \tag{50}$$

After solving the global system of equations the resulting displacements $\mathbf{U}^n$ and rotations $\boldsymbol{\phi}^n$ also refer to the neutral surface. During post-processing at the discretized configuration, a transformation according to

$$\mathbf{U}^d = \mathbf{U}^n + \overline{z}_i\overline{\mathbf{n}}_i \times \boldsymbol{\phi}^n \quad \text{and} \quad \boldsymbol{\phi}^d = \boldsymbol{\phi}^n \tag{51}$$

has to be carried out [15].

2.2.3 The membrane part

The inclusion of drill rotations, i.e. the rotation about the shell's normal, is a main issue of this paper. These in-plane rotational degrees of freedom are introduced using a recently proposed Cosserat-type functional [13, 12],

$$\delta\Pi_{membrane} = h\int_{\Omega}\delta\hat{\overline{\boldsymbol{\varepsilon}}}_s^T\hat{\mathbf{C}}_m\hat{\overline{\boldsymbol{\varepsilon}}}_s dA_e + 2\alpha h\int_{\Omega}\delta\hat{\overline{\varepsilon}}_a\hat{\overline{\varepsilon}}_a dA_e. \tag{52}$$

In (52), $\hat{\overline{\boldsymbol{\varepsilon}}}_s$ and $\hat{\overline{\varepsilon}}_a$ denote the symmetric and the antimetric part of the membrane strain tensor, respectively. The overbar indicates assumed strains, which can be assumed independently and are not directly related to prescribed deformations and rotations,

$$\hat{\boldsymbol{\varepsilon}}_s = \left[\begin{array}{ccc} u_{\hat{x},\hat{x}} & u_{\hat{y},\hat{y}} & u_{\hat{x},\hat{y}} + u_{\hat{y},\hat{x}}\end{array}\right]^T \quad \text{and} \quad \hat{\varepsilon}_a = {}^1\!/_2\left(u_{\hat{x},\hat{y}} - u_{\hat{y},\hat{x}}\right) + \varphi_{\hat{z}}. \tag{53}$$

For sake of convenience the direct strain-displacement-relation is given in (53), where u_i for $i = \hat{x}, \hat{y}$ and $\varphi_{\hat{z}}$ refer to membrane displacements and drill rotations, respectively. In (52) A_e denotes the area of the element (8) and $\hat{\mathbf{C}}_m$ refers to the plane stress elasticity matrix (43)

$$\hat{\mathbf{C}}_m = \frac{E_m}{1-\nu^2}\begin{bmatrix} 1 & \nu & 0 \\ \nu & 1 & 0 \\ 0 & 0 & \frac{1-\nu}{2} \end{bmatrix}. \tag{54}$$

The variable α represents an additional material constant relating the skew symmetric parts of stresses and strains. As frequently recommended (e.g. [14]), this constitutive parameter can be related to the shear modulus of the corresponding material,

$$\alpha = \overline{\alpha}\frac{E_m}{2\left(1+\nu\right)}, \tag{55}$$

where $\overline{\alpha}$ denotes an additional scaling factor. The present formulation can be optimized according to accuracy and efficiency, while avoiding any internal (incompatible) degrees of freedom to circumvent membrane shear locking in low order elements [18]. The predictive quality is nearly independent of $\overline{\alpha}$ and suitable scaling factors are discussed in [12]. The assumed strain fields are related to nodal displacements and rotations, i.e.

$$\hat{\overline{\boldsymbol{\varepsilon}}}_s = \hat{\overline{\mathbf{B}}}_{su0}\begin{bmatrix}\mathbf{U}_{\hat{x}}\\ \mathbf{U}_{\hat{y}}\end{bmatrix} + \hat{\overline{\mathbf{B}}}_{suH}\begin{bmatrix}\boldsymbol{\gamma} & \mathbf{0}\\ \mathbf{0} & \boldsymbol{\gamma}\end{bmatrix}\begin{bmatrix}\mathbf{U}_{\hat{x}}\\ \mathbf{U}_{\hat{y}}\end{bmatrix}, \tag{56}$$

$$\hat{\overline{\varepsilon}}_a = \frac{1}{2}\left(\hat{\overline{\mathbf{B}}}_{au0}\begin{bmatrix}\mathbf{U}_{\hat{x}}\\ \mathbf{U}_{\hat{y}}\end{bmatrix} + \hat{\overline{\mathbf{B}}}_{auH}\begin{bmatrix}\boldsymbol{\gamma} & \mathbf{0}\\ \mathbf{0} & \boldsymbol{\gamma}\end{bmatrix}\begin{bmatrix}\mathbf{U}_{\hat{x}}\\ \mathbf{U}_{\hat{y}}\end{bmatrix}\right) + \overline{\mathbf{N}}_{\varphi}\hat{\boldsymbol{\Phi}}, \tag{57}$$

where $\mathbf{U}_{\hat{x}} = \begin{bmatrix}\mathbf{U}_{\hat{x}1} & \cdots & \mathbf{U}_{\hat{x}4}\end{bmatrix}^T$ and $\mathbf{U}_{\hat{y}} = \begin{bmatrix}\mathbf{U}_{\hat{y}1} & \cdots & \mathbf{U}_{\hat{y}4}\end{bmatrix}^T$ are the inplane nodal displacements while $\hat{\boldsymbol{\Phi}} = \begin{bmatrix}\phi_{\hat{z}1} & \cdots & \phi_{\hat{z}4}\end{bmatrix}$ contains the drill rotation angles. The corresponding $\hat{\overline{\mathbf{B}}}$-matrices and the shape functions $\overline{\mathbf{N}}_{\varphi}$ read

$$\hat{\overline{\mathbf{B}}}_{su0} = \sqrt{\frac{j_0}{j}}\begin{bmatrix}\mathbf{b}_x & \mathbf{0}\\ \mathbf{0} & \mathbf{b}_y\\ \mathbf{b}_y & \mathbf{b}_x\end{bmatrix}, \quad \hat{\overline{\mathbf{B}}}_{suH} = \sqrt{\frac{j}{j_0}}\begin{bmatrix}\left(\xi\eta\right)_{,\hat{x}} & -\nu\left(\xi\eta\right)_{,\hat{y}}\\ -\nu\left(\xi\eta\right)_{,\hat{x}} & \left(\xi\eta\right)_{,\hat{y}}\\ 0 & 0\end{bmatrix}, \tag{58}$$

$$\hat{\overline{\mathbf{B}}}_{au0} = \sqrt{\frac{j_0}{j}}\begin{bmatrix}\mathbf{b}_y & -\mathbf{b}_x\end{bmatrix}, \quad \hat{\overline{\mathbf{B}}}_{auH} = 2\sqrt{\frac{j}{j_0}}\begin{bmatrix}\left(\xi\eta\right)_{,\hat{y}} & -\left(\xi\eta\right)_{,\hat{x}}\end{bmatrix}, \tag{59}$$

$$\overline{\mathbf{N}}_{\varphi} = \sqrt{\frac{j_0}{j}}\begin{bmatrix}N_1 & N_2 & N_3 & N_4\end{bmatrix}, \tag{60}$$

where $j = \det\mathbf{J}$ and $j_0 = \det\mathbf{J}_0 = \det\mathbf{J}(\xi=\eta=0)$ (see (2) - (8)). The prefactors $\sqrt{j/j_0}$ and $\sqrt{j_0/j}$ enable an analytical integration of all parts of the membrane stiffness matrix avoiding a four point Gaussian quadrature. The resulting membrane part of the stiffness matrix may be found in [25].

2.2.4 The bending part

The bending part of the stiffness matrix is based on the Mindlin-Reissner hypothesis and is valid for thin to moderately thick shell structures [17, 24, 12]. Equilibrium requires the potential Π_{plate} to be a minimum, i.e.

$$\Pi_{plate} = \Pi_b + \Pi_s - \Pi_{ext} \;\rightarrow \min, \tag{61}$$

with

$$\Pi_b = \frac{1}{2}\int_{\Omega}\hat{\overline{\boldsymbol{\epsilon}}}_b^T\hat{\mathbf{C}}_b\hat{\overline{\boldsymbol{\epsilon}}}_b d\Omega,$$

$$\Pi_s = \frac{1}{2}\alpha_s h \frac{E_b}{2(1+\nu)} \int\limits_{A_e} \hat{\overline{\boldsymbol{\gamma}}}_s^T \hat{\overline{\boldsymbol{\gamma}}}_s dA,$$

$$\Pi_{ext} = \int\limits_{A_e} p u_{\hat{z}} dA. \tag{62}$$

An overbar again indicates that the corresponding field can be interpolated independently, i.e. without any relation to strain displacement equations. The subscripts b and s indicate that the corresponding quantity refers to bending and shear, respectively, and Π_{ext} is due to the externally applied pressures p. The variables $\hat{\overline{\boldsymbol{\epsilon}}}_b$ and $\hat{\overline{\boldsymbol{\gamma}}}_s$ denote bending and transverse shear strains. In (62) $\hat{\mathbf{C}}_b$ refers to the bilinear plane stress elasticity matrix (44)

$$\hat{\mathbf{C}}_b = \frac{E_b}{1-\nu^2} \begin{bmatrix} 1 & \nu & 0 \\ \nu & 1 & 0 \\ 0 & 0 & \frac{1-\nu}{2} \end{bmatrix}, \tag{63}$$

while α_s denotes the shear correction factor (45). Following the procedure in [12, 24], the corresponding interpolations read

$$\hat{\overline{\boldsymbol{\epsilon}}}_b = \hat{\overline{\mathbf{B}}}_{b0} \begin{bmatrix} \boldsymbol{\Phi}_{\hat{x}} \\ \boldsymbol{\Phi}_{\hat{y}} \end{bmatrix} + \hat{\overline{\mathbf{B}}}_{bH} \begin{bmatrix} \boldsymbol{\gamma} & \mathbf{0} \\ 0 & \boldsymbol{\gamma} \end{bmatrix} \begin{bmatrix} \boldsymbol{\Phi}_{\hat{x}} \\ \boldsymbol{\Phi}_{\hat{y}} \end{bmatrix}, \tag{64}$$

with

$$\hat{\overline{\mathbf{B}}}_{b0} = \hat{z}\sqrt{\frac{j_0}{j}} \begin{bmatrix} \mathbf{0} & \mathbf{b}_x^T \\ -\mathbf{b}_y^T & \mathbf{0} \\ -\mathbf{b}_x^T & \mathbf{b}_y^T \end{bmatrix}, \quad \hat{\overline{\mathbf{B}}}_{bH} = \hat{z}\sqrt{\frac{j}{j_0}} \begin{bmatrix} \nu\,(\xi\eta)_{,\hat{y}} & (\xi\eta)_{,\hat{x}} \\ -\,(\xi\eta)_{,\hat{y}} & -\nu\,(\xi\eta)_{,\hat{x}} \\ 0 & 0 \end{bmatrix}, \tag{65}$$

and

$$\hat{\overline{\boldsymbol{\gamma}}}_s = \mathbf{J}_0^{-1} \mathbf{N}_s \boldsymbol{\Gamma} \tag{66}$$

with

$$\mathbf{N}_s = \sqrt{\frac{j_0}{j}} \begin{bmatrix} \frac{1}{2}(1-\eta) & 0 & \frac{1}{2}(1+\eta) & 0 \\ 0 & \frac{1}{2}(1+\xi) & 0 & \frac{1}{2}(1-\xi) \end{bmatrix}$$

and $\boldsymbol{\Gamma} = \mathbf{A}_{uz}\mathbf{U}_{\hat{z}} + \mathbf{A}_{\varphi x}\boldsymbol{\Phi}_{\hat{x}} + \mathbf{A}_{\varphi y}\boldsymbol{\Phi}_{\hat{y}}$. The coefficients $\mathbf{A}_{uz}$, $\mathbf{A}_{\varphi x}$ and $\mathbf{A}_{\varphi y}$ only depend on the element's geometry and read

$$\mathbf{A}_{uz} = \frac{1}{2} \begin{bmatrix} -1 & 1 & 0 & 0 \\ -1 & 0 & 0 & 1 \\ 0 & 0 & 1 & -1 \\ 0 & -1 & 1 & 0 \end{bmatrix},$$

$$\mathbf{A}_{\varphi x} = \frac{1}{4} \begin{bmatrix} \hat{y}_{12} & \hat{y}_{12} & 0 & 0 \\ \hat{y}_{14} & 0 & 0 & \hat{y}_{14} \\ 0 & 0 & \hat{y}_{43} & \hat{y}_{43} \\ 0 & \hat{y}_{23} & \hat{y}_{23} & 0 \end{bmatrix}, \; \mathbf{A}_{\varphi y} = \frac{1}{4} \begin{bmatrix} \hat{x}_{21} & \hat{x}_{21} & 0 & 0 \\ \hat{x}_{41} & 0 & 0 & \hat{x}_{41} \\ 0 & 0 & \hat{x}_{34} & \hat{x}_{34} \\ 0 & \hat{x}_{32} & \hat{x}_{32} & 0 \end{bmatrix}, \tag{67}$$

leading to a formulation, which ensures the satisfaction of the Kirchhoff patch test [26, 27]. Again, the prefactors $\sqrt{j/j_0}$ and $\sqrt{j_0/j}$ enable an analytical integration of all parts of the plate bending stiffness matrix, see e.g. [25].

2.3 Weak one-way coupling

The finite element formulation discussed in Sect. 2.2 is based on a weak form of the equilibrium conditions,

$$\delta\Pi = \int (\delta\boldsymbol{\varepsilon})^T \boldsymbol{\sigma} dV - \delta\Pi_{ext} = 0, \tag{68}$$

where any external loads are neglected in this paper[2]. The strain field in membrane directions reads

$$\begin{aligned}
\varepsilon_{\hat{x}\hat{x}} &= \frac{1}{E(\hat{z})}(\sigma_{\hat{x}\hat{x}} - \nu\sigma_{\hat{y}\hat{y}}) + \alpha(\hat{z})\Delta T(\hat{z}),\\
\varepsilon_{\hat{y}\hat{y}} &= \frac{1}{E(\hat{z})}(\sigma_{\hat{y}\hat{y}} - \nu\sigma_{\hat{x}\hat{x}}) + \alpha(\hat{z})\Delta T(\hat{z}),\\
\varepsilon_{\hat{z}\hat{z}} &= \frac{-\nu}{E(\hat{z})}(\sigma_{\hat{x}\hat{x}} + \sigma_{\hat{y}\hat{y}}) + \alpha(\hat{z})\Delta T(\hat{z}),\\
\gamma_{\hat{x}\hat{y}} &= \frac{2(1+\nu)}{E(\hat{z})}\sigma_{\hat{x}\hat{y}},
\end{aligned} \tag{69}$$

where we adopted a plane stress constraint, i.e. $\sigma_{\hat{z}\hat{z}} = 0$. The thermal expansion coefficient shows an arbitrary variation with respect to the thickness direction and is denoted by $\alpha(\hat{z})$. Solving (69) for the stresses yields

$$\begin{aligned}
\sigma_{\hat{x}\hat{x}} &= \frac{E(\hat{z})}{1-\nu^2}(\varepsilon_{\hat{x}\hat{x}} + \nu\varepsilon_{\hat{y}\hat{y}}) - \frac{E(\hat{z})\alpha(\hat{z})\Delta T(\hat{z})}{1-\nu},\\
\sigma_{\hat{y}\hat{y}} &= \frac{E(\hat{z})}{1-\nu^2}(\varepsilon_{\hat{y}\hat{y}} + \nu\varepsilon_{\hat{x}\hat{x}}) - \frac{E(\hat{z})\alpha(\hat{z})\Delta T(\hat{z})}{1-\nu},\\
\sigma_{\hat{x}\hat{y}} &= \frac{E(\hat{z})}{2(1+\nu)}\gamma_{\hat{x}\hat{y}},
\end{aligned} \tag{70}$$

or in matrix notation

$$\begin{bmatrix} \sigma_{\hat{x}\hat{x}} \\ \sigma_{\hat{y}\hat{y}} \\ \sigma_{\hat{x}\hat{y}} \end{bmatrix} = \frac{E(\hat{z})}{1-\nu^2}\begin{bmatrix} 1 & \nu & 0 \\ \nu & 1 & 0 \\ 0 & 0 & \frac{1-\nu}{2} \end{bmatrix}\begin{bmatrix} \epsilon_{\hat{x}\hat{x}} \\ \epsilon_{\hat{y}\hat{y}} \\ \epsilon_{\hat{x}\hat{y}} \end{bmatrix} - \frac{E(\hat{z})\alpha(\hat{z})\Delta T(\hat{z})}{1-\nu}\begin{bmatrix} 1 \\ 1 \\ 0 \end{bmatrix},$$

$$\boldsymbol{\sigma} = \mathbf{C}\boldsymbol{\varepsilon} - \frac{E(\hat{z})\alpha(\hat{z})\Delta T(\hat{z})}{1-\nu}\begin{bmatrix} 1 \\ 1 \\ 0 \end{bmatrix}. \tag{71}$$

Within the proposed weak one way coupling procedure we introduce (71) into (68) obtaining

$$\delta\Pi = \delta\Pi_m - \delta\Pi_t = \int\limits_{V_e} (\delta\boldsymbol{\varepsilon})^T \mathbf{C}\boldsymbol{\varepsilon} dV - \int\limits_{V_e} (\delta\boldsymbol{\varepsilon})^T \frac{E(\hat{z})\alpha(\hat{z})\Delta T(\hat{z})}{1-\nu}\begin{bmatrix} 1 \\ 1 \\ 0 \end{bmatrix} dV = 0. \tag{72}$$

[2]The inclusion of external loads can be done in a standard manner [18] and does not introduce any complications.

The first term on the RHS is devoted to the element stiffness matrix (Sect. 2.2.3 and Sect. 2.2.4), while the second part refers to internal forces and couples caused by thermal loading, which can be simplified according to

$$\delta\Pi_t = \int\limits_{V_e} \left[\begin{array}{cc} \delta\epsilon_{\hat{x}\hat{x}} & \delta\epsilon_{\hat{y}\hat{y}} \end{array}\right] \frac{E(\hat{z})\alpha(\hat{z})\Delta T(\hat{z})}{1-\nu} \left[\begin{array}{c} 1 \\ 1 \end{array}\right] dV. \tag{73}$$

The virtual normal-strain field is related to virtual displacements and rotations according to $\left[\begin{array}{cc} \delta\epsilon_{\hat{x}\hat{x}} & \delta\epsilon_{\hat{y}\hat{y}} \end{array}\right] = \left[\begin{array}{cc} \delta u_{\hat{x},\hat{x}} + \hat{z}\varphi_{\hat{y},\hat{x}} & \delta u_{\hat{y},\hat{y}} - \hat{z}\varphi_{\hat{x},\hat{y}} \end{array}\right]$. Interpolating the displacement and rotation field with classical bilinear shape-function (2),

$$\left[\begin{array}{c} u_{\hat{x}} \\ u_{\hat{y}} \end{array}\right] = \left[\begin{array}{cc} \mathbf{N} & \mathbf{0} \\ \mathbf{0} & \mathbf{N} \end{array}\right] \left[\begin{array}{c} \mathbf{U}_{\hat{x}} \\ \mathbf{U}_{\hat{y}} \end{array}\right] \text{ and } \left[\begin{array}{c} \varphi_{\hat{x}} \\ \varphi_{\hat{y}} \end{array}\right] = \left[\begin{array}{cc} \mathbf{N} & \mathbf{0} \\ \mathbf{0} & \mathbf{N} \end{array}\right] \left[\begin{array}{c} \mathbf{\Phi}_{\hat{x}} \\ \mathbf{\Phi}_{\hat{y}} \end{array}\right], \tag{74}$$

leads to

$$\delta\Pi_t = \left[\begin{array}{cc} \delta\mathbf{U}_{\hat{x}}^T & \delta\mathbf{U}_{\hat{y}}^T \end{array}\right] \left[\begin{array}{c} \mathbf{F}_{\hat{x}} \\ \mathbf{F}_{\hat{y}} \end{array}\right] + \left[\begin{array}{cc} \delta\mathbf{\Phi}_{\hat{x}}^T & \delta\mathbf{\Phi}_{\hat{y}}^T \end{array}\right] \left[\begin{array}{c} \mathbf{M}_{\hat{x}} \\ \mathbf{M}_{\hat{y}} \end{array}\right], \tag{75}$$

with

$$\begin{aligned} \mathbf{F}_{\hat{x}} &= \int\limits_{V_e} \mathbf{N}_{,\hat{x}} \frac{E(\hat{z})\alpha(\hat{z})\Delta T(\hat{z})}{1-\nu} dV \quad , \quad \mathbf{F}_{\hat{y}} = \int\limits_{V_e} \mathbf{N}_{,\hat{y}} \frac{E(\hat{z})\alpha(\hat{z})\Delta T(\hat{z})}{1-\nu} dV, \\ \mathbf{M}_{\hat{x}} &= -\int\limits_{V_e} \mathbf{N}_{,\hat{y}} \hat{z} \frac{E(\hat{z})\alpha(\hat{z})\Delta T(\hat{z})}{1-\nu} dV \quad , \quad \mathbf{M}_{\hat{y}} = \int\limits_{V_e} \mathbf{N}_{,\hat{x}} \hat{z} \frac{E(\hat{z})\alpha(\hat{z})\Delta T(\hat{z})}{1-\nu} dV. \end{aligned} \tag{76}$$

Differentiating the shape functions indicates that the integral over the element area can be carried out analytically, if the distributions of Young's modulus E, thermal expansion α and temperature ΔT are assumed to be constant. Thus, we get

$$\begin{aligned} \mathbf{F}_{\hat{x}} &= \frac{1}{2} \left[\begin{array}{c} \hat{y}_{24} \\ \hat{y}_{31} \\ \hat{y}_{42} \\ \hat{y}_{13} \end{array}\right] \int\limits_{-h/2}^{h/2} \frac{E(\hat{z})\alpha(\hat{z})\Delta T(\hat{z})}{1-\nu} d\hat{z} \quad , \quad \mathbf{F}_{\hat{y}} = \frac{1}{2} \left[\begin{array}{c} \hat{x}_{42} \\ \hat{x}_{13} \\ \hat{x}_{24} \\ \hat{x}_{31} \end{array}\right] \int\limits_{-h/2}^{h/2} \frac{E(\hat{z})\alpha(\hat{z})\Delta T(\hat{z})}{1-\nu} d\hat{z}, \\ \mathbf{M}_{\hat{x}} &= \frac{1}{2} \left[\begin{array}{c} \hat{x}_{24} \\ \hat{x}_{31} \\ \hat{x}_{42} \\ \hat{x}_{13} \end{array}\right] \int\limits_{-h/2}^{h/2} \hat{z} \frac{E(\hat{z})\alpha(\hat{z})\Delta T(\hat{z})}{1-\nu} d\hat{z} \quad , \quad \mathbf{M}_{\hat{y}} = \frac{1}{2} \left[\begin{array}{c} \hat{y}_{24} \\ \hat{y}_{31} \\ \hat{y}_{42} \\ \hat{y}_{13} \end{array}\right] \int\limits_{-h/2}^{h/2} \hat{z} \frac{E(\hat{z})\alpha(\hat{z})\Delta T(\hat{z})}{1-\nu} d\hat{z}. \end{aligned} \tag{77}$$

These element forces and couples refer to the discretized mid-surface and have to be transformed to the neutral surface by (50).

2.4 Stress evaluation

The stress components are evalutated element-wise at $\xi = \eta = 0$ based on an a posteriori procedure, requiring the nodal displacement and rotation vector in the elemental Cartesian base. The membrane strains at the elements center are evaluated with respect to the nodal degrees of freedom by

$$\left[\begin{array}{c} \epsilon_{\hat{x}\hat{x}} \\ \epsilon_{\hat{y}\hat{y}} \\ \gamma_{\hat{x}\hat{y}} \end{array}\right] = \left[\begin{array}{cc} \mathbf{b}_x & \mathbf{0} \\ \mathbf{0} & \mathbf{b}_y \\ \mathbf{b}_y & \mathbf{b}_x \end{array}\right] \left[\begin{array}{c} \mathbf{U}_{\hat{x}} \\ \mathbf{U}_{\hat{y}} \end{array}\right] + \hat{z}' \left[\begin{array}{cc} \mathbf{0} & \mathbf{b}_x^T \\ -\mathbf{b}_y^T & \mathbf{0} \\ -\mathbf{b}_x^T & \mathbf{b}_y^T \end{array}\right] \left[\begin{array}{c} \mathbf{\Phi}_{\hat{x}} \\ \mathbf{\Phi}_{\hat{y}} \end{array}\right]. \tag{78}$$

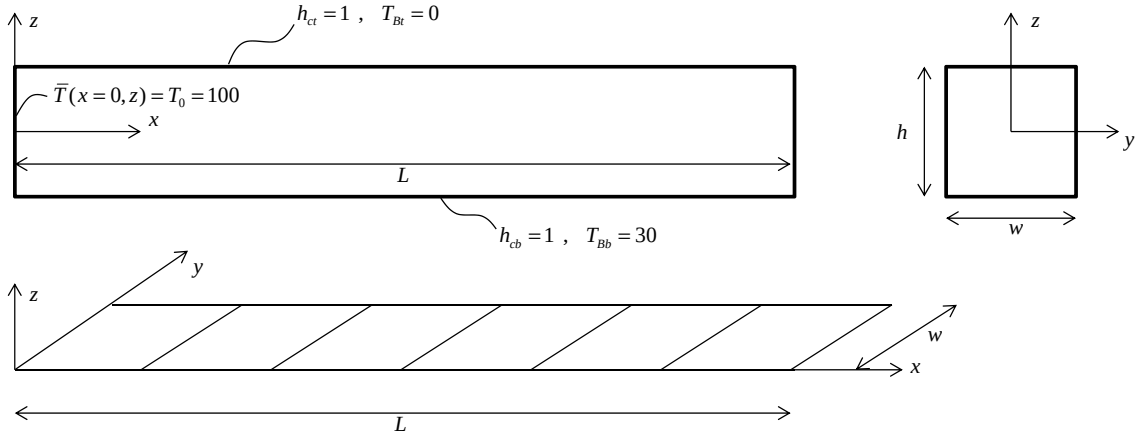

Figure 5: FGM fin with a discretization of $N = 6$

Consequently, the membrane stresses are found by applying the constitutive relation (71),

$$\begin{bmatrix} \sigma_{\hat{x}\hat{x}} \\ \sigma_{\hat{y}\hat{y}} \\ \sigma_{\hat{x}\hat{y}} \end{bmatrix} = \frac{E(\hat{z}')}{1-\nu^2} \begin{bmatrix} 1 & \nu & 0 \\ \nu & 1 & 0 \\ 0 & 0 & \frac{1-\nu}{2} \end{bmatrix} \begin{bmatrix} \epsilon_{\hat{x}\hat{x}} \\ \epsilon_{\hat{y}\hat{y}} \\ \epsilon_{\hat{x}\hat{y}} \end{bmatrix} - \frac{E(\hat{z}')\alpha(\hat{z}')\Delta T(\hat{z}')}{1-\nu} \begin{bmatrix} 1 \\ 1 \\ 0 \end{bmatrix}.$$

The definition of transverse shear strains read $\gamma_{\hat{x}\hat{z}} = u_{\hat{z},\hat{x}} + \varphi_{\hat{y}}$ and $\gamma_{\hat{y}\hat{z}} = u_{\hat{z},\hat{y}} - \varphi_{\hat{x}}$. The transverse displacement and the two bending angles are interpolated with classical bilinear shape functions yielding to the following estimates of the averaged shear strains

$$\begin{bmatrix} \overline{\gamma}_{\hat{x}\hat{z}} \\ \overline{\gamma}_{\hat{y}\hat{z}} \end{bmatrix} = \begin{bmatrix} \mathbf{b}_x \\ \mathbf{b}_y \end{bmatrix} \mathbf{U}_{\hat{z}} + \begin{bmatrix} 1/4 \sum_{i=1}^{4} \phi_{\hat{y}i} \\ -1/4 \sum_{i=1}^{4} \phi_{\hat{x}i} \end{bmatrix}. \tag{79}$$

Accordingly, the averaged shear stresses read $\overline{\tau}_{i\hat{z}} = \frac{E_b(\xi=\eta=0)}{2(1+\nu)}\overline{\gamma}_{i\hat{z}}$ for $i = \hat{x}, \hat{y}$, and the integrated shear force is given by $s_i = \alpha_s h \overline{\tau}_{i\hat{z}}$. Finally, we evaluate the shear stress distribution from

$$\tau_{i\hat{z}}(\hat{z}') = \frac{12 s_i}{E_b h^3} \int_{\hat{z}'}^{h/2-\overline{z}} E(\zeta)\zeta d\zeta \quad , \quad \gamma_{i\hat{z}}(\hat{z}') = \frac{2(1+\nu)\tau_{i\hat{z}}(\hat{z}')}{E(z')}, \tag{80}$$

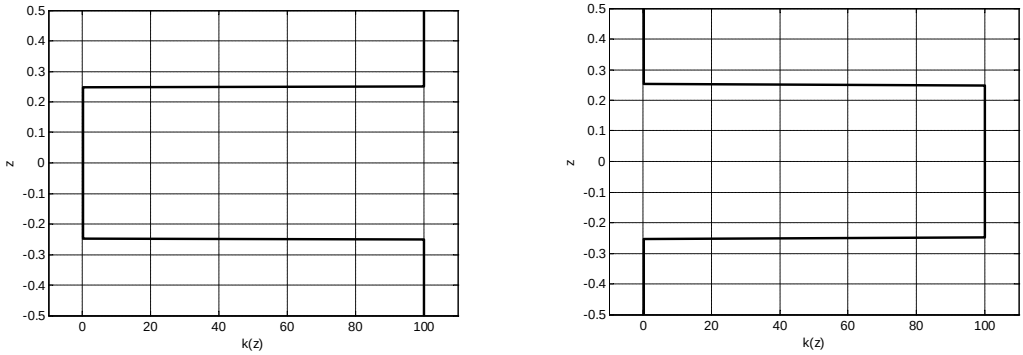
see [15]

3 Benchmark examples

In this Section we compare the proposed formulation to continuum solutions evaluated by ANSYS. A main issue of this paper is the correct estimation of temperature distributions based on the procedures discussed in Sect. 2.1. Consequently, a pure thermal problem is discussed in Sect. 3.1, which shows interesting results for two MLC structures with the same mean value of thermal conductivity. More examples can be found in [25].

3.1 Temperature distributions in a MLC fin

Consider a rectangular MLC structure of length $L = 10$, width $w = 1$ and height $h = 1$ shown in Fig. 5, which is discretized with N elements. On the top and bottom surface ($z = \pm h/2$) there is convection with $h_{ct} = h_{cb} = 1$ and a fluid temperature $T_{Bt} = 0$ and $T_{Bb} = 30$, while at the left end $x = 0$ the temperature is set to $\bar{T}(x = 0, z) = T_0 = 100$.



(a) Configuration 1 (b) Configuration 2

Figure 6: Distribution of thermal conductivity of layered fin

Interval in transverse direction	Configuration 1	Configuration 2
$-0.5 \leq z \leq -0.25$	$k = 100$	$k = 0.1$
$-0.25 \leq z \leq 0$	$k = 0.1$	$k = 100$
$0 \leq z \leq 0.25$	$k = 0.1$	$k = 100$
$0.25 \leq z \leq 0.5$	$k = 100$	$k = 0.1$

Table 1: Conductivity distribution

The fin is composed of four equidistant layers of height $h_L = {}^{h}/_{4}$, with two different thermal conductivities. We compare two symmetric configurations (i.e. Configuration 1 and Configuration 2) according to Tab. 1 (see Fig. 6). Configuration 1 is characterized by a high thermal conductivity on the top and bottom layer, while Configuration 2 has nearly isolating outside layers. The mean value $\overline{k}$ of thermal conductivity is equal for both configurations and classical approaches from literature assuming a constant temperature in thickness direction lead to equal temperature distributions in membrane direction for both configurations. The reference results are evaluated using ANSYS by discretizing the $x - z$ plane with 500×100 PLANE55 elements [28]. The application of the Dirichlet boundary condition, i.e. $T(x = 0, z) = T_0$, is in contrast to the applied convection boundary conditions at $x = 0$, $z = \pm {}^{h}/_{2}$, since the thermal gradient with respect to the thickness direction is not vanishing on the top and bottom side. Therefore, we apply a von Neumann boundary condition onto the ANSYS model based on Fourier's law, i.e.

$$q_n(x = 0,\, z) = -k(z)\bar{T}_{,x} = Ck(z), \tag{81}$$

where the constant C is found iteratively so that the evaluated mean value of the temperature distribution at $x = 0$ equals T_0. By this we obtain

$$\text{Config. 1: } q_n^{(1)}(x = 0,\, z) = -16.3613k(z), \tag{82}$$

$$\text{Config. 2: } q_n^{(2)}(x = 0,\, z) = -8.7069k(z). \tag{83}$$

The distribution of the mean value of temperature is depicted in Fig. 7, where we used $N = 20$ shell elements in membrane direction and ten elements through each layer in transverse direction ($n = 40$). The solid line corresponds to the present approach, while the dots refer to the ANSYS solution. Figure 7 indicates excellent accuracy of the proposed solution algorithm for

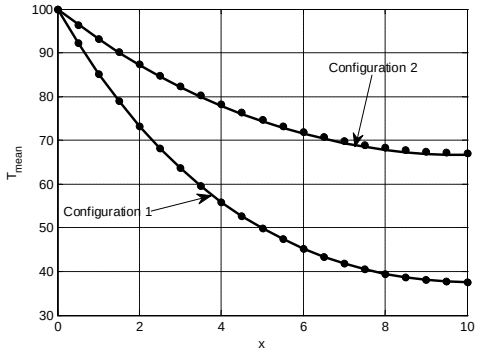


Figure 7: Mean temperature distribution of both configurations $N = 20,\ n = 40$

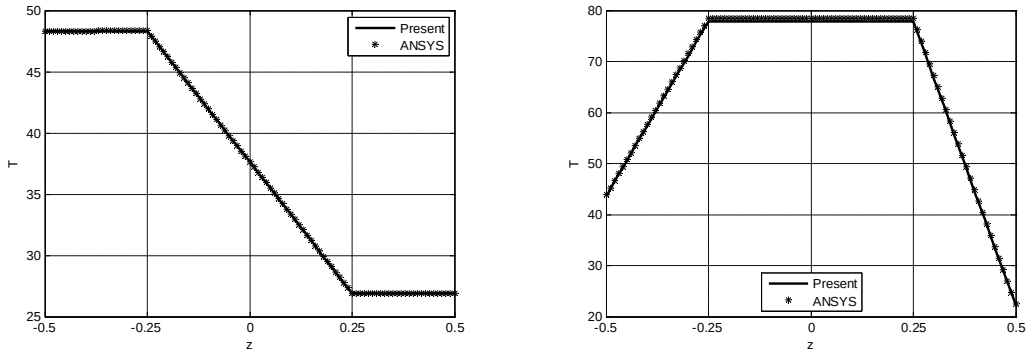

(a) Configuration 1 (b) Configuration 2

Figure 8: Temperature distribution in transverse direction at $x = L$, ($N = 20,\ n = 40$)

both configurations, and we observe large differences between the two configurations, even if the average value of the thermal conductivity is identical. The temperature distribution in transverse direction is shown in Fig. 8, and, again, indicates a good predictive quality of the proposed approach. The crucial step in our derivation is the iterative solution procedure discussed on page 5. The convergence rate is depicted in Fig. 9 for both configurations. We observe that in case of Configuration 2 (low conductivity on the top and bottom layer) about ten iterations are required to get accurate results, while Configuration 1 requires only two iterations.

3.2 Thermo-elastic analysis of a bi-quadratic FGM beam

In this example, originated by Lü et al. [29], a bi-directional FGM beam ($L = 0.1,\ h = w = 0.01$) depicted in Fig. 10 is analyzed. The state equations vary exponentially along the axial and transverse direction,

$$E(x, z) = E_0 e^{\alpha_1 x + \alpha_3 (z + h/2)}, \tag{84}$$

$$\beta(x, z) = \beta_0 e^{ax + b(z + h/2)}, \tag{85}$$

where β denotes the thermal stress constant,

$$\beta(x, z) = \frac{E(x, z)\alpha(x, z)}{1 - \nu}. \tag{86}$$

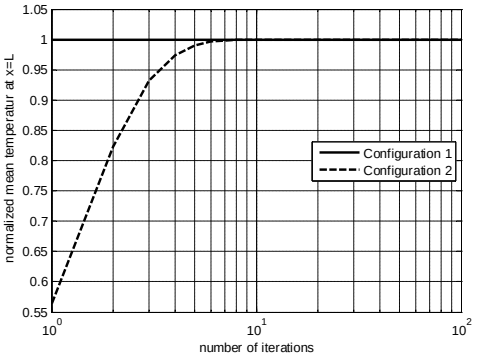

Figure 9: Convergence with respect to the number of iterations at $x = L$, ($N = 20$, $n = 40$)

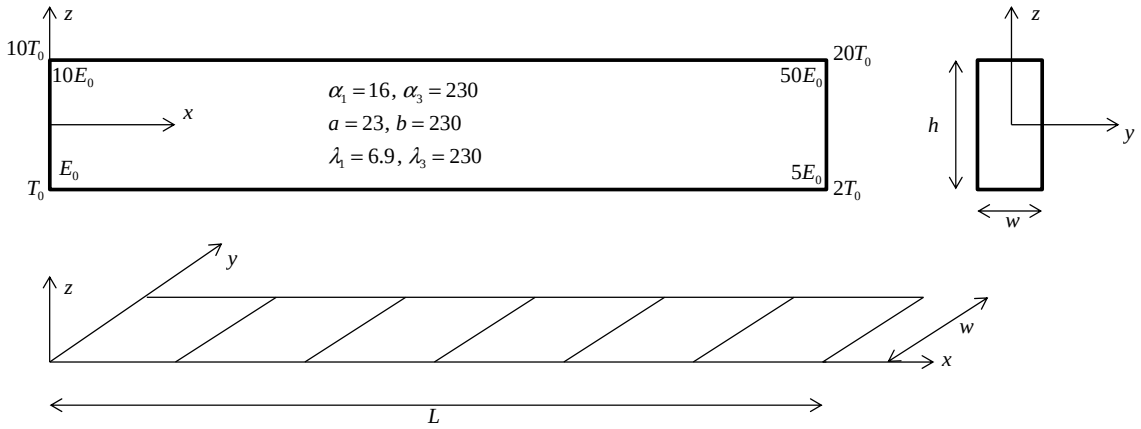

Figure 10: The schematic representation of a bi-quardratic FGM beam

Poisson's ratio is assumed to be constant $\nu = 0.25$ and the temperature field is prescribed by

$$T(x, z) = T_0 e^{\lambda_1 x + \lambda_3 (z + h/2)}. \tag{87}$$

We choose $E_0 = 1$, while β_0 is defined by $\beta_0 T_0 = \frac{10^{-4} E_0}{1-\nu}$. A clamped-clamped situation is analyzed. This example is solved analytically by Lü et al. [29] based on a two-dimensional thermo-elastic model. Lezgy-Nazargah [30] analyzed the same problem using a fully coupled isogeometric two-dimensional finite element approach. For sake of comparison we consider an ANSYS solution with a very fine mesh (1000x100) of fully integrated quadrilateral plane stress elements. A study of the transverse displacements is depicted in Fig. 11. We observe a close agreement of the evaluated bending line compared to ANSYS (Fig. 11(a)). A convergence study with respect to the number of elements over the length N and thickness n is given in Fig. 11(b), indicating a fast rate of convergence. For $N = n \geq 6$ a relative error of less than $\pm 3\%$ is provided, while the present approach converges to a 3% stiffer solution compared to ANSYS. In Fig. 12 the stress distributions at $x = L/2$ are compared to ANSYS and to the solutions published in [29, 30]. The axial thermal stress distribution σ_{xx} is in good agreement compared to the reference solutions (see Fig. 12(a)). The transverse shear stress distributions τ_{xz} are less accurate (see Fig. 12(b)). Considering the maximum shear the analytical solutions of Lü et al. are in good agreement to ANSYS, Lezgy-Nazargah's results show a relative error of 13%, while our proposed algorithm delivers a relative error of 10%. A qualitative comparison indicates that our peak stress is located at $z = 0.0018$ (neutral plane) while the continuum solutions show a

peak-location of $z = 0.0023$. This may stem from stress rearrangements in the two-dimensional regime which are not covered in our proposed approach.

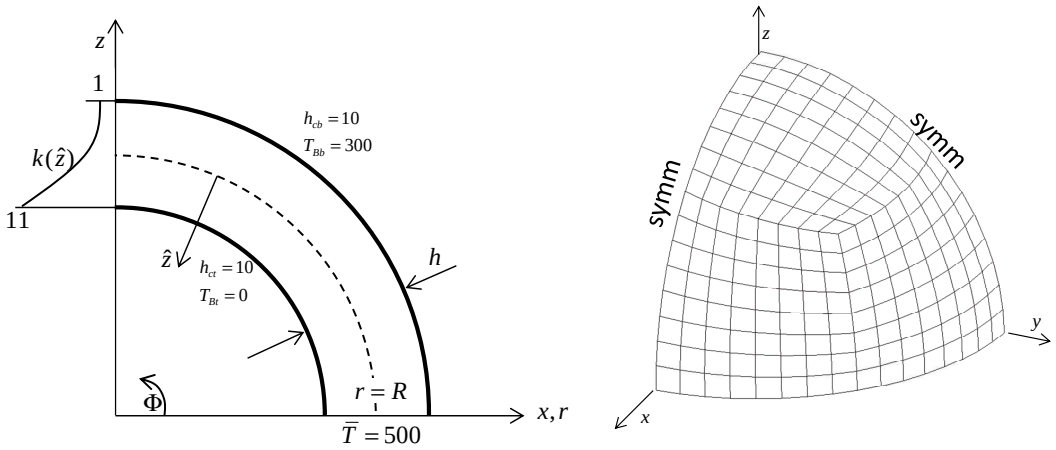
3.3 FGM shell structure

Consider a hemisphere with a radius $R = 10$ and a thickness of $h = 0.5$ (Fig. 13(a)). Due to symmetry only one quarter of the structure is discretized by a mesh according to Fig. 13(b). The material properties and boundary conditions depend only on the radial coordinate r, thus, only one quarter of the structure needs to be analyzed[3]. The model is loaded at the inner and outer surface with a convection boundary condition,

$$h_{ct} = h_{cb} = 10 \ , \ \ T_{Bt} = 0 \ , \ \ T_{Bb} = 300. \tag{88}$$

At the equator the mean temperature is kept at $\overline{T} = 500$. Due to these thermal boundary conditions we expect strong variations of temperature in thickness direction $\hat{z}$ and in membrane

[3]This axisymmetric problem could be analyzed with less than a quarter, however, in order to check the performance of the proposed formulation regarding warped element configurations, we use on quarter of the structure.



(a) FGM shell structure (b) Shell mesh: $N = 192$

Figure 13: Problem description - FGM shell structure

	u_r	u_z	Error in u_r	Error in u_z
ANSYS	0.2104	-0.1256	-	-
Present $N = 48$ elements	0.2646	-0.1216	25.7%	3.2%
Present $N = 192$ elements	0.2261	-0.1211	7.5%	3.6%
Present $N = 768$ elements	0.2100	-0.1210	0.2%	3.7%

Table 2: Displacements of FGM shell structure

direction ϕ. The material parameters show only spatial variations of the thermal conductivity,

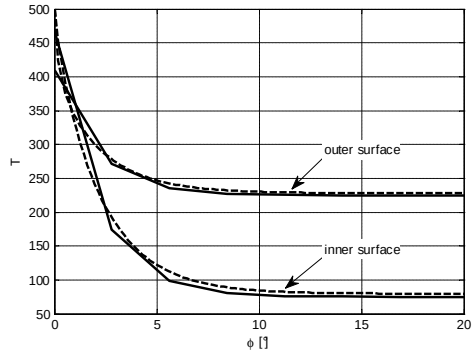
$$k(\hat{z}) = 3.5 + 20\hat{z} + 40\hat{z}^2, \tag{89}$$

representing a parabolic distribution with low conductivity at the outside, $k(\hat{z} = -h/2) = 1$, and high conductivity at the inner surface, $k(\hat{z} = h/2) = 11$. Since we focus mainly on temperature effects Young's modulus E, Poisson's ratio ν and thermal expansion α are assumed constant with respect to the thickness direction, i.e.

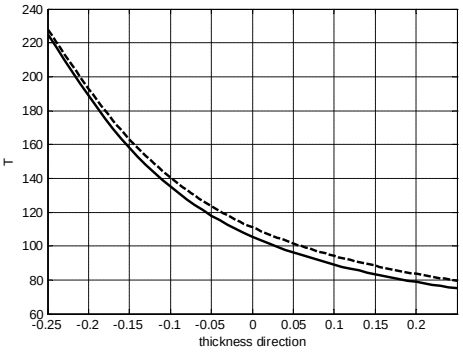
$$E = 10 \ , \ \ \nu = 0.3 \ , \ \ \alpha = 1 \cdot 10^{-4}. \tag{90}$$

Elastic solutions of an FGM hemisphere with a varying Young's modulus can be found in [16]. The reference results are evaluated using an axisymmetric model in ANSYS with the fully coupled PLANE 13 element and a very fine discretization of 100×500. For sake of convenience we apply a thermal Dirichlet boundary condition of $T(R - h/2 \leq x \leq R + h/2) = 500$ accepting some error discussed in Sect. 3.1. The temperature distributions with respect to the meridian $0 \leq \phi \leq 90$ are shown in Fig. 14(a). Due to high[4] convection coefficients $h_{cb} = h_{ct} = 10$ the results do not show any variations for $\phi > 20$. The temperature field with respect to the thickness direction is depicted in Fig. 14(b). The distributions evaluated with the present formulation (solid lines) are compared to the ANSYS solutions, indicting a good accuracy. The displacements in radial direction u_r and in height direction u_z are listed in Tab. 2 for different numbers of shell elements. We observe a clear convergence with respect to N for displacements

[4]The term "high" can not be seen absolutely, however, it causes large thermal gradients with respect to the meridian direction ϕ.



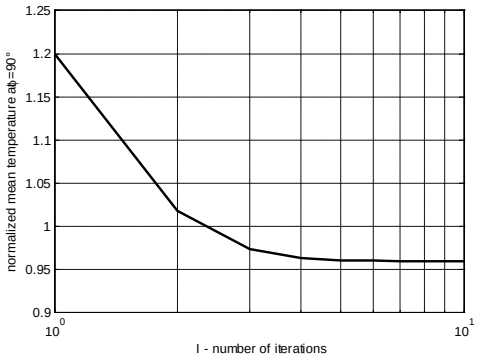
(a) Temperature distribution along the meridian



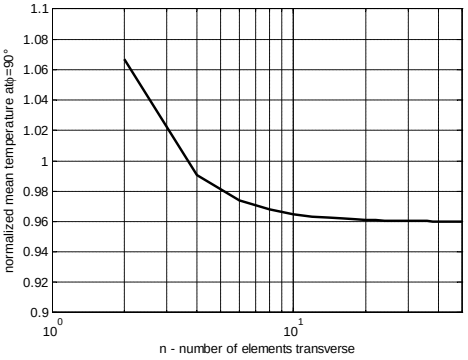
(b) Temperature distribution with respect to $\hat{z}$ at $\phi = 90$

Figure 14: Temperature distributions in FGM shell structure (Solid line: Present formulation, Dashed line: ANSYS) - $N = 768$, $n = 50$, $I = 10$

in radial direction leading to very accurate results for $N = 768$. In terms of displacements in height direction some error of $< 4\%$ has to be accepted. Since a main issue of the proposed



(a) Convergence of $\overline{T}$ at $\phi = 90$ with respect to I



(b) Convergence of $\overline{T}$ at $\phi = 90$ with respect to n

Figure 15: Convergence issues in FGM shell structure

procedure is the iterative strategy discussed on page 5, the convergence of mean temperature $\overline{T}$ (normalized to the ANSYS result) at $\phi = 90$ with respect to the number of iterations I is studied in Fig. 15(a). There, a stable value is reached after six iterations. A final error of less than four percent is also indicated in Fig. 14 and stems from the large temperature gradient in meridian direction at the equator, which may not be resolved properly with low numbers of N. Figure 15(b) indicates convergence with respect to the number of elements discretizing the transverse direction. Obviously, using fifty elements in transverse direction leads to accurate solutions.

4 Conclusion

In this paper a novel approach to the evaluation of thermo-elastic effects in FGM or multi-layer shell structures is proposed. The temperature field is evaluated by an iterative procedure assuming non-constant temperature variations with respect to the thickness direction. A key issue is the decomposition of $T(\hat{x}, \hat{y}, \hat{z})$ according to (11). The resulting displacement fields are evaluated with the aid of a quadrilateral shell element based on effective elastic quantities.

Suitable projection schemes enable an independent derivation of the membrane and the plate bending part. Drilling rotations are included based on an enlarged functional, where the symmetry of stress and strain is enforced only in a weak sense. Special strain field interpolations ensure that all parts of the stiffness matrix can be given analytically even for arbitrarily shaped element configurations, thus, any Gaussian quadrature is avoided. It is shown that thermal expansion causes internal forces and couples, which are applied onto the proposed shell element. The resulting analysis procedure can be termed efficient and leads to accurate results compared to ANSYS solutions where continuum formulations are used.

Keywords: Piezoelectric Material, FGM, FEM, Beam Element, Transient Analysis

Abstract. *New smart materials have been developed in material science, that are suitable for mechatronic applications. Modern mechatronic systems are focusing on minimizing size, active control and low energy consumption. All this attributes can be incorporated into term Micro Electro Mechanical Systems (MEMS). To improve performance of MEMS system, new materials and technologies are developed - one of them, which found broad application usage is Functionally graded material (FGM). MEMS application usually contains multilayer structure and in some application class MEMS systems contain piezoelectric layers. Piezoelectric structures offer facilities to make motions. Piezoelectric layers can be also used to damp vibrations as an active damping or as an active sensor. For better understanding these multiphysical problems new mathematical models are developed.*

The paper deals with finite beam element with piezoelectric layers and functionally graded material of core. In the paper homogenization of FGM material properties and homogenization of core and piezoelectric layers is presented. In the process of homogenization direct integration method and multilayer method is used. There is also presented the derivation of individual submatrices of local stiffness and mass matrix, where concept of transfer constants is used. Functionality of new FGM finite beam with piezoelectric layers is presented by numerical experiments.

1 INTRODUCTION

New materials have been introduced in the area of mechanisms and mechatronic applications. Contemporary mechanical systems are focusing on minimizing size, active control and low energy consumption. All these attributes can be incorporated into term Micro Electro Mechanical System (MEMS). MEMS applications usually contain multilayer structure and some of these layers can have piezoelectric properties. Piezoelectric structures offer facilities to make motions or they can be used to damp vibrations as an active damper or as an active sensor.

2 PIEZOELECTRIC CONSTITUTIVE EQUATIONS

Piezoelectric constitutive equations describe the relationship between mechanical and electrical quantities [1]. This relationship is derived in tensor notation, but for practical usage it can be rewritten into matrices notation.

2.1 Tensor notation of piezoelectric constitutive equations

The form of the constitutive equations depends on chosen mechanical and electrical quantities and can be expressed in two basic configurations [2]. The first configuration is expressed by mechanical stress tensor components σ_{kl} and vector components of electric intensity E_k and has a form

$$D_i = \epsilon^{\sigma}_{ik} E_k + d_{ikl}\sigma_{kl} \tag{1}$$

$$\varepsilon_{ij} = d_{ijk} E_k + s^{E}_{ijkl}\sigma_{kl} \tag{2}$$

where ε_{ij} are strain tensor components, D_i are components of electric displacement vector, d_{ikl} are tensor components of piezoelectric constants, ϵ^{σ}_{ik} are components of permittivity tensor under constant mechanical stress and s^{E}_{ijkl} are components of compliance tensor under constant electric intensity.
The constitutive equations can be also expressed by strain tensor components ε_{kl} and vector components of electric intensity E_k and has a form

$$\sigma_{ij} = c^{E}_{ijkl}\varepsilon_{kl} - e_{ijk} E_k \tag{3}$$

$$D_i = e_{ikl}\varepsilon_{kl} + \epsilon^{\varepsilon}_{ik} E_k \tag{4}$$

where new quantities are components of stiffness tensor under constant electric intensity c^{E}_{ijkl} and components of piezoelectric modulus tensor e_{ijk}.

2.2 Matrix notation of piezoelectric constitutive equations

If we use symmetric properties of individual tensor in constitutive tensor equations, we can rewrite constitutive equations into matrix notation [3]. Then equations (1) and (2) have a form

$$D_i = \epsilon^{\sigma}_{ik} E_k + d_{iq}\sigma_q \tag{5}$$

$$\varepsilon_p = d_{pk} E_k + s^{E}_{pq}\sigma_q \tag{6}$$

and equations (3) and (4) can be rewritten in the form

$$\sigma_p = c^{E}_{pq}\varepsilon_q - e_{pk} E_k \tag{7}$$

$$D_i = e_{iq}\varepsilon_q + \epsilon^{\varepsilon}_{ik} E_k \tag{8}$$

D_i and E_k are vectors with three components, σ_q and ε_q are vectors with six components, matrices s^E_{pq} and c^E_{pq} have dimension 6×6, matrices d_{iq} and e_{pk} have dimension 3×6 and matrix $\epsilon^{\varepsilon}_{ik}$ has dimension 3×3. Constitutive equations (5) and (6) written in a component form can be rewritten as

$$\boldsymbol{\varepsilon} = \mathbf{s}^E \boldsymbol{\sigma} + \mathbf{d}^T \mathbf{E} \tag{9}$$

$$\mathbf{D} = \mathbf{d}\boldsymbol{\sigma} + \boldsymbol{\epsilon}^{\sigma} \mathbf{E} \tag{10}$$

and equations (7) and (8) can be rewritten as

$$\boldsymbol{\sigma} = \mathbf{c}^E \boldsymbol{\varepsilon} - \mathbf{e}^T \mathbf{E} \tag{11}$$

$$\mathbf{D} = \mathbf{e}\boldsymbol{\varepsilon} + \boldsymbol{\epsilon}^{\varepsilon} \mathbf{E} \tag{12}$$

3 BASIC FEM EQUATIONS FOR PIEZOELECTRIC STRUCTURE

To obtain basic FEM equations for piezoelectric structure, the Hamilton's principle is used and can be expressed in the form

$$\int_{t_1}^{t_2} (\delta L + \delta W)\, dt = 0 \tag{13}$$

where L is Lagrangian, W is work of external mechanical and electrical forces and t_1 and t_2 defined considered time interval.
Lagrangian of piezoelectric structure is given by

$$\begin{aligned} L =& T - U + W_e = \\ &= \int_V \frac{1}{2} \rho \dot{\mathbf{u}}^T \dot{\mathbf{u}} dV - \int_V \frac{1}{2} \boldsymbol{\varepsilon}^T \boldsymbol{\sigma} dV + \int_V \frac{1}{2} \mathbf{E}^T \mathbf{D} dV \end{aligned} \tag{14}$$

where T is kinetic energy of structure, U is potential energy of structure and W_e is electric energy stored in piezoelectric material. In kinetic energy term $\dot{\mathbf{u}}$ represents velocity vector.
Virtual work of external mechanical and electrical forces can be expressed as

$$\delta W = \sum \left(\delta \mathbf{u}^T \mathbf{F}\right) - \sum \left(\delta \boldsymbol{\phi}^T \mathbf{Q}\right) \tag{15}$$

where $\mathbf{F}$ and $\mathbf{Q}$ represents discrete forces and electric charges, respectively and $\mathbf{u}$ and $\boldsymbol{\phi}$ are displacement vector and scalar electric potential, respectively.
Equation (13) can be rewritten using (14) and (15)

$$\begin{aligned} \int_{t_1}^{t_2} \Bigg[& \delta \int_V \frac{1}{2} \rho \dot{\mathbf{u}}^T \dot{\mathbf{u}} dV - \delta \int_V \frac{1}{2} \boldsymbol{\varepsilon}^T \boldsymbol{\sigma} dV + \delta \int_V \frac{1}{2} \mathbf{E}^T \mathbf{D} dV + \\ & + \sum \left(\delta \mathbf{u}^T \mathbf{F}\right) - \sum \left(\delta \boldsymbol{\phi}^T \mathbf{Q}\right) \Bigg] dt = 0 \end{aligned} \tag{16}$$

After some manipulation and using constitutive equations (11) and (12) Hamilton's principle for piezoelectric system can be expressed in form

$$\begin{aligned} \int_{t_1}^{t_2} \Bigg[& - \int_V \rho \delta \mathbf{u}^T \ddot{\mathbf{u}} dV - \int_V \delta \boldsymbol{\varepsilon}^T \mathbf{c}^E \boldsymbol{\varepsilon} dV + \int_V \delta \boldsymbol{\varepsilon}^T \mathbf{e}^T \mathbf{E} dV + \int_V \delta \mathbf{E}^T \mathbf{e} \boldsymbol{\varepsilon} dV + \\ & + \int_V \delta \mathbf{E}^T \boldsymbol{\epsilon}^{\varepsilon} \mathbf{E} dV + \sum \left(\delta \mathbf{u}^T \mathbf{F}\right) - \sum \left(\delta \boldsymbol{\phi}^T \mathbf{Q}\right) \Bigg] dt = 0 \end{aligned} \tag{17}$$

Using shape functions ($\mathbf{N}_u$, $\mathbf{N}_\phi$), we can write relationship between displacement of point and nodal displacement of finite element and between scalar electric potential of point and nodal scalar electric potential of finite element

$$\mathbf{u} = \mathbf{N}_u \mathbf{u}^e \tag{18}$$

$$\boldsymbol{\phi} = \mathbf{N}_\phi \boldsymbol{\phi}^e \tag{19}$$

Relationship between components of strain and components of nodal displacements has form

$$\boldsymbol{\varepsilon} = \mathbf{B}_u \mathbf{u}^e \tag{20}$$

Similarly relationship between components of electric field intensity and components of nodal potential can be written as

$$\mathbf{E} = -\mathbf{B}_\phi \boldsymbol{\phi}^e \tag{21}$$

Virtual strain and virtual electric field intensity can be expressed as

$$\delta\boldsymbol{\varepsilon} = \mathbf{B}_u \delta\mathbf{u}^e \tag{22}$$

$$\delta\mathbf{E} = -\mathbf{B}_\phi \delta\boldsymbol{\phi}^e \tag{23}$$

Equation (17) can be modified using equations (18)-(23)

$$\begin{aligned}
&\int_{t_1}^{t_2} \delta(\mathbf{u}^e)^T \left[-\left(\int_{V^e} \mathbf{N}_u^T \rho \mathbf{N}_u dV \right) \ddot{\mathbf{u}}^e - \left(\int_{V^e} \mathbf{B}_u^T \mathbf{c}^E \mathbf{B}_u dV \right) \mathbf{u}^e - \right. \\
&\left. - \left(\int_{V^e} \mathbf{B}_u^T \mathbf{e}^T \mathbf{B}_\phi dV \right) \boldsymbol{\phi}^e + \mathbf{N}_u^T \mathbf{F} \right] dt + \\
&+ \int_{t_1}^{t_2} \delta(\boldsymbol{\phi}^e)^T \left[\left(-\int_{V^e} \mathbf{B}_\phi^T \mathbf{e} \mathbf{B}_u dV \right) \mathbf{u}^e + \left(\int_{V^e} \mathbf{B}_\phi^T \boldsymbol{\epsilon}^\varepsilon \mathbf{B}_\phi dV \right) \boldsymbol{\phi}^e - \mathbf{N}_\phi^T \mathbf{Q} \right] dt = 0
\end{aligned} \tag{24}$$

From equations (24) we obtain finite element equations for piezoelectric analysis

$$\begin{bmatrix} \mathbf{M}_{uu}^e & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \ddot{\mathbf{u}}^e \\ \ddot{\boldsymbol{\phi}}^e \end{bmatrix} + \begin{bmatrix} \mathbf{C}_{uu}^e & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \dot{\mathbf{u}}^e \\ \dot{\boldsymbol{\phi}}^e \end{bmatrix} + \begin{bmatrix} \mathbf{K}_{uu}^e & \mathbf{K}_{u\phi}^e \\ \mathbf{K}_{\phi u}^e & \mathbf{K}_{\phi\phi}^e \end{bmatrix} \begin{bmatrix} \mathbf{u}^e \\ \boldsymbol{\phi}^e \end{bmatrix} = \begin{bmatrix} \mathbf{F}^e \\ \mathbf{Q}^e \end{bmatrix} \tag{25}$$

where

$$\mathbf{M}_{uu}^e = \int_V \mathbf{N}_u^T \rho \mathbf{N}_u dV \tag{26}$$

$$\mathbf{K}_{uu}^e = \int_V \mathbf{B}_u^T \mathbf{c}^E \mathbf{B}_u dV \tag{27}$$

$$\mathbf{K}_{u\phi}^e = \int_V \mathbf{B}_u^T \mathbf{e}^T \mathbf{B}_\phi dV \tag{28}$$

$$\mathbf{K}_{\phi u}^e = \int_V \mathbf{B}_\phi^T \mathbf{e} \mathbf{B}_u dV \tag{29}$$

$$\mathbf{K}_{\phi\phi}^e = -\int_V \mathbf{B}_\phi^T \boldsymbol{\epsilon}^\varepsilon \mathbf{B}_\phi dV \tag{30}$$

$$\mathbf{F}^e = \mathbf{N}_u^T \mathbf{F} \tag{31}$$

$$\mathbf{Q}^e = -\mathbf{N}_\phi^T \mathbf{Q} \tag{32}$$

4 FEM EQUATIONS OF FGM BEAM WITH PIEZOELECTRIC LAYERS

2D beam element with piezoelectric layers, where beam core is made from functionally graded material is shown in Figure 1, where all degrees of freedom are depicted. Mechanical degrees of freedom in each node are two displacements (in direction x a y) and rotation (in plane $x-y$) [6]. Electric degrees of freedom are electric potentials ϕ_i on 4 electrodes. The height of beam core made from FGM is h, the height of piezoelectric layer is h_p, the depth and the length of the beam element are b and L, respectively.
Material properties of FGM core are function of longitudinal and transversal coordinate x and y, material properties of piezoelectric layers are constants.

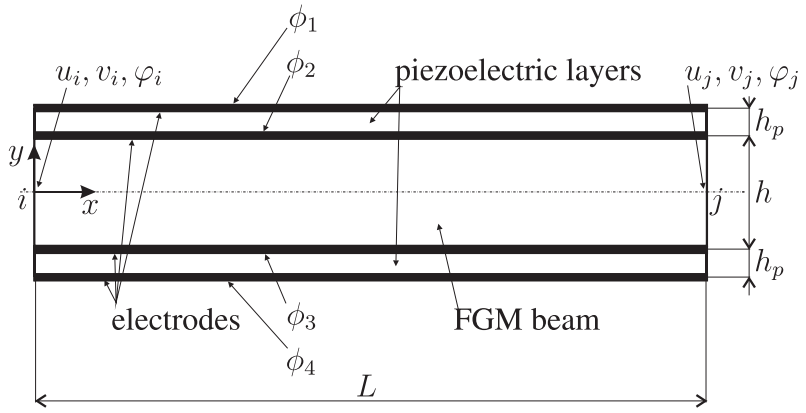

Figure 1: Electric DOF in 2D beam element

In order to derive individual submatrices of the beam element with piezoelectric layers and FGM core, two steps in homogenization process have to be performed. At first, homogenization of material properties of FGM core have to be performed, where direct integration method is used [6]. In the next step, homogenization of piezoelectric layers and homogenized FGM core (from step one) is performed. After these two operations, homogenized material properties of the beam vary through the length of the beam as a function of longitudinal coordinate x and are constant in transversal direction.

4.1 Equations for structural analysis

The structural submatrix $\mathbf{K}^e_{uu}$ for the beam element with piezoelectric layers can be expressed in a form

$$\mathbf{K}^e_{uu} = \begin{bmatrix} k'_u & 0 & 0 & -k'_u & 0 & 0 \\ & k'_{v2} & k'_{v3} & 0 & -k'_{v2} & k_{v2} \\ \mathrm{S} & & k'_{v33} & 0 & -k'_{v3} & k_{v3} \\ & \mathrm{Y} & & k'_u & 0 & 0 \\ & & \mathbf{M} & & k'_{v2} & -k_{v2} \\ & & & & & k_{v23} \end{bmatrix} \tag{33}$$

where individual components contain the influence of FGM core stiffness and also the influence of piezoelectric layers stiffness. The calculation of components is identical for classical multilayer or FGM beam without piezoelectric layer and is described in [6]. Mass matrix $\mathbf{M}^e_{uu}$ can be calculated numerically using classical shape functions and homogenized density of FGM beam with piezoelectric layers according equation (26).

4.2 Equations for electric analysis

Electric field intensity in piezoelectric layer is constant and for top layer can by expressed as [4, 5]

$$E_1 = -\frac{\partial \phi}{\partial y} = \frac{\phi_2 - \phi_1}{h_p} \tag{34}$$

and for bottom layer as

$$E_2 = -\frac{\partial \phi}{\partial y} = \frac{\phi_4 - \phi_3}{h_p} \tag{35}$$

Both components of electric field intensity can be written in a form

$$\mathbf{E} = \begin{bmatrix} E_1 \\ E_2 \end{bmatrix} = -\begin{bmatrix} 1/h_p & -1/h_p & 0 & 0 \\ 0 & 0 & 1/h_p & -1/h_p \end{bmatrix} \begin{bmatrix} \phi_1 \\ \phi_2 \\ \phi_3 \\ \phi_4 \end{bmatrix} = -\mathbf{B}_\phi \boldsymbol{\phi}^e \tag{36}$$

For 1D problems the matrix of material properties for electric field – permittivity is reduced to only one material property ϵ^ε, but because the beam element contains two identical layers, we can write

$$\boldsymbol{\epsilon}^{\boldsymbol{\varepsilon}} = \begin{bmatrix} \epsilon^\varepsilon & 0 \\ 0 & \epsilon^\varepsilon \end{bmatrix} \tag{37}$$

Then the equation (30) has a form

$$\mathbf{K}^e_{\phi\phi} = -\int_V \mathbf{B}^T_\phi \boldsymbol{\epsilon}^\varepsilon \mathbf{B}_\phi dV = -\int_L \mathbf{B}^T_\phi \boldsymbol{\epsilon}^\varepsilon \mathbf{B}_\phi A_p dx \tag{38}$$

where A_p is cross-section of one piezoelectric layer, i.e. $A_p = bh_p$.
After some mathematical manipulations the equation (38) can be expressed as

$$\mathbf{K}^e_{\phi\phi} = \begin{bmatrix} -\frac{A_p L \epsilon^\varepsilon}{h_p^2} & \frac{A_p L \epsilon^\varepsilon}{h_p^2} & 0 & 0 \\ \frac{A_p L \epsilon^\varepsilon}{h_p^2} & -\frac{A_p L \epsilon^\varepsilon}{h_p^2} & 0 & 0 \\ 0 & 0 & -\frac{A_p L \epsilon^\varepsilon}{h_p^2} & \frac{A_p L \epsilon^\varepsilon}{h_p^2} \\ 0 & 0 & \frac{A_p L \epsilon^\varepsilon}{h_p^2} & -\frac{A_p L \epsilon^\varepsilon}{h_p^2} \end{bmatrix} \tag{39}$$

4.3 Coupling of structural and electrical analysis

Piezoelectric material properties express coupling between mechanical and electrical field - matrices $\mathbf{e}$ or $\mathbf{d}$. The relationship between these two matrices can be expressed by elasticity matrix. In 1D problem in $x - y$ plane (in index notation $x_1 - x_2$) we have only one material property – e_{21} or d_{21}, where index 2 represents direction of piezoelectric layer polarization and also the direction of electric field intensity vector and index 1 defines direction of mechanical deformation. The relationship between these two quantities is reduced to expression $e_{21} = d_{21}E_p$ [7, 8], where E_p is Young modulus of elasticity of piezoelectric material. In reality, relationship between matrices $\mathbf{e}$ and $\mathbf{d}$ is more complicated and the quantity e_{21} computed from matrix $\mathbf{d}$ and elastic matrix for 3D system and the quantity e_{21} computed from d_{21} and E_p have

different values. Therefore if we have quantities e_{21} and d_{21} computed from matrix relationship, it is better to used them then simplified relationship.
Piezoelectric material properties of both piezoelectric layers are defined as

$$\mathbf{e} = \begin{bmatrix} e_{21} & 0 & -ye_{21} \\ e_{21} & 0 & -ye_{21} \end{bmatrix} \tag{40}$$

The expression $\mathbf{e}^T\mathbf{E}$ defines mechanical stress caused by piezoelectric effect. In the beam elements, internal quantities are not mechanical stress but internal forces and moments, then the first and the third column of matrix (40) multiplied by corresponding components of $\mathbf{B}_u$ and $\mathbf{B}_\phi$ as well as corresponding components of displacement $\mathbf{u}$ and potential $\boldsymbol{\phi}$ represents axial forces and bending moments, respectively.
Description of piezoelectric behaviour by e_{21} is more suitable for sensor equation – matrix $\mathbf{K}^e_{\phi u}$, description by d_{21} is more suitable for actuator equation – matrix $\mathbf{K}^e_{u\phi}$, i.e.

$$\mathbf{e} = \begin{bmatrix} d_{21}E_p & 0 & -yd_{21}E_p \\ d_{21}E_p & 0 & -yd_{21}E_p \end{bmatrix} \tag{41}$$

Using equations (40) and (41) we can write (28) and (29) in form

$$\mathbf{K}^e_{u\phi} = \begin{bmatrix} -\frac{A_p d_{21} E_p}{h_p} & \frac{A_p d_{21} E_p}{h_p} & -\frac{A_p d_{21} E_p}{h_p} & \frac{A_p d_{21} E_p}{h_p} \\ 0 & 0 & 0 & 0 \\ \frac{A_y d_{21} E_p}{h_p} & -\frac{A_y d_{21} E_p}{h_p} & \frac{A_y d_{21} E_p}{h_p} & -\frac{A_y d_{21} E_p}{h_p} \\ \frac{A_p d_{21} E_p}{h_p} & -\frac{A_p d_{21} E_p}{h_p} & \frac{A_p d_{21} E_p}{h_p} & -\frac{A_p d_{21} E_p}{h_p} \\ 0 & 0 & 0 & 0 \\ -\frac{A_y d_{21} E_p}{h_p} & \frac{A_y d_{21} E_p}{h_p} & -\frac{A_y d_{21} E_p}{h_p} & \frac{A_y d_{21} E_p}{h_p} \end{bmatrix} \tag{42}$$

and

$$\mathbf{K}^e_{\phi u} = \begin{bmatrix} -\frac{A_p e_{21}}{h_p} & 0 & \frac{A_y e_{21}}{h_p} & \frac{A_p e_{21}}{h_p} & 0 & -\frac{A_y e_{21}}{h_p} \\ \frac{A_p e_{21}}{h_p} & 0 & -\frac{A_y e_{21}}{h_p} & -\frac{A_p e_{21}}{h_p} & 0 & \frac{A_y e_{21}}{h_p} \\ -\frac{A_p e_{21}}{h_p} & 0 & \frac{A_y e_{21}}{h_p} & \frac{A_p e_{21}}{h_p} & 0 & -\frac{A_y e_{21}}{h_p} \\ \frac{A_p e_{21}}{h_p} & 0 & -\frac{A_y e_{21}}{h_p} & -\frac{A_p e_{21}}{h_p} & 0 & \frac{A_y e_{21}}{h_p} \end{bmatrix} \tag{43}$$

where parameter A_y represents first moment of cross-section of piezoelectric layer

$$A_y = \frac{1}{2} A_p (h + h_p) \tag{44}$$

4.4 FEM equations for the beam element with piezoelectric layers

FEM equations for beam element with piezoelectric layers and FGM core for transient analysis have classical form

$$\begin{bmatrix} \mathbf{M}^e_{uu} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \ddot{\mathbf{u}}^e \\ \ddot{\boldsymbol{\phi}}^e \end{bmatrix} + \begin{bmatrix} \mathbf{C}^e_{uu} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \dot{\mathbf{u}}^e \\ \dot{\boldsymbol{\phi}}^e \end{bmatrix} + \begin{bmatrix} \mathbf{K}^e_{uu} & \mathbf{K}^e_{u\phi} \\ \mathbf{K}^e_{\phi u} & \mathbf{K}^e_{\phi\phi} \end{bmatrix} \begin{bmatrix} \mathbf{u}^e \\ \boldsymbol{\phi}^e \end{bmatrix} = \begin{bmatrix} \mathbf{F}^e \\ \mathbf{Q}^e \end{bmatrix} \tag{45}$$

where individual submatrices are defined by (33), (39), (42) and (43), vector of nodal unknowns is defined as

$$\begin{bmatrix}\mathbf{u}^e\\ \boldsymbol{\phi}^e\end{bmatrix} = \begin{bmatrix}u_i & v_i & \varphi_i & u_j & v_j & \varphi_j & \phi_1 & \phi_2 & \phi_3 & \phi_4\end{bmatrix}^T \tag{46}$$

and vector of nodal loads is defined as

$$\begin{bmatrix}\mathbf{F}^e\\ \mathbf{Q}^e\end{bmatrix} = \begin{bmatrix}F_{xi} & F_{yi} & M_i & F_{xj} & F_{yj} & M_j & Q_1 & Q_2 & Q_3 & Q_4\end{bmatrix}^T \tag{47}$$

where Q_1, Q_2, Q_3 and Q_4 are electric charge on electrodes 1, 2, 3 and 4, respectively.

5 NUMERICAL EXAMPLES

All derived equations for FGM beam with piezoelectric layers were implemented in our FEM code MultiFEM.
In this section three numerical examples are presented:

- Example 1 – considered simple beam is made from FGM with attached piezoelectric layers, only static analysis is considered
- Example 2 – the same simple beam as in Example 1 is considered, but analysis is transient
- Example 3 – considered structure contains three beam parts with partially attached piezoelectric layers, two beam parts are made from FGM and one beam part has constant material properties

5.1 Material properties of FGM structure and piezoelectric layers

In all three examples, the same functionally graded material is considered. Material of matrix (index m) is NiFe with constant density and Young's modulus and material of fibre (fibre – index f) is tungsten with constant density and Young's modulus:

- Young's modulus: $E_m = 255$ GPa, $E_f = 400$ GPa
- density: $\rho_m = 9200$ kg/m^3, $\rho_f = 19300$ kg/m^3

Volume fractions of both constituents $v_m(x,y)$ and $v_f(x,y)$ vary along the length (axis x) and height (axis y) of beams according equations:

$$v_m(x,y) = -1.\overline{3}\times 10^8 x^3y^2 + 1333.\overline{3}x^3 + 2.\times 10^7 x^2y^2 - 200.x^2 - 40000.y^2 + 1. \quad [\text{-}] \tag{48}$$

$$v_f(x,y) = 1.\overline{3}\times 10^8 x^3y^2 - 1333.\overline{3}x^3 - 2.\times 10^7 x^2y^2 + 200.x^2 + 40000.y^2 \quad [\text{-}] \tag{49}$$

Both functions of volume fractions for beam with length 0.1 m and height 0.01 m are shown in Figure 2.

Effective material properties of FGM are defined by material properties of constituents and their variations and Young's modulus and density of considered FGM have form

$$\begin{aligned}E_{\text{FGM}}(x,y) =& 1.9\overline{3}\times 10^{19}x^3y^2 - 1.9\overline{3}\times 10^{14}x^3 - 2.9\times 10^{18}x^2y^2 + \\ &+ 2.9\times 10^{13}x^2 + 5.8\times 10^{15}y^2 + 2.55\times 10^{11} \quad [\text{Pa}]\end{aligned} \tag{50}$$

$$\begin{aligned}\rho_{\text{FGM}}(x,y) =& 1.34667\times 10^{12}x^3y^2 - 1.34667\times 10^{7}x^3 - 2.02\times 10^{11}x^2y^2 + \\ &+ 2.02\times 10^{6}x^2 + 4.04\times 10^{8}y^2 + 9200. \quad [\text{kg/m}^3]\end{aligned} \tag{51}$$

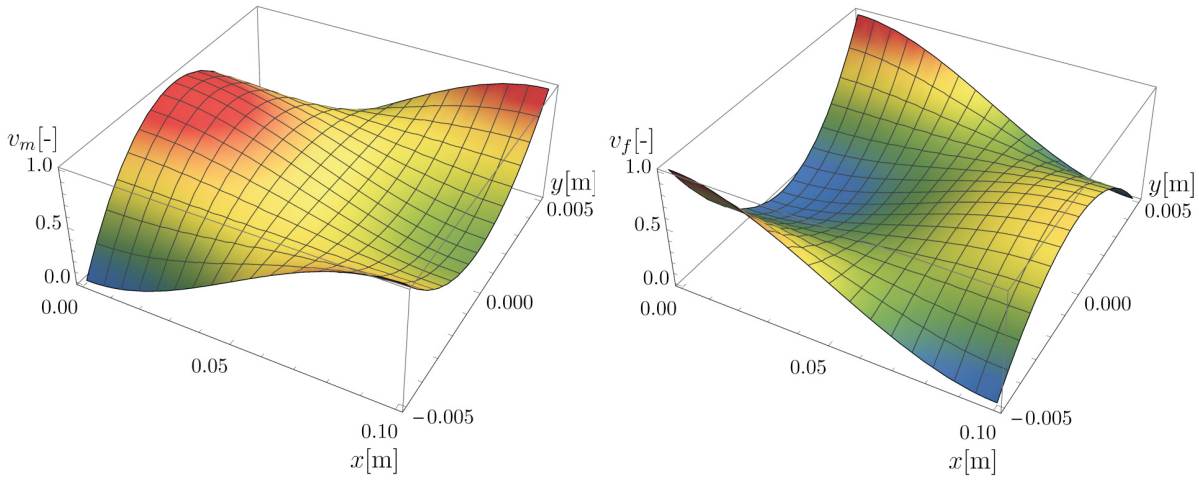

Figure 2: Left – volume fraction of matrix, right – volume fraction of fibre

In all three examples, height and depth of beam cross-section is 0.01m. Homogenized material properties of investigated FGM beams can be calculated by defined cross-section parameters of beams and by effective material properties and have following forms:

$$E^N_{\text{FGM}}(x) = -3.\overline{2} \times 10^{13}x^3 + 4.8\overline{3} \times 10^{12}x^2 + 3.0\overline{3} \times 10^{11} \quad \text{[Pa]} \tag{52}$$

$$E^M_{\text{FGM}}(x) = 9.\overline{6} \times 10^{13}x^3 - 1.45 \times 10^{13}x^2 + 3.42 \times 10^{11} \quad \text{[Pa]} \tag{53}$$

$$\rho_{\text{FGM}}(x) = -2.2\overline{4} \times 10^{6}x^3 + 33666.\overline{6}x^2 + 12566.\overline{6} \quad \text{[kg/m}^3\text{]} \tag{54}$$

$E^N_{\text{FGM}}(x)$ and $E^M_{\text{FGM}}(x)$ represent homogenized Young's modulus for axial loading and for bending, respectively.

Piezoelectric layers in investigated beams are made from PZT5A piezoelectric material. PZT5A is orthotropic material and has following material properties (direction of poling has index 3):

- mechanical properties:
  - Young's moduli: $E_1 = 61$ GPa, $E_2 = 61$ GPa, $E_3 = 53,2$ GPa
  - Poisson numbers: $\mu_{12} = 0.35$, $\mu_{13} = 0.38$, $\mu_{23} = 0.38$
  - shear moduli: $G_{12} = 22.6$ GPa, $G_{13} = 21.1$ GPa, $G_{23} = 21.1$ GPa
  - density: 7750 kg/m^3
- piezoelectric properties: $d_{31} = -171 \times 10^{-12}$ C/N, $d_{33} = 374 \times 10^{-12}$ C/N, $d_{15} = 584 \times 10^{-12}$ C/N, $d_{24} = 584 \times 10^{-12}$ C/N
- relative permittivity: $\epsilon^{\sigma}_{11} = 1728.8$, $\epsilon^{\sigma}_{22} = 1728.8$, $\epsilon^{\sigma}_{33} = 1694.9$

5.2 Example 1 – static analysis of piezoelectric beam

Figure 3 shows simple cantilever made of FGM with piezoelectric layers, which is loaded by transversal force F at free end. Electrodes on top and bottom piezoelectric layers are short circuited. The goal of analysis is to investigate static responds of structure on prescribed loading and compare results of 1D model with results of 2D model.

Geometry parameters of beam are:

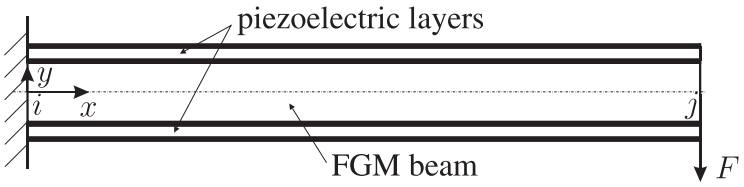

Figure 3: Example 1: static analysis of FGM beam with piezoelectric layers

- length 0.1 m
- height of FGM core 0.01 m, height of piezoelectric layer 0.001 m
- depth of beam 0.01 m

Material of beam:

- core of beam is made from FGM (NiFe-tungsten) and its effective and homogenized material properties are described by equations (50)-(54)
- piezoelectric layers are made from PZT5A – reduced properties $\overline{e}_{31} = \dfrac{d_{31}}{s^E_{11}} = -10.43$ C/m^2

Using multilayered method homogenized Young's modulus for axial loading and for bending and homogenized density of whole beam can be calculated using homogenized material properties of FGM core and constant material properties of piezoelectric layers and they have form

$$E^N(x) = -2.68519 \times 10^{13}x^3 + 4.02778 \times 10^{12}x^2 + 2.62944 \times 10^{11} \quad \text{[Pa]} \tag{55}$$

$$E^M(x) = 5.59414 \times 10^{13}x^3 - 8.3912 \times 10^{12}x^2 + 2.23616 \times 10^{11} \quad \text{[Pa]} \tag{56}$$

$$\rho(x) = -1.87037 \times 10^{6}x^3 + 280556.x^2 + 11763.9 \quad \text{[kg/m}^3\text{]} \tag{57}$$

Boundary conditions:

- left end – fixed
- right end – transversal force $F = 10$ N

The static analysis of system was performed by new FGM beam element with piezoelectric layers. The analysis was performed by 1, 2, 4 and 10 elements – see Figure 4 left.

Deformed shape of beam is shown in Figure 4 right. Displacement in y direction of free end is -10.63×10^{-6} m. Electric charge on top electrodes for FEM models with different number of elements are summarized in Table 1.

The same problem was analyzed by FEM code ANSYS, where two types of plane elements were used – PLANE223 with piezoelectric capabilities and PLANE183. Because material properties of FGM core vary along the length and height of beam, discretized 2D model contains 6400 elements. Displacement in y direction of free end was -10.70×10^{-6} m and total electric charge on top electrode was 9.2715×10^{-8} C.
As we can see from obtained results, new FGM beam element with piezoelectric layers is very accurate and effective in static analysis, because variation of material properties of FGM core of beam is directly incorporated into stiffness matrix.

Figure 4: Example 1: left – discretized beam with node and element numbers, right – deformation of beam

Number of elements	1	2	4	10
$Q_{\text{elem 1}}$ [C]	9.2650×10^{-8}	6.8159×10^{-8}	3.9209×10^{-8}	1.6939×10^{-8}
$Q_{\text{elem 2}}$ [C]		2.4491×10^{-8}	2.8950×10^{-8}	1.5256×10^{-8}
$Q_{\text{elem 3}}$ [C]			1.8203×10^{-8}	1.3624×10^{-8}
$Q_{\text{elem 4}}$ [C]			6.2883×10^{-9}	1.1998×10^{-8}
$Q_{\text{elem 5}}$ [C]				1.0343×10^{-8}
$Q_{\text{elem 6}}$ [C]				8.6318×10^{-9}
$Q_{\text{elem 7}}$ [C]				6.8450×10^{-9}
$Q_{\text{elem 8}}$ [C]				4.9743×10^{-9}
$Q_{\text{elem 9}}$ [C]				3.0245×10^{-9}
$Q_{\text{elem 10}}$ [C]				1.0157×10^{-9}
Q_{SUM} [C]	9.2650×10^{-8}	9.2650×10^{-8}	9.2650×10^{-8}	9.2650×10^{-8}

Table 1: Example 1: Electric charge on individual electrodes

5.3 Example 2 – transient analysis of piezoelectric beam

In Example 2 transient analysis of FGM beam with piezoelectric layers with the same geometry and material parameters as in Example 1 was performed. Electrodes on top and bottom piezoelectric layers are short circuited. The goal of analysis is to investigate free vibration of structure without considering damping.
Boundary conditions:

- left end – fixed
- right end – free

Initial conditions:

- initial displacement of nodes – initial deformation of system is defined by prescribed displacement of free end in vertical direction $+0.01$m
- initial velocity of nodes – all nodes have zero initial velocities

The transient analysis of system was performed by new FGM beam element with piezoelectric layers. In the analysis Newmark integration scheme was used. Total simulation time was 5 ms

and number of equidistant substeps was 80. 1D model of system was discretized by 10 elements – see Figure. 4 left.
Displacement of nodes 4, 8 and 11 in direction y as function of time are shown in Figure 5 left. Time variations of electric charge in top electrode on elements 2 and 4 are shown in Figure 5 right.

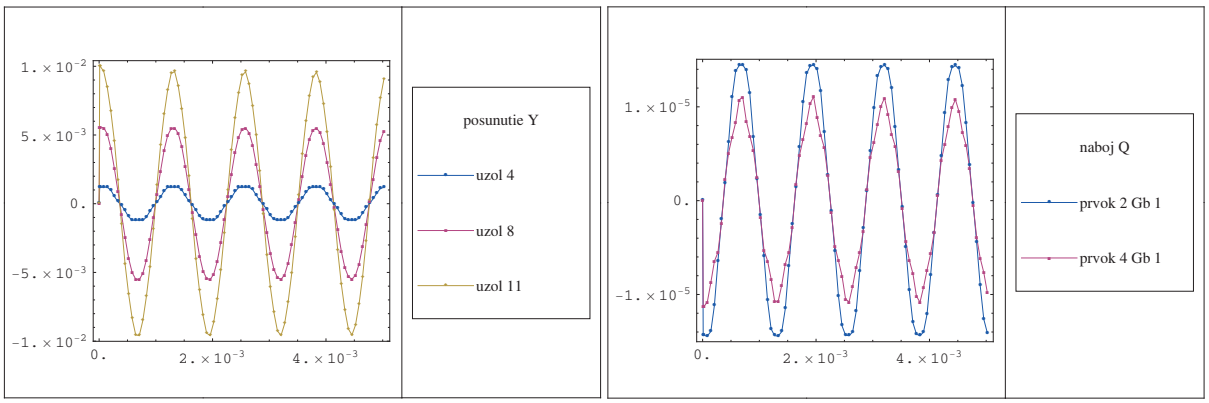

Figure 5: Example 2: left – Y displacement time variation of nodes (4, 8, 11), right – charge time variation of top electrodes on elements (2, 4)

5.4 Example 3 – transient analysis of simple structure

Figure 6 shows simple structure, which contains three beams. Piezoelectric layers are partially attached to the beam 1 and 2. Electrodes on top and bottom piezoelectric layers are short circuited. The goal of analysis is to investigate free vibration of structure with considering damping.

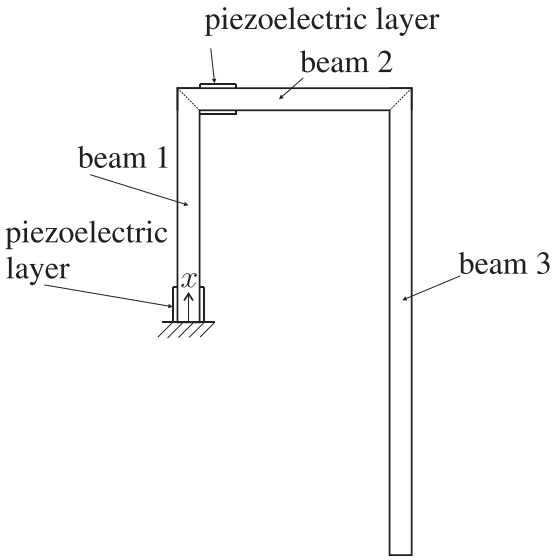

Figure 6: Example 3: free vibration of structure with piezoelectric elements

Geometry parameters of beams are:

- cross-section – all beams have height and depth of cross-section 0.01 m, height of piezoelectric layers is 0.001 m and its depth is 0.01 m
- length – beam 1 and 2 have length 0.05 m and beam 3 has length 0.1 m, length of piezoelectric layers is 0.01 m

Material parameters of beam are:

- core of beam – beam 1 and 2 are made from FGM, homogenized material properties are defined by equations (52)-(54), beam 3 has constant material properties: $E = 319.4$ GPa, $\rho = 13989.6$ kg/m^3
- piezoelectric layer – PZT5A

Three different types of beam finite elements were used in transient analysis of system: FGM beam element, FGM beam element with piezoelectric layers and beam element with Hermite shape functions. Discretized 1D model of system is shown in Figure 7, where nodes and element types are depicted.

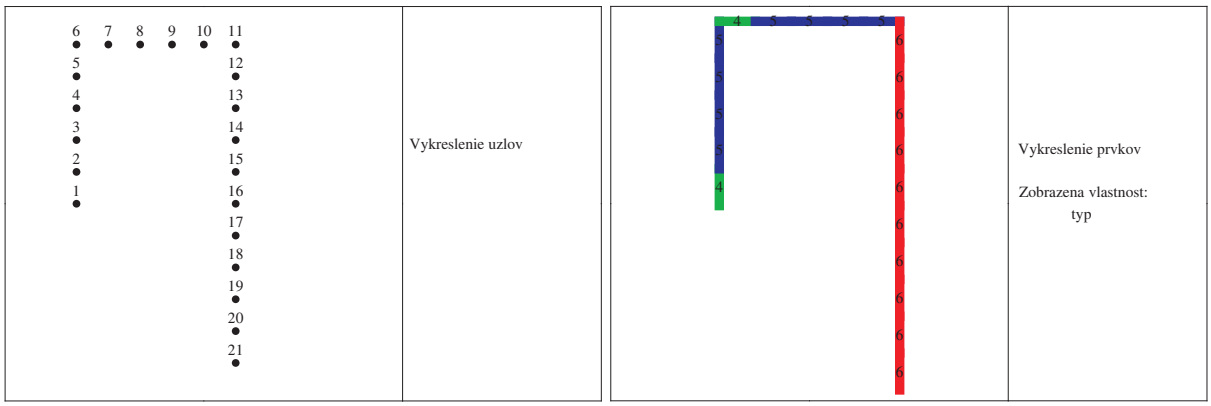

Figure 7: Example 3: left – nodes, right – elements with element types numbering

Boundary conditions:

- left end – fixed
- right end – free

Initial conditions:

- initial displacement of nodes – initial deformation of system is defined by prescribed displacement of free end in horizontal direction $+0.01$m
- initial velocity of nodes – all nodes have zero initial velocities

In the analysis Newmark integration scheme was used. Total simulation time was 7.5 ms and number of equidistant substeps was 400. In the analysis Rayleigh damping was used. Mass-proportional damping coefficient and stiffness-proportional damping coefficient had the same value 1×10^{-5}.
Deformed shape of system at the end of simulation time (7.5 ms) is shown in Figure 8 left. Figure 8 right shows time variation of electric charge in top electrode on elements 1 and 6. Displacements of nodes 8 and 21 as function of time in direction x and y are shown in Figure 9 left and right, respectively.

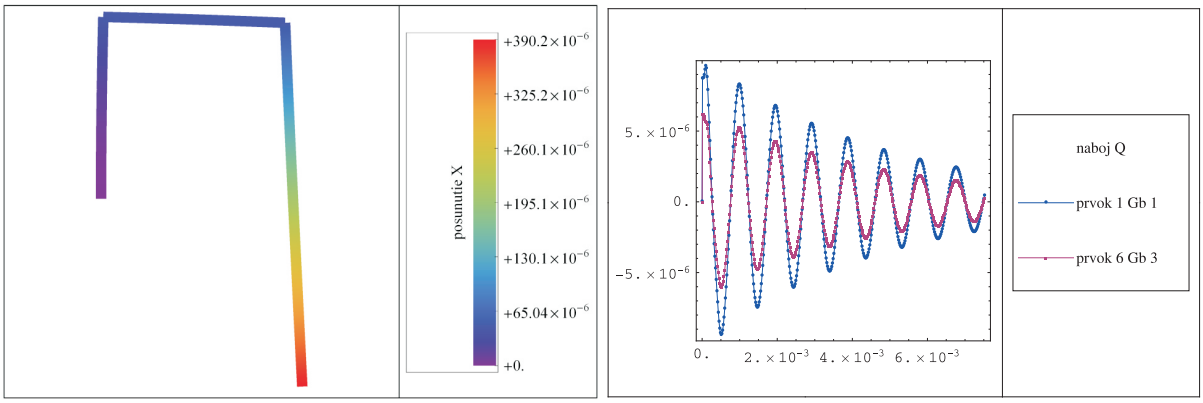

Figure 8: Example 3: left – X displacement of structure at time 7.5ms, right – charge time variation of top electrode on element 1 and 6

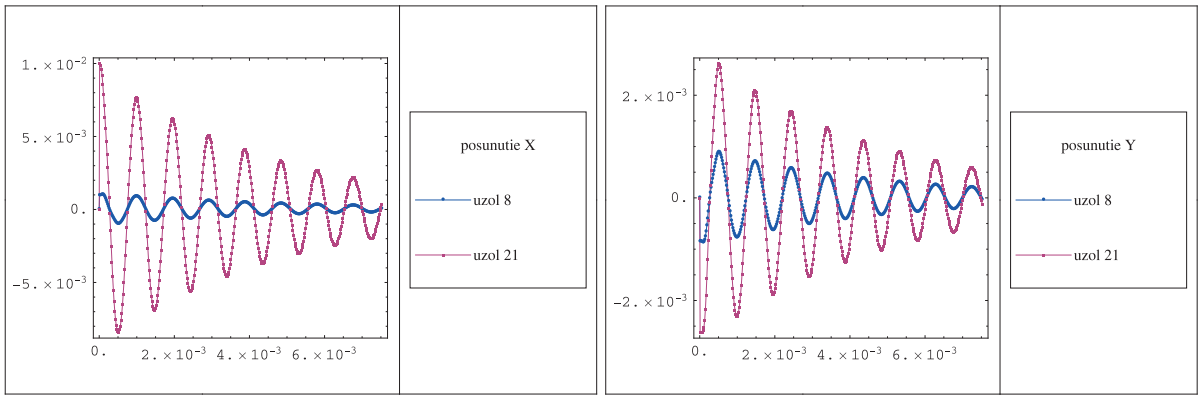

Figure 9: Example 3: left – X displacement time variation of nodes (8, 21), right – Y displacement time variation of nodes (8, 21)

6 CONCLUSIONS

The paper presents new beam finite element with piezoelectric layers, where core of the beam can be made of FGM materials. Such combination of materials is very attractive for mechatronic applications, because material composition of FGM core can be optimized for design stress state and deformation can be controlled by voltages on electrodes. The beam finite element can be used for analysis of such systems very effectively and accurately.

Keywords: differential equation with non-constant coefficients, transfer functions, transfer constants, Functionally Graded Material

Abstract. *Nowadays, new materials like Functionally Graded Material (FGM) are necessary for sophisticated structures like MEMS systems, advanced electronic devices, etc. Computer modelling of such complex systems, like structures with spatial variation of material properties (e.g. FGM) are, using commercial FEM code with classic elements, needs remarkable effort during preparation phase and sufficient computer equipment for solution phase because of necessity the numbers of elements and material models. Therefore new methods for modeling and simulation of FGM beams with spatial variation of material properties are developed.*

In the proposed contribution, semi-analytical method (based on calculation of transfer functions and transfer constants) for solution of differential equation with non-constant polynomial coefficients, is presented. This method is used in derivation process (for setting up the transfer matrix) of our new beam finite elements for modeling and simulation of Functionally Graded Material (FGM) beam structures (e.g. new 3D FGM beam finite element for modal and structural analysis, new FGM beam finite elements for coupled electro-thermo-mechanical analysis). Numerical experiments are made to show the accuracy and effectiveness of this method.

1 INTRODUCTION

Physical processes in materials, such as heat transfer, conduction of electric current, mechanical stress, etc., are often described by partial differential equations or by system of partial differential equations. An exact analytical solution is usually possible only for simplified investigated domains (e.g. one dimensional link parts - bars) and simple boundary conditions of the investigated system, where the geometry allows to reduce the partial differential equations into ordinary differential equations. The geometry of the bar, as well as the boundary conditions fulfil the requirements that are needed to apply analytical methods for solving the differential equations.

One example, let us write general partial differential equation for heat transfer in considered domain:

$$\frac{\partial T(x,y,z,\tau)}{\partial \tau} = \frac{\lambda}{c\rho} \bigtriangledown^2 T(x,y,z,\tau) + \frac{Q}{c\rho} \tag{1}$$

Quantity $T(x,y,z,\tau)$ [K] is the unknown temperature of the system, τ [s] is the time, λ [$\mathrm{Wm^{-1}K^{-1}}$] is the thermal conductivity of considered material, c [$\mathrm{Jkg^{-1}K^{-1}}$] is its specific heat, ρ [$\mathrm{kgm^{-3}}$] is the density of the material and Q [$\mathrm{Wm^{-3}}$] is the volume heat sources in the system. For steady state and for 1D geometry (bar construction) we can simplify this partial differential equation into the form of ordinary differential equation:

$$\frac{d^2T(x)}{dx^2} = -\frac{Q}{c\lambda} \tag{2}$$

with two boundary conditions, e.g.:

$$\begin{aligned} T(0) &= T_0 \\ T(L) &= T_L \end{aligned} \tag{3}$$

It is possible to write similar ordinary differential equations also for other physical fields (e.g. electric field, structural analysis, etc.). When we consider variable material properties of the bar (e.g. Functionally Graded Material - FGM) the ordinary differential equations contain variable (nonconstant) coefficients.

In this contribution, semi-analytical method based on calculation of transfer functions (transfer constants), for solution of differential equation with polynomial coefficients [1] is presented. This method is used in derivation process (for setting up the transfer matrix) of our new beam finite elements for modeling and simulation of FGM beam structures with 3D spatial variation of material properties (e.g. new 3D FGM beam finite element for modal, structural and buckling analysis [2][3], new FGM beam finite elements for coupled electro-thermo-mechanical analysis[4]).

2 SEMI-ANALYTICAL METHOD FOR SOLUTION OF LINEAR DIFFERENTIAL EQUATION WITH NON-CONSTANT COEFFICIENTS

There will be set out a procedure for solving differential equations with variable coefficients and right-hand side, which is taken from Rubins article [1]. These differential equations must fulfil the following requirements:

- differential equation of one independent variable
- polynomial character of variable coefficients and right side of the differential equation

- known interval of the independent variable, where the solution of the differential equation needs to be determined ($x \in \langle 0, L \rangle$)

The order of differential equation and also the order of its right side are arbitrary.

2.1 Solving of the differential equation with non-constant coefficients

Let us consider 1D differential equation with non-constant coefficients and the right side in the form:

$$\sum_{u=0}^{m} \eta_u(x)\, y^{(u)}(x) = \sum_{j=0}^{g} q_j\, a_j(x) \tag{4}$$

where m is a order of the differential equation, $y(x)$ is an unknown function of independent variable x, $y^{(u)}(x)$ is u^{th} derivative of the unknown function $y(x)$ $\left(y^{(u)}(x) = d^u y(x)/dx^u\right)$, $\eta_u(x)$ is a polynomial variable coefficient for u^{th} derivation of the differential equation, g is the order of a polynomial on the right side of the differential equation, q_j is a constant coefficient for j^{th} power of the right side polynomial. Function $a_j(x)$ is an auxiliary function for polynomial formulation

$$\begin{aligned} a_j(x) &= \frac{x^j}{j!} \qquad j > 0 \\ a_j(x) &= 1 \qquad j = 0 \\ a_j(x) &= 0 \qquad j < 0 \end{aligned} \tag{5}$$

Polynomial coefficients $\eta_u(x)$ of the differential equation (4) for $u = \{0; m\}$ can be written as:

$$\begin{aligned} \eta_u(x) &= \sum_{r=0}^{p_u} \rho_{ur}(x) \\ \rho_{ur}(x) &= \eta_{ur}\, a_r(x) \end{aligned} \tag{6}$$

where η_{ur} is a constant coefficient for r^{th} power of polynomial for u^{th} derivation, p_u is an order of polynomial for u^{th} derivation and $a_r(x)$ is an auxiliary function according to (5) for polynomial formulation.
According to this notation, derivation and integration of polynomial can be written in general form:

$$\begin{aligned} a_j^{'}(x) &= a_{j-1}(x) \\ \int_0^x a_j(x) &= a_{j+1}(x) \end{aligned} \tag{7}$$

Then the solution of the differential equation (4) has according to [1] the form:

$$y(x) = \sum_{j=0}^{m-1} y_0^{(j)}\, c_j(x) + \sum_{j=0}^{g} q_j\, b_{j+m}(x) \tag{8}$$

where $y_0^{(j)}$ is j^{th} derivative of the function $y(x)$ at the position $x = 0$ $\left(y_0^{(j)} = y^{(j)}(x)|_{x=0}\right)$, $c_j(x)$ is a transfer function for uniform solution of the differential equation and $b_{j+m}(x)$ is a

transfer function for particular solution of the differential equation (4).
Then the derivative of the solution (8) has a form:

$$y^{(u)}(x) = \sum_{j=0}^{m-1} y_0^{(j)}\, c_j^{(u)}(x) + \sum_{j=0}^{g} q_j\, b_{j+m}^{(u)}(x) \tag{9}$$

For $u = 0$ is Eq. (9) equal to Eq. (8). The solution (8) of the differential equation (4) and its derivatives (9) can be written in the matrix form:

$$\begin{aligned}\begin{bmatrix} y(x) \\ y'(x) \\ y''(x) \\ \vdots \\ y^m(x) \end{bmatrix} &= \begin{bmatrix} c_0 & c_1 & c_2 & \dots & c_{m-1} \\ c_0' & c_1' & c_2' & \dots & c_{m-1}' \\ c_0'' & c_1'' & c_2'' & \dots & c_{m-1}'' \\ \vdots & \vdots & \vdots & \ddots & \\ c_0^m & c_1^m & c_2^m & \dots & c_{m-1}^m \end{bmatrix} \cdot \begin{bmatrix} y_0 \\ y_0' \\ y_0'' \\ \vdots \\ y_0^m \end{bmatrix} \\ &+ \begin{bmatrix} b_m & b_{m+1} & b_{m+2} & \dots & b_{j+m} \\ b_m' & b_{m+1}' & b_{m+2}' & \dots & b_{j+m}' \\ b_m'' & b_{m+1}'' & b_{m+2}'' & \dots & b_{j+m}'' \\ \vdots & \vdots & \vdots & \ddots & \\ b_m^m & b_{m+1}^m & b_{m+2}^m & \dots & b_{j+m}^m \end{bmatrix} \cdot \begin{bmatrix} q_0 \\ q_1 \\ q_2 \\ \vdots \\ q_g \end{bmatrix}\end{aligned} \tag{10}$$

The solution (8) and its derivatives (9) of the differential equation (4) are based on determination of the transfer functions generally labelled $c(x)$ and $b(x)$. The calculation of functions $b_{j+m}^{(u)}(x)$ is based on the use of power series and recursive process, considering $u = \{0; m\}$ and $j = \{0; g\}$. It is necessary to guarantee the convergence of the series for a given interval $x \in \langle 0; L\rangle$ for successful calculation of these functions. It is always fulfil for differential equation with constant coefficients η_u but for differential equation with variable (polynomial) coefficients $\eta_u(x)$ it is often necessary to divide the interval of x into the shorter sections (in our case the independent variable is geometric variable, for example $x = L$ is the length of the bar), and thus determine the solution also for inner region of the bar (where $x \in (0; L)$). This division of the interval is implemented in an algorithm. Calculated functions $b_{j+m}^{(u)}(x)$ are used for next calculation of the functions $c_j^{(u)}(x)$, where $u = \{0; m\}$ and $j = \{0; m-1\}$.

2.2 Recursive calculation of the transfer functions using the power series

We can write (6) again:

$$\rho_{ur}(x) = \eta_{ur}\, a_r(x) \tag{11}$$

with assumption for $u = \{0; m\}$ and $r = \{0; p_u\}$.
Let us introduce the following equation:

$$\widetilde{\rho}_{ur}(x) = \rho_{m-u,r}(x)\frac{x^u}{\eta_{m0}} \tag{12}$$

where $u = \{0; m\}$ and $r = \{0; p_{m-u}\}$.
The calculation itself is based on determining of the power series members $e_s^{(u)}$:

$$b_j^{(u)} = \sum_{s=0}^{\infty} e_s^{(u)}(x) \tag{13}$$

where $j = \{m; \max j\}$ and $u = \{0; m\}$. The value max$j$ = max(j_e, j_g) where $j_e = m+g$ ensures correct calculation for the high order of the polynomial on the right-hand side of the differential equation (order of the right-hand side polynomial is higher than order of any polynomial on the left-hand side of the differential equation) and the value $j_g = \max(p_t - t + 2m - 1)$ where $t = \{0; m-1\}$ ensures correct calculation for the high order of the polynomials for derivatives on the left-hand side of the differential equation.
First members of the series $(s = 0)$ are:

$$e_0^{(u)}(x) = \frac{a_{j-u}(x)}{\eta_{m0}} \tag{14}$$

Next members for $s = 0$ are calculated using matrix $\varepsilon_{s,ur}(x)$ where $u = \{0; m\}$ and $r = \{0; p_{m-u}\}$. For the members of matrix $\varepsilon_{0,ur}(x)$ it holds:

$$\begin{aligned} \varepsilon_{0,00}(x) &= e_0^{(m)}(x) \\ \varepsilon_{0,ur}(x) &= 0 \end{aligned} \tag{15}$$

For the rest of series members where $s > 0$ we can write a recursive rule:

$$\begin{aligned} \varepsilon_{s,ur}(x) &= \varepsilon_{s-1,u,r-1}(x); \quad u = \{0; m\}, r = \{1; p_{m-u}\} \\ \varepsilon_{s,u0}(x) &= \frac{\varepsilon_{s-1,u-1,0}(x)}{j - m + s}; \quad u = \{1; m\} \\ \varepsilon_{s,00}(x) &= -\Big(\sum_{u=1}^{m} \varepsilon_{s,u0}(x)\widetilde{\rho}_{u0}(x) + \sum_{u=0}^{m} \sum_{r=1}^{p_{m-u}} \varepsilon_{s,ur}(x)\widetilde{\rho}_{ur}(x) \Big) \end{aligned} \tag{16}$$

Backward recursion has then a form:

$$\begin{aligned} e_s^{(m)}(x) &= \varepsilon_{s,00}(x) \\ e_s^{(m)}(x) &= \frac{x}{j + s - u} e_s^{(u+1)}(x) \end{aligned} \tag{17}$$

where $u = \{m-1; 0\}$.

Equation (13) then can be used for calculation the functions $b_j^{(u)}(x)$. But we can see that $s \in \langle 0; \infty \rangle$ so it is necessary to choose maximum permissible limit for s. The fact of lack of convergence or divergence of the series is accepted when this limit is reached. In that case it is necessary to determine the functions $b_j^{(u)}(x)$ using shorter interval, so primary interval $x \in \langle 0; L \rangle$ needs to be divided.

The functions of uniform solution of the differential equation are calculated as follows:

$$c_j^{(u)}(x) = a_{j-u}(x) - \sum_{t=0}^{j} \sum_{r=0}^{p_t} \binom{j-t+r}{r} \eta_{tr} b_{j-t+r+m}^{(u)}(x) \tag{18}$$

where $u = \{0; m-1\}$ and $j = \{0; m-1\}$.

2.3 Characteristics of the algorithm for solving of the differential equations

The result of the calculation of the differential equation with variable coefficients and the right-hand side is the solution according to the equation (8). It should be noted that this is a solution for selected point x of the considered interval of the independent variable, so the

program is designed for calculation of values $c_j(x)$ in given point x for $j = \{0; m-1\}$ where m is the order of the differential equation. The values $b_{j+m}(x)$ for selected point x are also calculated for $j = \{0; g\}$ where g is order of the right-hand side polynomial of the differential equation. It means that functions $c(x)$ and $b(x)$ cannot be calculated analytically but only at discrete points x, where x is from interval $\langle 0; L\rangle$.

The algorithm calculates matrices of discrete values $c_j^{(u)}(x)$ and $b_{j+m}^{(u)}(x)$ in defined point x where $u = \{0; m-1\}$ represents derivative for calculations according to (9). It always holds:

$$\begin{aligned} c_j^{(u)}(x)|_{x=0} &= 1; \quad \text{if } i = u \\ c_j^{(u)}(x)|_{x=0} &= 0; \quad \text{if } i \neq u \\ c_{j+m}^{(u)}(x)|_{x=0} &= 0; \quad \text{forall } j = \{0; g\} \end{aligned} \tag{19}$$

For the calculation of $c_j^{(u)}(x)$ and $b_{j+m}^{(u)}(x)$ we do not need to know the the polynomial functions of the right side (does not enter into calculation) of the differential equation but only the degree of the right side polynomial. Its coefficients q_j are used only in the solution (8) and its derivatives (9). So we can use calcualted $c_j^{(u)}(x)$ and $b_{j+m}^{(u)}(x)$ for different coefficients q_j of the right side polynomial if its degree does not change.

Using power series gives us exact solution and because advanced numerical operations as numerical integration are not required in the calculation of the transfer functions $c_j^{(u)}(x)$ and $b_{j+m}^{(u)}(x)$ this procedure is fast and can be easy implemented into the FEM code. Only the differential equations with one independent variable can be solved and the variable coefficients and the term on the right side of the differential equation has to be polynomial.

The whole procedure of calculation transfer functions $c_j^{(u)}(x)$ and $b_{j+m}^{(u)}(x)$ is described in [1] in detail - the block diagram of this procedure is shown in Figure 1. This approach for calculation differential equation with non-constant parameters was implemented into the software Mathematica [5].

3 NUMERICAL EXAMPLE

Let us consider differential equation of 2^{nd} order on the interval $y \in \langle 0, L\rangle$, $L = 0.1$ with non-constant polynomial coefficients:

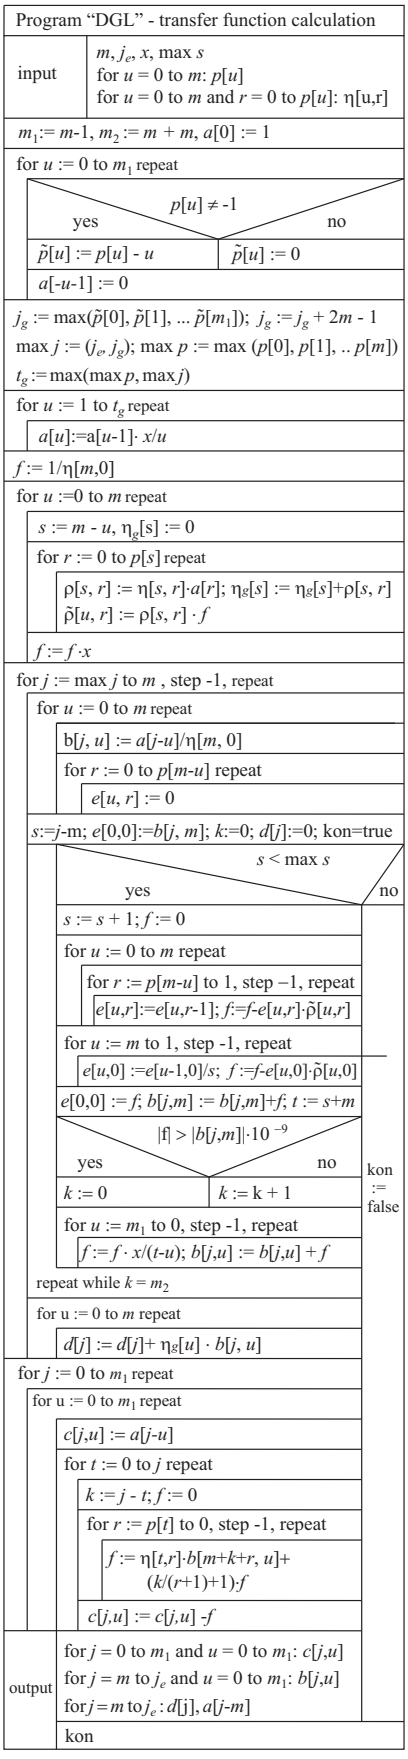
$$\eta_2(x)y''(x) + \eta_1(x)y'(x) + \eta_0(x)y(x) = q \tag{20}$$

where

$$\begin{aligned} \eta_0 =& -637\,500\,000\,000x^4 + 146\,625\,000\,000x^3 - 10\,965\,000\,000x^2 \\ &+ 267\,750\,000x + 60\,000 \\ \eta_1 =& \frac{129\,417\,900}{121}x^2 - \frac{12\,941\,790}{121}x \\ \eta_2 =& \frac{43\,139\,300}{121}x^3 - \frac{6\,470\,895}{121}x^2 + \frac{2\,217\,793}{7\,260} \\ q =& -6\,375\,000\,000\,000x^4 + 1\,459\,950\,000\,000x^3 - 109\,650\,000\,000x^2 + \\ &+ 2\,742\,500\,000x + 610\,000 \end{aligned} \tag{21}$$

with boundary conditions:

$$y[0] = y_0 = 10 \qquad y'[L] = y_L = -122.623 \tag{22}$$



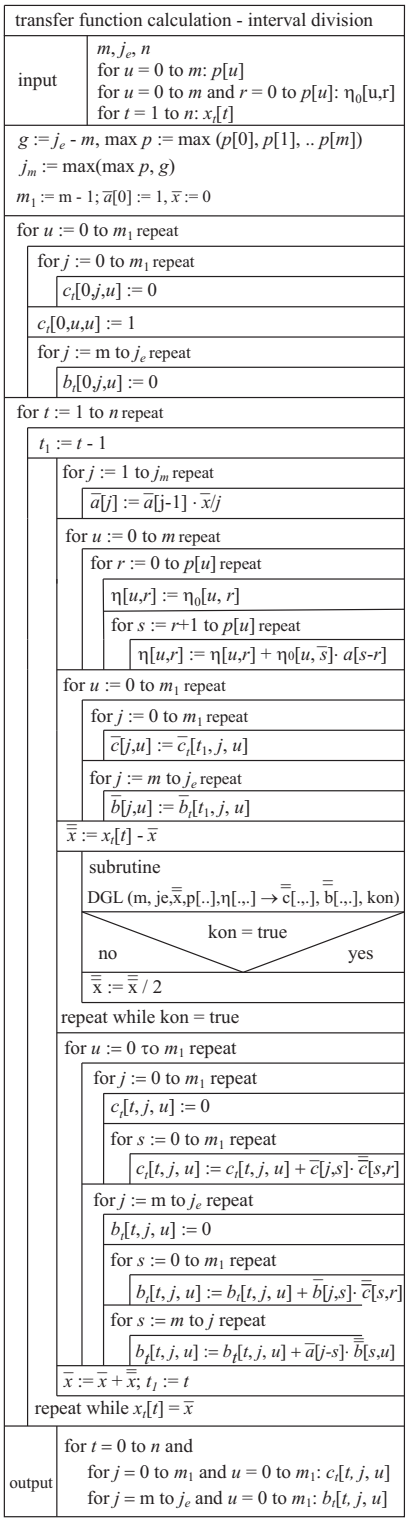


Figure 1: Block diagram of calculation transfer functions [1]

This differential equation can represent differential equation for heat transfer (consideration of the convective effect and internal heat generation) in the form:

$$-\lambda(x)\frac{d^2T(x)}{dx^2} - \frac{d\lambda}{dx}\frac{xT(x)}{dx} + \alpha(x)T(x)\frac{o}{A} = Q(x) + \alpha(x)T_{amb}\frac{o}{A} \tag{23}$$

where we consider that thermal conductivity $\lambda(x)$ [Wm^{-1}K^{-1}], coefficient of convective heat transfer $\alpha(x)$ [Wm^{-2}K^{-1}] and volume heat $Q(x)$ [Wm^{-3}] are polynomial functions. A is a cross-section of the bar, o is a perimeter ot the bar ant T_{amb} is a constant ambient temperature.

The solution of differential equation (20) according to (8) is:

$$y(x) = \sum_{j=0}^{m-1=1} y_0^{(j)} c_j(x) + \sum_{j=0}^{g=4} \varepsilon_j b_{j+2}(x) = c_0(x)y_0 + c_1(x)y_0' + \sum_{j=0}^{g=4} \varepsilon_j b_{j+2}(x) \tag{24}$$

where $m = 2$ and $g = 4$. The transfer functions $c_j^{(u)}(x = L)$ and $b_{j+m}^{(u)}(x = L)$ for differential equation (20) with non-constant coefficient (21) according the proposed method have a form:

$$c_j^{(u)}(x = L) = \begin{bmatrix} c_0 & c_1 \\ c_0' & c_1' \end{bmatrix} = \begin{bmatrix} 202.258 & 3.33436 \\ 9722.66 & 160.297 \end{bmatrix} \tag{25}$$

$$b_{j+m}^{(u)}(x = L) = \begin{bmatrix} b_2 & b_3 & b_4 & b_5 & b_6 \\ b_2' & b_3' & b_4' & b_5' & b_6' \end{bmatrix} = \tag{26}$$

$$= \begin{bmatrix} -0.000159832 & -2.67325 \times 10^{-6} & -4.87898 \times 10^{-8} & -8.52047 \times 10^{-10} & -1.33152 \times 10^{-11} \\ -0.007846 & -0.000141612 & -2.89679 \times 10^{-6} & -5.68637 \times 10^{-8} & -9.91117 \times 10^{-10} \end{bmatrix}$$

The solution of differential equation (20) according the proposed method for $n = 50$ internal points compared with solution obtained by numerical solution in software Mathematica [5](explicit RungeKutta method) is shown in Figure 2 and its first derivative is shown in Figure 3.

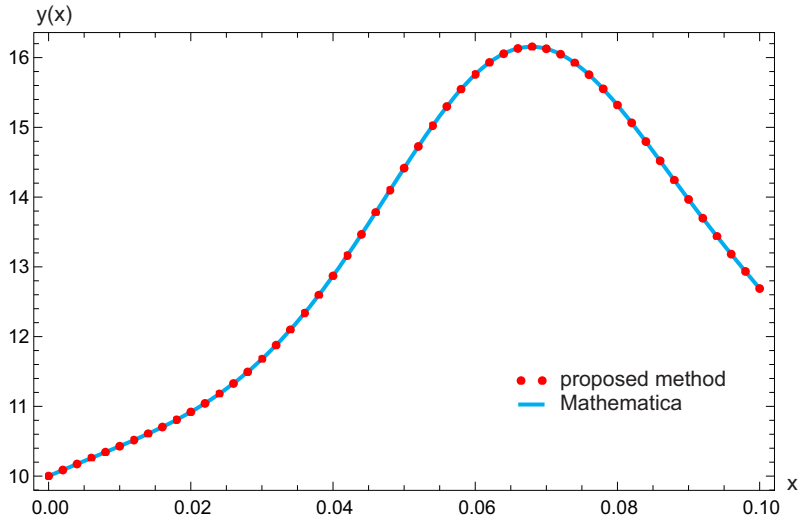

Figure 2: The solution of differential equation

As it can be seen in Figures 2 and 2, a very good agreement of both solution results has been obtained.

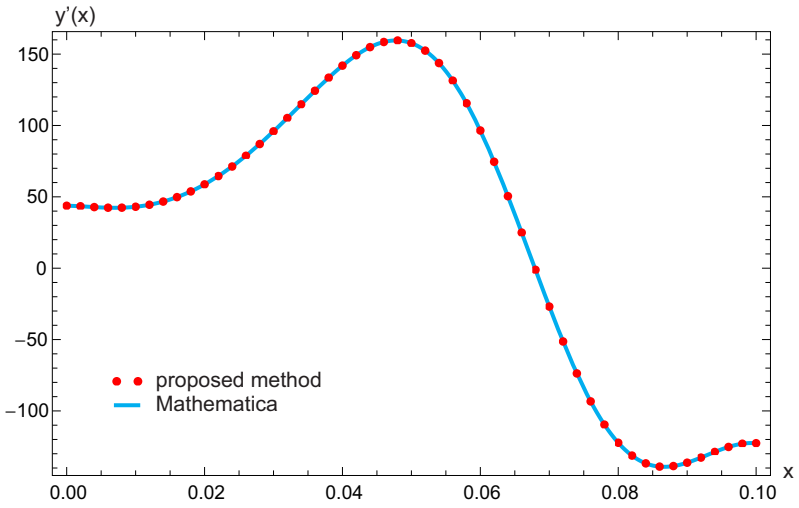

Figure 3: The 1^{st} derivation of the solution of differential equation

4 CONCLUSIONS

In this contribution the approach for solving differential equation with non-constant (polynomial) coefficient has been presented. The general solution of the homogeneous differential equation is formulated with the transfer functions $c_j^{(u)}(x)$ and the particular solution with $b_{j+m}^{(u)}(x)$. The transfer functions $b_{j+m}^{(u)}(x)$ are calculated with the help of series formulas and then the functions $c_j^{(u)}(x)$ may be determined with these $b_{j+m}^{(u)}(x)$.

The numerical example solution of differential equation of $2^n d$ order with non-constant polynomial coefficients using proposed approach and comparison with results obtained in software Mathematica have been . On base of the transfer relations the effective matrix of the 3D beam finite elements for modal, structural and buckling analysis [2][3] or coupled electro-thermo-mechanical analysis [4] of the FGM single beams and beam structures can be established. Material properties of the FGM can vary in all three direction x, y, z. Homogenization of the spatially varying material properties in the real FGM beam (material properties vary in all three direction) and the calculation of effective parameters of the homogenized beam (material properties vary only in longitudinal direction) are done by the extended mixture rules and the multilayer method.

Abstract. *The paper deals with derivation process of new FEM equations for steady thermoelectric two-way coupled analysis of link conductor made of Functionally Graded Material (FGM). One example of coupled analysis will be introduced to demonstrate accuracy and effectiveness of our new approach in computer modelling of such systems.*

INTRODUCTION

Nowadays, new materials are necessary for sophisticated structures like MEMS systems, advanced electronic devices, etc. Computer modelling of such complex systems, like structures with spatial variation of material properties (e.g. FGM) are, using commercial FEM code with classic elements, needs remarkable effort during preparation phase and sufficient computer equipment for solution phase because of necessity the numbers of elements and material models.

Finite elements for electric-thermal analyses of FGM materials considering Joule heat have been developed in [1]. This paper deals with derivation of new link finite element for two-way coupled static thermoelectric analyses considering Joule heat and also thermoelectric effects like Seebeck and Peltier effects. These effects describe direct conversion of thermal energy into electric energy (Seebeck effect) and conversion of electric energy into the temperature difference within the system (Peltier effect).

Let us consider straight link conductor, the conductor is a slender construction. Let the conductor is made of a mixture of two or more materials so its thermal, electric and thermoelectric material properties change according to chosen function. Under these conditions, we can consider one-dimensional system of differential equations and original method further explained in [2] for solving the differential equations for thermoelectric coupled analysis.

HOMOGENIZATION OF MATERIAL PROPERTIES

Let us consider FGM conductor with length L [m], and rectangular cross-section area A [m^2] (height h [m] and width b [m]) with nodes symbolically denoted "0" and "L", see Figure 1.

Let the conductor is made of mixture of two component materials – matrix (index m) and fibre (index f). Let the change of material properties is only in longitudinal and transversal direction (2D change). Let the thermal conductivities λ_m and λ_f, and electric conductivities σ_m and σ_f are known values for matrix and fibre, respectively. Then, according to the homogenization process described in [1] we can calculate homogenized thermal and electric conductivities for whole conductor. These homogenized material properties need to be polynomials.

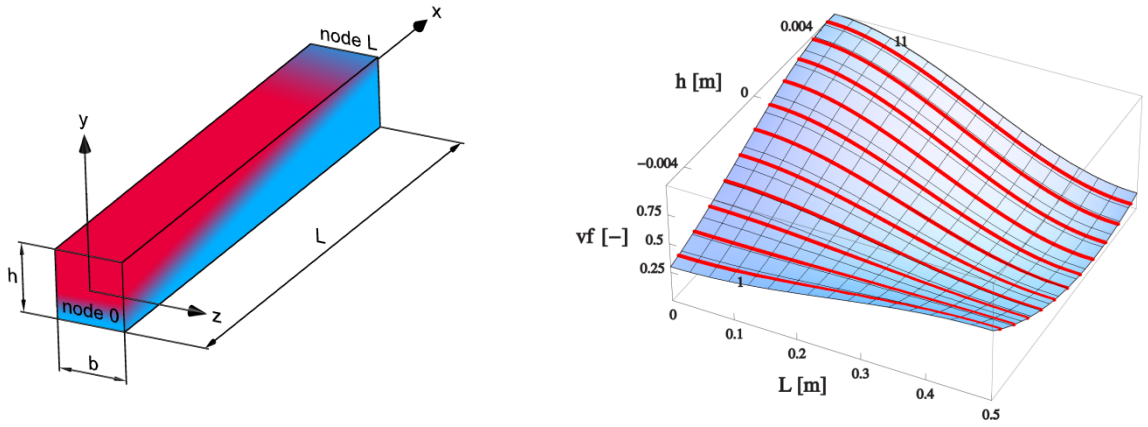

Figure 1: FGM conductor (left) and fibre volume fraction in the conductor – division into layers (right)

Homogenization process supposes that volume fractions of matrix and fibre are known and have also polynomial form, see Figure 1. Then, homogenization includes two steps:

- In the first step the real link is transformed to a multilayered link, real link is divided into chosen number of layers in transversal direction ($N = 11$ for the case shown in Figure 1). The extended mixture rule [3] is used for calculation of material properties of the layers. Then, each layer will have constant volume fraction and material properties of the constituents through its height, see Figure 2. Polynomial variation of these parameters will appear only in the longitudinal direction of the layers.
- In the next step, these layers will be used for calculation of homogenized material properties for whole link (see Figure 2) according to laminate theory described in [4]. This homogenized material properties will interpret material changes in the whole FGM link and they will have polynomial form with just one independent variable (x).

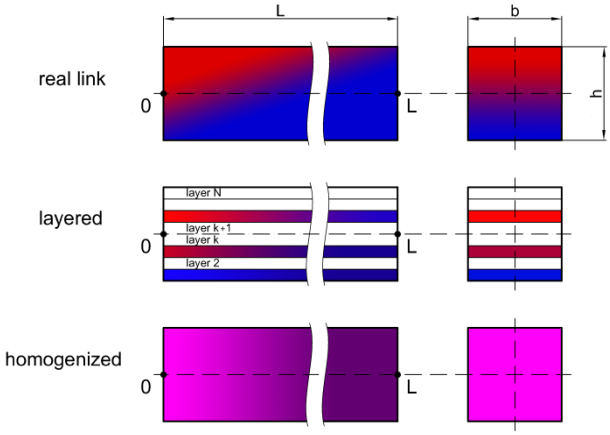

Figure 2: Graphic form of the homogenization process

For thermoelectric coupling that results in Seebeck and Peltier effects, Seebeck coefficient $\alpha(x, y)$ of the whole conductor needs to be known. This material property cannot be calculated according to the homogenization process based on extended mixture rule and laminate theory, because this material property is not given according to volume fractions of individual material components (expect the Joule heat, thermoelectric effects are significant especially for semiconductor materials and the behaviour of the semiconductors is given according to atomic structure, not according to volume fraction of individual admixtures). Moreover, the value of Seebeck coefficient can also be negative number. The determination of final Seebeck coefficient according to material properties of individual components is beyond the scope of this article. For our model case the final Seebeck coefficient will be chosen as a polynomial function $\alpha(x)$ for longitudinal direction of the homogenized conductor.

MATHEMATICAL BACKGROUND FOR TWO-WAY COUPLED THERMOELECTRIC ANALYSIS

Thermoelectric and electric-thermal effects like Joule heat, Seebeck, Peltier and Thomson effects are described by set of two thermoelectric constitutive equations (static analysis) [5]:

$$\begin{aligned} \mathbf{q} &= [\![\Pi]\!] \cdot \mathbf{J} - [\![\lambda]\!] \cdot \nabla T \\ \mathbf{J} &= [\![\sigma]\!] \cdot (\mathbf{E} - [\![\alpha]\!] \cdot \nabla T) \end{aligned} \tag{1}$$

where $\mathbf{q}$ [Wm^{-2}] is heat flux vector, $\mathbf{J}$ [Am^{-2}] is electric current density vector, $[\![\Pi]\!]$ [V] is Peltier coefficient matrix, $[\![\lambda]\!]$ [Wm^{-1}K^{-1}] is thermal conductivity matrix, T [K] is absolute

temperature, $\mathbf{E}$ [Vm^{-1}] is electric field intensity vector, $[\![\sigma]\!]$ [Sm^{-1}] is electric conductivity matrix and $[\![\alpha]\!]$ [VK^{-1}] is Seebeck coefficient matrix.

These constitutive equations are coupled by set of governing equations for static thermal and electric fields:

$$\begin{aligned} \nabla \cdot \mathbf{q} &= P \\ \nabla \cdot \mathbf{J} &= 0 \end{aligned} \tag{2}$$

where P [Wm^{-3}] is heat generation per volume unit.

In general, we can write for electric field intensity, Peltier coefficient and heat generation:

$$\begin{aligned} \mathbf{E} &= -\nabla\varphi & P &= P_J + P_{aux} \\ [\![\Pi]\!] &= T[\![\alpha]\!] & P_J &= [\![\sigma]\!]^{-1}\mathbf{J}^2 \end{aligned} \tag{3}$$

where φ [V] is electric potential, P_J [Wm^{-3}] is Joule heat per volume unit and P_{aux} [Wm^{-3}] is auxiliary heat generation per volume unit.

Applying (1) and (3) into (2) we can write for 1D system (longitudinal direction x):

$$\begin{aligned} \frac{d}{dx}[T(x)\alpha(x)J(x)] - \frac{d}{dx}\left[\lambda(x)\frac{dT(x)}{dx}\right] &= \frac{J^2(x)}{\sigma(x)} + P_{aux}(x) \\ \frac{d}{dx}\left[\sigma(x)\frac{d\varphi(x)}{dx}\right] + \frac{d}{dx}\left[\sigma(x)\alpha(x)\frac{dT(x)}{dx}\right] &= 0 \end{aligned} \tag{4}$$

DERIVATION OF NEW FGM EQUATIONS FOR FGM LINK CONDUCTOR

We can use the method for solving 1D differential equation with non-constant coefficients and with right-hand side described in [2] for our system of equations (4). But all non-constant coefficients on the left-hand side and right-hand side itself have to be in polynomial form (it is the condition of used approach). So general formulation of one-dimensional differential equation suitable for the method has the form:

$$\sum_{u=0}^{m} \eta_u(x) y^{(u)}(x) = \sum_{j=0}^{g} \varepsilon_j a_j(x) \tag{5}$$

where:

m	– degree of the differential equation
$y(x)$	– unknown function of independent variable x
$y^{(u)}(x)$	– u^{th} derivation of the unknown function
$\eta_u(x)$	– polynomial variable coefficient for u^{th} derivation on the left-hand side of the differential equation
g	– degree of a polynomial on the right-hand side of the differential equation
ε_j	– constant coefficient for j^{th} power of the right-hand side polynomial
$a_j(x) = \frac{x^j}{j!}$	– auxiliary function for the right-hand side polynomial formulation

at which $x \in \langle 0; L \rangle$, where L is the length of considered interval of unknown solution.

Considering function $a_j(x)$ for formulation the polynomials, we can write general rules for derivation and integration of such function:

$$\begin{aligned} a_j'(x) &= a_{j-1}(x) \\ \int_0^x a_j(x)\,dx &= a_{j+1}(x) \end{aligned} \tag{6}$$

According to [2] the solution of the differential equation (5) has the form:

$$y(x) = \sum_{i=0}^{m-1} y_0^{(i)} c_i(x) + \sum_{j=0}^{g} \varepsilon_j b_{j+m}(x) \tag{7}$$

where:

$y_0^{(i)}$ i^{th} derivation of the function y in $x = 0$, thus $y_0^{(i)} = y^{(i)}(x)\big|_{x=0}$

$c_i(x)$ function for uniform solution of the differential equation

$b_{j+m}(x)$ function for particular solution of the differential equation

And derivation of the solution (7) is in the form:

$$y^{(u)}(x) = \sum_{i=0}^{m-1} y_0^{(i)} c_i{}^{(u)}(x) + \sum_{j=0}^{g} \varepsilon_j b_{j+m}^{(u)}(x) \qquad u = \{0, m-1\} \tag{8}$$

The solution of differential equation (7) lies in determining the functions generally labelled $c(x)$[1] and $b(x)$ that appear in the solution.

The result of calculation of the differential equation with variable coefficients and the right-hand side is the solution according to equation (7). It should be noted that this is a solution for selected point x of the considered interval of independent variable, so the program is designed for calculation of values $c_i(x)$ in given point x for $i = \{0, m-1\}$ where m is the degree of the differential equation. Then the values $b_{j+m}(x)$ for selected point x are also calculated for $j = \{0, g\}$ where g is degree of the right-hand side polynomial of the differential equation. It means that functions $c(x)$ and $b(x)$ cannot be calculated analytically but only at discrete points x, where x is from interval $\langle 0; L \rangle$.

The program algorithm, also described in [2], efficiently calculates matrixes of discrete values $c_i^{(u)}(x)$ and $b_{j+m}^{(u)}(x)$ for user defined point x where $u = \{0, m-1\}$ represents derivation for calculations according to (8).

It should be noted that the polynomial function of the right-hand side of the differential equation itself does not enter into the calculation. For the calculation of $c(x)$ and $b(x)$ it is only necessary to know the degree of the right-hand side polynomial. The values of the coefficients ε_j of the right-hand side only enter into the final equation – solution (7) or derivation (8), respectively.

Programming code offers the possibility of automatic uniform interval division calculation, and the values of $c(x)$ and $b(x)$ for interval dividing points are included in the output. So during single run of the program we can get all the necessary values to solve the differential equation also for selected internal points in the interval $x \in (0; L)$, in our case for conductor inner region.

This program for solving differential equations is used in process of deriving new FEM equations for two-way coupled thermoelectric analysis in FGM link conductor mentioned above. Figure 3 shows geometry and physical quantities used during the derivation process.

[1] denoting is symbolical – general; correctly it should be mentioned that it is a set of values $c_i(x)$ within the range $i = \{0, m-1\}$; it is also similar for $b_j(x)$ with the range $j = \{0, m-1\}$

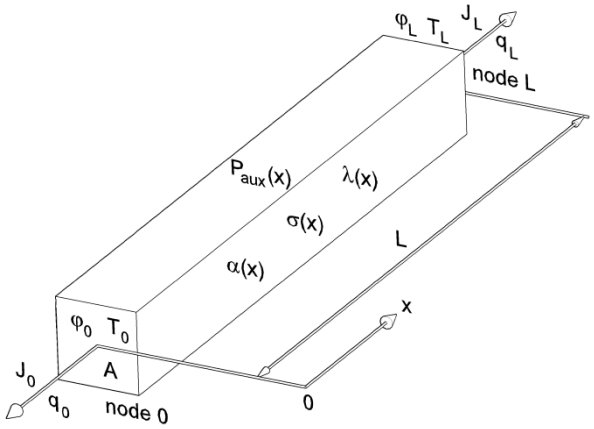

Figure 3: Two-nodal conductor for thermoelectric analysis

Let us write the governing function (4) for heat flux in the form suitable for calculation according [2]. Comparing the general form of the differential equation (5) with governing function (4) in expanded form:

$$\sum_{u=0}^{m} \eta_u(x) y^{(u)}(x) = \sum_{j=0}^{g} \varepsilon_j a_j(x) \tag{9}$$

$$-\lambda(x)T''(x) + [\alpha(x)J(x) - \lambda'(x)]T'(x) + \left[\alpha'(x)J(x) + \alpha(x)J'(x)\right]T(x) = \frac{J^2(x)}{\sigma(x)} + P_{aux}(x)$$

we get:

$m = 2$ – degree of the differential equation

$y(x) \equiv T(x)$ – unknown function of independent variable x is function of temperature

$y^{(u)}(x) \equiv T^{(u)}(x)$ – u^{th} derivation of unknown temperature

$\eta_0(x) = \alpha'(x)J(x) + \alpha(x)J'(x)$ – 0^{th} derivation of the temperature on the left-hand side of the differential equation

$\eta_1(x) = \alpha(x)J(x) - \lambda'(x)$ – non-constant coefficient of the 1st derivation of the temperature

$\eta_2(x) = -\lambda(x)$ – non-constant coefficient of the 2nd derivation

$g > 0$ – degree of the polynomial on the right-hand side

ε_j – constant coefficient of the j^{th} power of the right-hand side polynomial

$a_j(x) = \frac{x^j}{j!}$ – auxiliary function for formulation of polynomial

Now, we can rewrite the solution of the differential equation for our case and its derivation:

$$T(x) = \sum_{i=0}^{1} T_0^{(i)} c_i(x) + \sum_{j=0}^{g} \varepsilon_j b_{j+2}(x) = c_0(x)T_0 + c_1(x)T_0' + \sum_{j=0}^{g} \varepsilon_j b_{j+2}(x) \tag{10}$$

$$T'(x) = c_0'(x)T_0 + c_1'(x)T_0' + \sum_{j=0}^{g} \varepsilon_j b_{j+2}'(x) \tag{11}$$

Let us write again the constitutive equation (1) for 1D heat flux:

$$q(x) = T(x)\alpha(x)J(x) - \lambda(x)T'(x) \tag{12}$$

Let the boundary conditions for thermal field are:

$$T(L) = T_L \qquad q(0) = q_0 \tag{13}$$

Then we can put together equation (12) expressed for position $x = 0$ (position at node 0) and equation (10) expressed for $x = L$ (node L), and using boundary conditions (13) after some mathematical operations we can write in matrix form (lower index "0" and "L" for used physical quantities means that concerned quantity is evaluated for position $x = 0$ or $x = L$, respectively):

$$\begin{bmatrix} c_0(L) + \frac{\alpha_0 J_0}{\lambda_0} c_1(L) & -1 \end{bmatrix} \begin{bmatrix} T_0 \\ T_L \end{bmatrix} = \left[\frac{c_1(L)}{\lambda_0} q_0 - \sum_{j=0}^{g} \varepsilon_j b_{j+2}(L) \right] \tag{14}$$

Now, let the boundary conditions are changed:

$$T(0) = T_0 \qquad q(L) = q_L \tag{15}$$

Then we can put together equation (12) expressed for position $x = L$, equation (11) expressed for node L and equation (10) expressed for node L, and using boundary conditions (15) after some mathematical operations we can write in matrix form:

$$\begin{bmatrix} c_0(L) - \frac{c_1(L) c_0'(L)}{c_1'(L)} & \frac{c_1(L)\alpha_L J_L}{c_1'(L)\lambda_L} - 1 \end{bmatrix} \begin{bmatrix} T_0 \\ T_L \end{bmatrix} = \left[\frac{c_1(L)}{c_1'(L)} \left(\frac{q_L}{\lambda_L} + \sum_{j=0}^{g} \varepsilon_j b_{j+2}'(L) \right) - \sum_{j=0}^{g} \varepsilon_j b_{j+2}(L) \right] \tag{16}$$

The matrixes (14) and (16) can be put together. Comparing mathematical formulation and FEM formulation of our task we can find out, that there is sign difference in heat flux at node L (heat flux at node L for FEM formulation has opposite direction than it is in mathematical formulation). Considering these facts we get the system of FEM equations for thermal field in the conductor:

$$\begin{bmatrix} c_0(L) + \frac{\alpha_0 J_0}{\lambda_0} c_1(L) & -1 \\ c_0(L) - \frac{c_1(L) c_0'(L)}{c_1'(L)} & \frac{c_1(L)\alpha_L J_L}{c_1'(L)\lambda_L} - 1 \end{bmatrix} \begin{bmatrix} T_0 \\ T_L \end{bmatrix} = \begin{bmatrix} \frac{c_1(L)}{\lambda_0} q_0 - \sum_{j=0}^{g} \varepsilon_j b_{j+2}(L) \\ \frac{c_1(L)}{c_1'(L)} \left(\frac{-q_L}{\lambda_L} + \sum_{j=0}^{g} \varepsilon_j b_{j+2}'(L) \right) - \sum_{j=0}^{g} \varepsilon_j b_{j+2}(L) \end{bmatrix} \tag{17}$$

We can also evaluate the temperature within the range of the conductor. Using equation (12) expressed for node 0 and substituting it into equation (10) then we can write:

$$T(x) = c_0(x) T_0 + c_1(x) \frac{T_0 \alpha_0 J_0 - q_0}{\lambda_0} + \sum_{j=0}^{g} \varepsilon_j b_{j+2}(x) \tag{18}$$

Now, comparing the general form of the differential equation (5) with governing function (4) for electric current density in expanded form:

$$\sum_{u=0}^{m} \eta_u(x) y^{(u)}(x) = \sum_{j=0}^{g} \varepsilon_j a_j(x) \tag{19}$$

$$\sigma(x)\varphi''(x) + \sigma'(x)\varphi'(x) = -\alpha'(x)\sigma(x)T'(x) - \alpha(x)\sigma'(x)T'(x) - \alpha(x)\sigma(x)T''(x)$$

we get:

$m = 2$ – degree of the differential equation
$y(x) \equiv \varphi(x)$ – unknown function of independent variable x is function of el. potential
$y^{(u)}(x) \equiv \varphi^{(u)}(x)$ – u^{th} derivation of unknown electric potential
$\eta_0(x) = 0$ – 0^{th} derivation of the potential is not present on the left-hand side

$\eta_1(x) = \sigma'(x)$ – non-constant coefficient of the 1st derivation of the potential
$\eta_2(x) = \sigma(x)$ – non-constant coefficient of the 2nd derivation of the potential
$g > 0$ – degree of the polynomial on the right-hand side
ε_j – constant coefficient of the j^{th} power of the right-hand side polynomial
$a_j(x) = \frac{x^j}{j!}$ – auxiliary function for formulation of polynomial of the right side

Similar to the derivation process for thermal field we can derive also FEM equations for electric field:

$$\begin{bmatrix} -c_0(L) & 1 \\ -c_0(L) + \dfrac{c_1(L)c_0'(L)}{c_1'(L)} & 1 \end{bmatrix} \begin{bmatrix} \varphi_0 \\ \varphi_L \end{bmatrix} = \begin{bmatrix} -\dfrac{c_1(L)}{\sigma_0} J_0 - c_1(L)\alpha_0 T_0' + \displaystyle\sum_{j=0}^{g} \varepsilon_j b_{j+2}(L) \\ -\dfrac{c_1(L)}{c_1'(L)} \left(\dfrac{-J_L}{\sigma_L} + \alpha_L T_L' + \displaystyle\sum_{j=0}^{g} \varepsilon_j b_{j+2}'(L) \right) + \displaystyle\sum_{j=0}^{g} \varepsilon_j b_{j+2}(L) \end{bmatrix} \tag{20}$$

And similar to the equation (18) for thermal field we can also evaluate the electric potential within the range of the conductor:

$$\varphi(x) = c_0(x)\varphi_0 - c_1(x)\left(\frac{J_0}{\sigma_0} + \alpha_0 T_0'\right) + \sum_{j=0}^{g} \varepsilon_j b_{j+2}(x) \tag{21}$$

The temperature and electric potential are primary variables for thermal and electric field analyses, respectively. Calculating the secondary variables, like heat flux and electric current density, is possible using equation (1) expressed for one-dimensional task. But this is suitable only for 1D model where we calculate one longitudinal distribution of the heat flux or electric current density for homogenized model, respectively. However, our 1D model results from real 3D FGM conductor, so it is more realistic to calculate the secondary variables in layers that were considered during homogenization process (see [1] for details).

FEM equations for two-way coupled thermoelectric analysis are equations (17) and (20). They are solved using iterative algorithm. During iteration process it is necessary to find substitutional functions for results obtained from FEM equations (results of these FEM equations are not continuous functions but only sets of discrete values) and also it is necessary to convert non-polynomials into polynomials (e.g. see P_J in equation (3)). Iteration process can be set ahead by evaluating equations (1) expressed for one-dimensional task also within individual iterative steps.

THERMOELECTRIC ANALYSIS OF FGM LINK CONDUCTOR - NUMERICAL EXPERIMENT

In this chapter there will be one academic example of thermoelectric analysis of given FGM link conductor presented. The task will be solved using our new approach, by commercial FEM code ANSYS and also by numerical solution of differential equations in software Mathematica due to comparison reasons.

Let us consider electric conductor with rectangular cross-section according to Figure 1. Its length is $L = 500$ [mm], height $h = 10$ [mm] and width $b = 20$ [mm]. Let the conductor consists of mixture of two component materials – matrix (index m) with constant electric conductivity $\sigma_m(x, y) = 1.429 \times 10^6$ [Sm^{-1}] and thermal conductivity $\lambda_m(x, y) = 2$ [$\text{Wm}^{-1}\text{K}^{-1}$], and fibre (index f) with electric conductivity $\sigma_f(x, y) = 1.111 \times 10^7$ [Sm^{-1}] and thermal conductivity $\lambda_m(x, y) = 400$ [$\text{Wm}^{-1}\text{K}^{-1}$]. Volume fraction of individual com-

ponents is functionally changed according to chosen polynomial, graphically shown in Figure 1:

$$v_f(x,y) = 0.7125 - 7.2214x^2 + 9.6286x^3 + 92.500y - 1658.57x^2y + 2211.43x^3y - 2500y^2 + 1.5514 \times 10^5 x^2y^2 - 2.0686 \times 10^5 x^3y^2 - 9 \times 10^5 y^3 + 1.08 \times 10^7 x^2y^3 - 1.44 \times 10^7 x^3y^3 \ [-]$$

$$v_m(x,y) = 1 - v_f(x,y) \ [-]$$

Using extended mixture rule for chosen number of layers ($N = 11$) we get longitudinal variation of effective electric and thermal conductivities for individual layers and using laminate theory we can calculate also homogenized electric and thermal conductivity of FGM conductor, see Figure 4.

The equations of homogenized electric and thermal conductivities are:

$$\sigma^H(x) = 8.1273 \times 10^6 - 5.7507 \times 10^7 x^2 + 7.6676 \times 10^7 x^3 \ [\mathrm{Sm^{-1}}]$$

$$\lambda^H(x) = 277.352 - 2363.82x^2 + 3151.77x^3 \ [\mathrm{Wm^{-1}K^{-1}}]$$

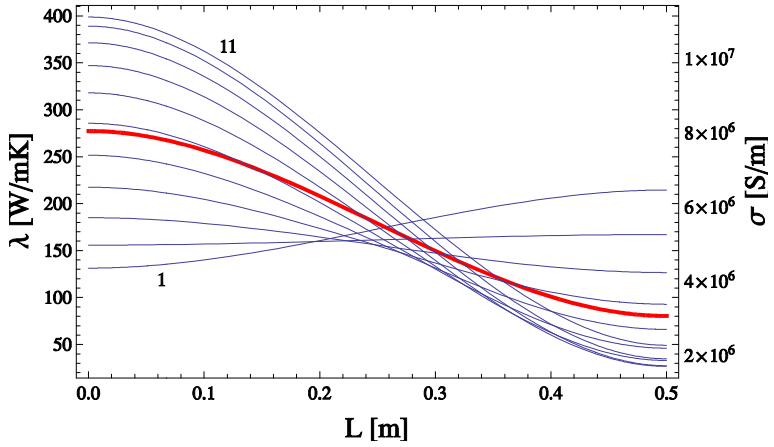

Figure 4: Longitudinal distribution of the homogenized electric and thermal conductivity (red) and the effective electric and thermal conductivities in respective layers for $N = 11$ (blue)

Let us consider final Seebeck coefficient for whole conductor according to chosen polynomial function (academic example, without considering homogenization process based on mixture of the components):

$$\alpha(x) = -4 \times 10^{-4} + 28 \times 10^{-4} x^2 \ [\mathrm{VK^{-1}}]$$

We assume static state for thermoelectric analysis. In nodes 0 and L there are electric potentials and temperatures specified and there is variable auxiliary heat generation in the conductor, so boundary conditions (see Figure 5) are:

$$\varphi(0) = 0.11 \ [\mathrm{V}]; \quad T(0) = 273 \ [\mathrm{K}]$$

$$\varphi(L) = 0 \ [\mathrm{V}]; \quad T(L) = 283 \ [\mathrm{K}]$$

$$P_{aux}(x) = 2 \times 10^5 - 6.4 \times 10^6 x^5 \ [\mathrm{Wm^{-3}}]$$

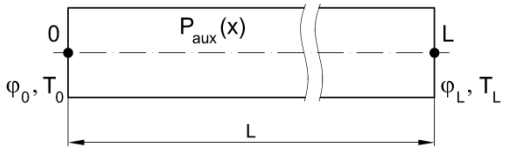

Figure 5: Boundary conditions of the model

We also created 2D model in code ANSYS [6], we used 55 000 PLANE223 elements (8 node quad-elements). The task was also solved in software Mathematica [7], where the differential equations (4) with specified boundary conditions and homogenized material properties were numerically solved using iterative algorithm. Finally, the task was also solved by only one our new developed two-nodal link element using FEM equations (17) and (20) for nodal points of the link and with equations (18) and (21) for chosen points within the link. In Figure 6 and Figure 8 we can see calculated longitudinal distribution of the electric potential and temperature in the conductor, respectively. In Figure 7 and Figure 9 there are shown distributions of the electric current densities and heat fluxes for chosen layers (1st, 6th and 11th layer), respectively. Summary of calculated results is in Table 1.

Table 1: Comparison of calculated electric and thermal quantities for chosen layers and homogenized values in nodal points of the conductor

There is small difference in the results (secondary variables) between ANSYS solution and calculation using the new approach in nodal points because of substitutional functions used for conversion non-polynomials into polynomials during iterative process. But we can see

from Figure 6 – Figure 9 that obtained results correspond to ANSYS 2D simulation very well. Differences in the results for primary variables in the conductor inner region are due to fact that our approach is based on reduction of the real 3D system into 1D problem.

CONCLUSIONS

New finite link element for two-way coupled static thermoelectric analyses has been developed in this contribution. New FEM equations with consideration Joule heat, auxiliary heat, and thermoelectric effects, like Seebeck and Peltier effects, were derived. Numerical example with good agreement between calculations with just only one new link element and commercial FEM code that uses numbers of classic elements have been presented. The new approach fully agrees with numerical solution for 1D differential equation of thermal and electric fields calculated using iterative algorithm. So, effectiveness and accuracy of the new developed link element for these analyses are excellent.

Abstract. *Partial or total progressive collapse under abnormal loading conditions (e.g. deliberate terrorist attacks, uncontrolled gas releases, and vehicle or aircraft impacts) is one of the most vivid examples of low probability-high consequence (LPHC) event that may occur in the lifetime of a structure. Despite this, structural safety for extreme loads that may lead to disproportionate (or progressive) collapse has been probabilistically assessed and controlled in a few cases, thus neglecting uncertainties in loads and system capacity. As such, this paper moves from a deterministic to a probabilistic framework, proposing fragility models at multiple damage states for low-rise reinforced concrete (RC) framed bare structures which may be applied for progressive collapse risk assessment and management. Two building classes representative of structures designed for either gravity loads or earthquake resistance in accordance with current European rules were investigated. Monte Carlo (MC) simulation was used to generate random realizations of two-dimensional (2D) and three-dimensional (3D) structural models. Their fiber-based finite element (FE) representations were developed within an open source platform for nonlinear static pushdown analysis. The output consisted of fragility functions for each damage state of interest. Such fragility models were then compared to those derived through incremental dynamic analysis (IDA) in a previous study. IDA-based and pushdown-based capacities were additionally used to propose regression models for quick estimation of dynamic amplification factor (DAF) at a given displacement/drift target. The analysis results show a significant influence of both seismic design/detailing and secondary beams on robustness of the case-study building classes.*

1 INTRODUCTION

Accidental and man-made extreme events such as impacts, fires or explosions can induce abnormal loads on building structures, which in turn may suffer heavy damage and finally experience a partial or total building collapse. This depends on the fact that structural systems designed according to conventional approaches are not necessarily able to withstand extreme loads. To confirm this scenario, several residential, iconic and public buildings resulted in significant casualties and property loss as a consequence of a disproportionately high propagation of direct damage to their key components [1-5].

Following the early interest in blast- and progressive collapse-resistant building analysis and design, which was triggered by the 1968 partial collapse of Ronan Point tower in UK, the occurrence of further dramatic accidents and deliberate attacks either in urban or industrial environments has led homeland security to become a primary concern for public authorities and stakeholders, causing the protection of structures against extreme loads to have a larger and larger impact on economy and society. Several definitions of progressive collapse, the most known of which is based on the significant disproportion in size between the initial and final damage configurations, have appeared in the literature [6-12]. Acting on building exposure, the contribution of nonstructural protective measures such as barriers, sacrificial elements and limitation or control of public access have been reaffirmed to be crucial in order to increase structural safety and to mitigate progressive collapse-related risk in a cost-effective manner. Moving from passive to active strengthening strategies, extensive efforts have been more recently made in design and simulation [13-35] to propose approaches and rules for structural integrity and robustness against abnormal loads. Codified methodologies [13-16] have emerged in the last two decades providing design guidelines to inhibit cascade or domino effects as a result of a local failure, which progresses in time to a collapse encompassing the entire structure or essential parts of it. Focusing on performance of structures and structural components, the key role played by requirements such as robustness, integrity, continuity, redundancy and ductility has been recognized [17-19]. Besides direct and indirect design provisions prescribed in codes and standards [13-16], a huge amount of analytical studies on blast and progressive collapse phenomena have been done [11, 12, 17-35], thus quantifying the influence of modeling assumptions and analysis techniques. Solid or shell FE [25, 28, 33, 34], lumped-plasticity [18, 22-24, 26, 27] and spread-plasticity [11, 12, 17, 19, 25, 29-32, 35] approaches have been examined for progressive collapse analysis of different building typologies ranging from civilian to strategic and military facilities. In this respect, conventional or alternative pushdown procedures and implicit or explicit nonlinear dynamic analyses have been explored using general purpose codes or open platforms.

Despite the large number of deterministic investigations, probabilistic approaches have been applied to a lesser extent in this field and a few research works have appeared in the literature so far (see e.g. [1, 6, 36-41]), emphasizing the need for probabilistic risk assessment and management of disproportionate collapse under blast loads and/or sudden column loss scenarios. In light of this, a framework for fragility analysis of European RC framed buildings was implemented, integrating fiber-based FE modeling with Monte Carlo simulation for random realizations of structural prototypes and pushdown analysis techniques for progressive collapse assessment. Two 4-story building populations, each of which analyzed using two types of numerical representation (i.e. 2D models and 3D models), were studied in a probabilistic fashion in order to propose fragility models at multiple damage states. The former class was designed only for gravity loads according to Eurocode 2 (EC2) [42], and the latter was designed for earthquake resistance in compliance with Eurocode 8 (EC8) [43]. For each building class under consideration (i.e. EC2-compliant structures and EC8-compliant structures),

fragility analysis was based on (i) the random generation of 2D and 3D fiber-based models through MC simulation, (ii) pushdown analysis of each structural model including dynamic effects in a simplified manner [15], and (iii) derivation of fragility functions for each structural model and damage state of interest. Considering design criteria and structural idealizations, four groups of fragility models were presented, thus quantifying the sensitivity of progressive collapse to design rules (i.e. seismic or non-seismic) and redistribution capacity of secondary beam systems. A comparison was then provided between such pushdown-based fragility models and those obtained by Brunesi et al. [40] using incremental-mass nonlinear dynamic analysis. Finally, the influence of dynamic effects on progressive collapse potential was estimated by taking advantage of IDA-based predictions [40] and pushdown capacity curves, which were determined without introducing any aprioristic amplification factor for specific structural portions. Pushdown and IDA estimates resulting from the application of the same uniform mass/load distribution over the entire structure were normalized in order to construct a set of DAF-vertical displacement/drift curves and to fit a corresponding regression model for each building class and structural representation under study, thus permitting a quick analytical assessment of DAF at a given displacement/drift design target.

2 FRAGILITY ANALYSIS: METHODOLOGY AND PROCEDURES

In a general framework for probabilistic risk analysis (PRA) using either hazard- or scenario-based approaches, the annual probability of disproportionate collapse can obtained through the conditional probabilities of two limit states: (1) local damage given an extreme event, and (2) global (structural) collapse given a local damage [6]. These two conditional probabilities can be in turn quantified using a multilevel analysis where uncertainties related to abnormal loading and structural system are modeled and propagated. The probability of damage to structural components and systems can be then obtained by means of reliability computations in which demand is convolved with capacity [44]. As such, PRA is a quantitative and rational tool for an effective risk-informed decision making process in case of LPHC events and fragility analysis can be considered as one of its fundamental components, which is indeed used in conventional risk management techniques to investigate and describe the physical vulnerability of a population of buildings or structural assemblies to specific damage scenarios. Although such concepts currently pertain to a well-established approach for disaster mitigation in earthquake engineering (see e.g. [45-50]), only a few applications have been recently presented for disproportionate collapse under blast loads and/or sudden column loss scenarios [36-41].

Several methodologies may be proposed to provide a mathematical formulation to vulnerability, either in terms of damage probability matrices or vulnerability curves, and there cannot be a unanimous consensus on a unique approach for derivation of vulnerability models to be implemented in PRA, due to a variety of structural modeling options, analysis techniques, and damage criteria. Even though any model with its level of sophistication presents peculiar advantages and drawbacks, the development of fragility models is recognized to be a key aspect for disaster mitigation actions, as those functions characterize the conditional probability of exceeding a certain damage level for a prescribed load intensity. The conditional probability may be defined as follows:

$$P_{ik} = P\left[D \geq d_i \middle| S = s_k\right] \tag{1}$$

where D is the damage measure (DM) used to describe structural or nonstructural damage, S is the scalar or vector-valued intensity measure (IM) used to describe the load intensity, and P_{ik} is the probability that the damage level d_i is reached or exceeded for a given IM level s_k.

Therefore, vulnerability to progressive collapse may be regarded as a measure of how prone a building is to damage for a given severity of the selected column removal scenario and the corresponding fragility models at multiple damage states may be regarded as a graphical representation of vulnerability to this type of mechanism, providing estimates of the proportion of a building class falling within discrete damage bands from a specified IM.

In light of the aforementioned considerations, this study presents a probabilistic mechanics-based assessment procedure for fragility analysis of structures subjected to disproportionate collapse. Analytical fragility curves were derived in case of gravity-load designed [42] and earthquake resistant [43] RC framed buildings. As discussed in the following, concepts of methodologies developed for earthquake engineering applications [45-50] and recently applied in this field [39, 40] were integrated with specific analysis techniques for progressive collapse simulation. A flowchart presenting the proposed routine and their prevailing components is shown in Fig. 1, while the rationale behind this framework is summarized hereafter.

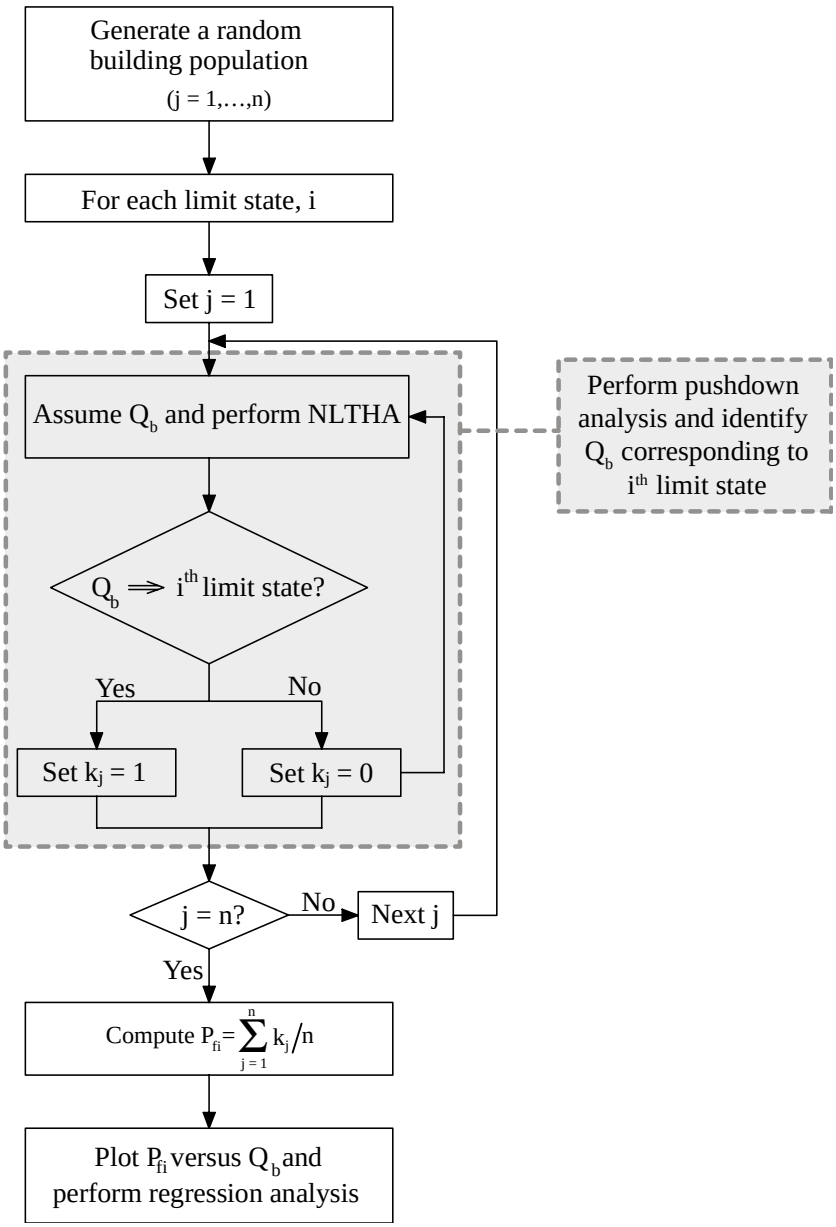

Figure 1: Flowchart for derivation of progressive collapse fragility models.

According to Brunesi et al. [40], fragility was estimated by means of a MC simulation consisting of the following three steps:

1) Generation of the building population which implied modeling of random variables (RVs) in compliance with statistics and probability distribution functions for material properties, geometrical parameters and design loads.
2) Damage analysis of each random realization which implied identifying simulated design criteria and numerical modeling strategies to predict progressive collapse potential and assess whether a prescribed amount of damage at a given IM level is reached or not.
3) Analytical derivation of progressive collapse fragility which implied adopting procedures for nonlinear regression analysis in order to fit cumulative fragility points, after that capacity and demand were convolved.

In this latter step, the distribution of buildings in each damage state of interest was used to derive the statistical parameters – i.e. mean (μ), standard deviation (σ) and coefficient of determination (R^2) – of each lognormal fragility function, fitting discrete points from damage probability matrices through the least squares technique. To evaluate progressive collapse fragility, several thousands of structural prototypes for each building class were randomly generated on the basis of statistics and probability distributions for each RV, as specified in Section 3, and their capacity was estimated by means of classical fiber force-based [51] FE approaches commonly adopted in earthquake [46, 48, 50, 52] and progressive collapse analysis [11, 12, 17, 19, 25, 29-32, 35, 40]. To this aim, pushdown simulation techniques [11, 17, 18, 23, 24, 31] rather than IDA procedures [19, 26, 40] were implemented and the downward load on beams (Q_b) was assumed as reference IM. Three criteria, either at local/sectional or global/structural levels, were selected for the identification of limit states corresponding to slight damage (LS1), significant damage (LS2) and complete damage (LS3), thus allowing the evaluation of structural performance. Based on capacity/demand convolution, fragility models for EC2-compliant [42] and EC8-compliant [43] buildings analyzed using either 2D or 3D prototypes were finally computed, allowing a two-way comparison between functions obtained (i) by different design solutions for the same type of structural representation (i.e. EC2-conforming versus EC8-conforming), and (ii) by different modeling types for the same design rules (i.e. 2D versus 3D).

3 UNCERTAINTY MODELING AND COMPUTATIONAL STRATEGY

Pushdown analysis was implemented in a fragility analysis framework to provide the probability of exceedance of different damage states induced by column loss events. In this study, two design rules (i.e. according to EC2 [42] and EC8 [43]) and two structural idealizations (i.e. 2D and 3D models) were considered, resulting in four types of structural models each of them characterized by different kinds of uncertainty. Thousands of samples of RC framed structures were randomly generated for each of the two building populations (i.e. gravity-load and earthquake resistant prototypes). Uncertainties in geometry, material properties and loads were modeled according to Brunesi et al. [40], as a further aim of this paper is to compare IDA-based and pushdown-based fragility models, thus quantifying the mismatch between the two analysis methods. As discussed in Section 6, corrective coefficients were proposed for the statistical parameters (i.e. μ and σ) of each lognormal fragility function derived from the latter approach in direct relation to those computed through nonlinear dynamic simulations. As such, every simulation realization analyzed herein was assumed to be equal to the corresponding random idealization studied in the comparative research [40]. A summary of selected RVs with their peculiar probabilistic features was provided in the following, while more compre-

hensive details regarding the statistical background of MC sampling can be found in [40]. A similar consideration can be drawn in terms of FE idealization of each case-study of the two building classes, as specified in the upcoming discussion.

As shown in Fig. 2, the structures under study were 4-story, 4×4-bay RC framed buildings, which had a lateral force-resisting system (LFRS) composed of five primary frames connected each other by one-way RC joist slabs and continuous cast-in-situ secondary beams. Following typical layouts and building practice, the span lengths in both longitudinal and transverse directions, namely L_x and L_y, were assumed as RVs with uniform distribution in the range [4.0 m, 6.0 m]. A similar criterion was applied in past studies for random sampling associated with seismic vulnerability analysis of RC structures (see e.g. [45, 46, 48, 50]). The center-to-center plan dimensions were equal at any floor, but varied in length (*x*-direction) and width (*y*-direction) according to different random combinations of column spacing in the two directions. As progressive collapse resistance was found to be almost insensitive to changes in the interstory height [19], the latter was considered as a deterministic parameter equal to 3.0 m. Material uncertainties were taken into account by randomly selecting steel yielding strengths of 380 MPa and 450 MPa and cubic concrete strengths of 25 MPa, 30 MPa and 35 MPa, each of them assumed to have the same probability of occurrence [48]. Those values were considered as nominal strengths which were then multiplied by a normally distributed (dimensionless) RV with mean equal to 1.1 in case of reinforcing steel and 1.5 in case of concrete, and with coefficient of variation (CoV) equal to 10%. Finally, a normal distribution was assigned to dead load (DL) with mean of 3.0 kN/m^2 and CoV = 17%, whereas live load (LL) was considered as a deterministic parameter equal to 2.0 kN/m^2 because the case-study buildings were assumed to be employed for housing. In order to permit a representation of the sample in the low probability region of the distribution, the Latin Hypercube algorithm was adopted for MC sampling of RVs with normal distribution [40, 48].

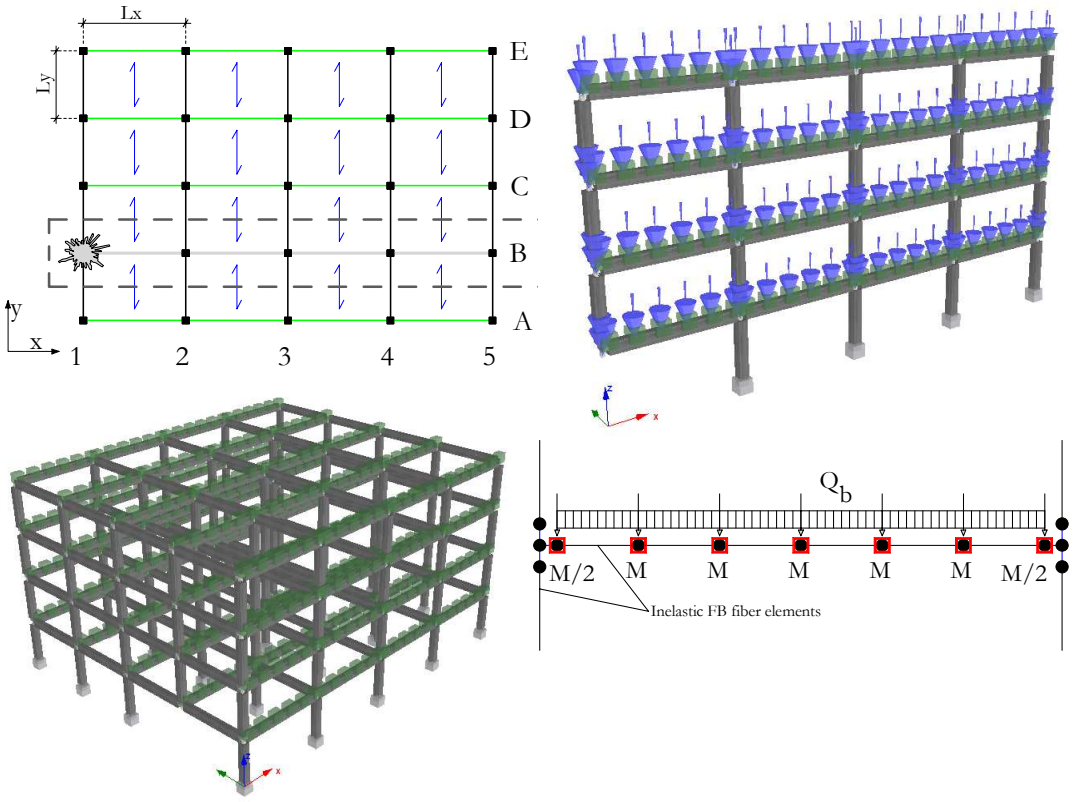

Figure 2: Example of a representative structural prototype.

Fig. 2 shows isometric and plan views of a representative building model used for damage analysis through distributed-plasticity approach and pushdown simulation techniques. While high-definition solid FE models based on classical principles of nonlinear fracture mechanics [53-55] represent an attractive solution for interpreting the evolution of crack patterns and damage mechanisms of RC structures at a local level [25, 33, 34], fiber-based idealizations were shown to be a transparent and viable approach to accurately characterize the inelastic response of such building typology in a computationally efficient manner [32]. To this aim, the open FE platform SeismoStruct [56] was adopted to prepare 2D and 3D models of EC2-compliant and EC8-compliant structures and to play out the series of pushdown analyses explicitly including material and geometric nonlinearities. Potential large displacements/rotations and P-Delta effects were taken into account using a total corotational transformation [52] and the spreading of inelasticity over the member length and cross section was reproduced through a direct integration of the uniaxial material response of individual fibers. Each inelastic beam-column element had 5 integration points and each cross section was discretized in 400 fibers to accurately represent its stress/strain state during incremental monotonic loading. A one-to-six correspondence between structural members and model elements was assumed to reduce numerical instability and accommodate the deformed shape during progressive collapse analysis (Fig. 3). A simple bilinear constitutive rule with isotropic strain hardening was assigned to reinforcing steel, whereas the uniaxial uniform confinement model proposed by Mander et al. [57] was assumed to simulate the inelastic behavior of concrete, explicitly accounting for tension softening [40].

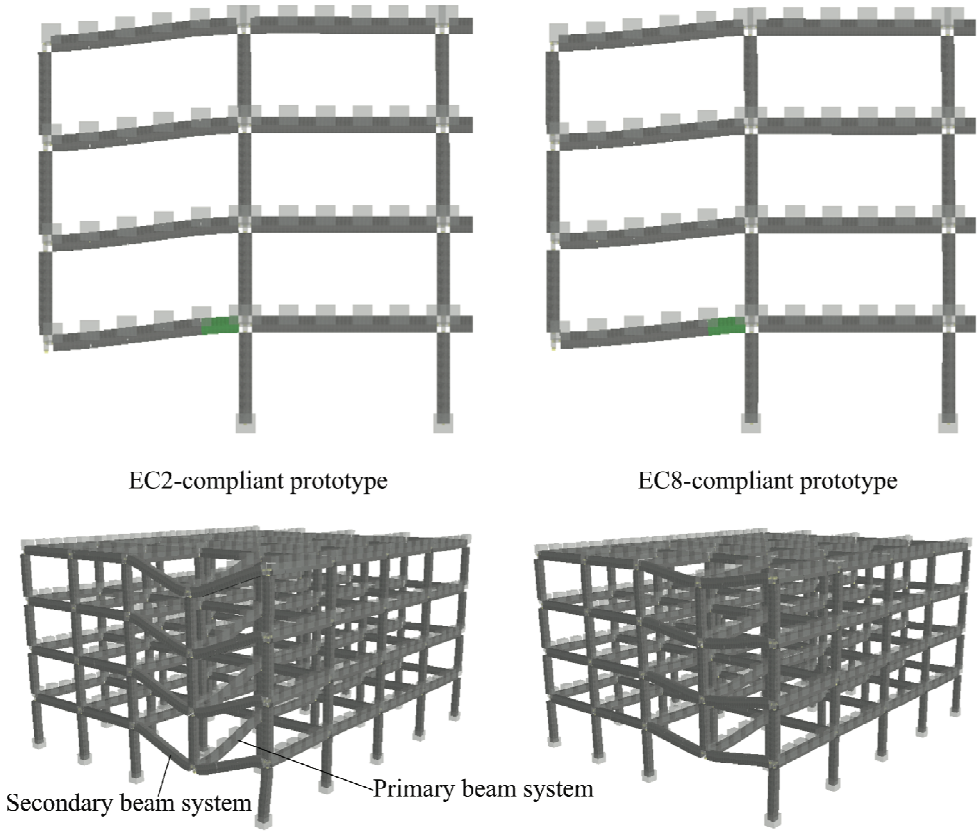

Figure 3: Deformed shapes at ultimate conditions of EC2-compliant and EC8-compliant buildings.

In order to characterize the nonlinear response of random populations of case-study buildings, two analysis types can be used in both direct and indirect progressive collapse-resistant

assessment procedures: nonlinear static (or pushdown) analysis, and nonlinear dynamic analysis. The former is a relatively simple approach and provides a load-displacement capacity curve that, similarly to seismic analysis, permits one identifying whether a structure has adequate capacity to withstand extreme loads or not, in a static fashion. Material and geometric nonlinearities such as large displacements/rotations (i.e. beam-catenary action), second order effects, coupled axial-flexural inelastic behavior and plastic hinge formation (i.e. stiffness/strength degradation and ductility exploitation) can be included in the analysis using a nonlinear static method. Nonetheless, the main disadvantage of a static simulation is the inability to take into account the dynamic behavior of a structure in case that one or more bearing elements are instantaneously removed from the frame. This loading condition may cause highly dynamic effects which in turn may lead a statically safe structure to become dynamically unsafe due to the fact that time-dependent overloads produced by column loss may induce a progressive fracture of other members before a new equilibrium state is achieved [19, 22, 29, 34, 40]. As a result of this cascade effect, a different dissipative mechanism and related propagation of damage through the cross section depth may be predicted to occur by different analysis methods. If pushdown analysis is based on the application of a monotonically increased downward load or load distribution, during dynamic analysis the structure is damaged under cyclic reversals, as it oscillates upward and downward in such a way that more closely reflects the physical nature of progressive collapse.

In light of those considerations, procedures were proposed to equivalently include dynamic effects in a static fashion whether pushdown techniques are adopted for progressive collapse assessment [14, 15, 26]. In particular, the new Unified Facility Criteria (UFC) released in 2009 [15] prescribed the application of a non-uniform downward load distribution to the structure, explicitly identifying structural portions characterized by different levels of dynamic amplification (i.e. adjacent spans and areas away from the removed column). As such, this code-compliant approach was integrated within the probabilistic simulations performed to carry out fragility analysis, thus accounting for the dynamic nature of progressive collapse phenomena in a simplified and computationally efficient manner. As discussed in [40], fragility analysis needs an iterative procedure in case of dynamic analysis because a step function with monotonically increasing magnitude is required for an aprioristic factorization of Q_b that is able to simulate the different dynamic loading conditions corresponding to attainment of each limit state for each structure realization (Fig. 1). On the other hand, a single incremental analysis can be more rapidly performed in a static fashion and directly provides a set of displacement-controlled Q_b values for each building prototype which allows one evaluating multiple damage states at once.

The effectiveness of this equivalent nonlinear static procedure [15] was evaluated in comparison with IDA estimates [40] and a further set of standard pushdown analyses [14] was carried out assuming a uniform downward load distribution consistent with that selected for vertical mass when performing dynamic simulations. Therefore, pushdown capacity curves obtained by this latter approach were normalized with respect to IDA envelopes in order to compute a series of specific force-based DAFs for the two populations of EC2-conforming and EC8-conforming case-study buildings. Regression analyses were then performed using predictions for both 2D and 3D structural models and simplified equations were proposed to allow DAF to be estimated as a function of vertical displacement/beam drift. Furthermore, sensitivity of progressive collapse potential to simulation techniques with different levels of sophistication (i.e. IDA [40] versus pushdown [15]) was probabilistically assessed in terms of fragility functions.

The prevailing trends emerged from pushdown analysis with and without consideration of equivalent dynamic effects [15], namely P1 and P2, are discussed in the following.

4 PUSHDOWN ANALYSIS OF EC2-CONFORMING STRUCTURES

In the first stage of this research, progressive collapse capacity of EC2-compliant buildings was predicted by means of 2D and 3D structural models in combination with pushdown analysis techniques including or not dynamic effects in a static fashion (i.e. P1 and P2). This allowed the authors to carry out a two-way comparison between response predictions obtained (i) by different types of structural idealization for the same type of analysis (i.e. 2D versus 3D models), and (ii) by different analysis types for the same structural representation (i.e. P1 versus P2). Thus, the influence of dynamic effects and secondary beam systems on robustness of EC2-conforming case-study prototypes was quantified. The conclusions drawn from capacity curves presented in this section were then compared to those derived for earthquake resistant building class examined in Section 5 and finally extended in terms of fragility models, as discussed in Section 6.

4.1 Two-dimensional versus three-dimensional models: EC2-compliant buildings

To assess and compare the progressive collapse potentials of gravity-load designed structures in terms of analysis method and structural modeling, an internal 2D frame was first extracted from each 3D model and then analyzed by removing the leftmost ground column. That scenario was considered as it is the most demanding single column-removal condition in case of framed buildings [19]. As shown in Fig. 4, response estimates for the 2D models were then collected and compared to those provided by nonlinear static analysis of 3D models, in order to quantify the effects of secondary beam systems in the redistribution of gravity loads from a removed column. This sensitivity was initially investigated considering the results of standard pushdown analysis (i.e. P2) and the trends observed were then compared to those obtained by pushdown assuming a non-uniform load distribution (i.e. P1), thus exploring the influence of dynamic effects and corresponding equivalent load pattern on the resisting/redistribution mechanisms enforced in both primary and secondary frames.

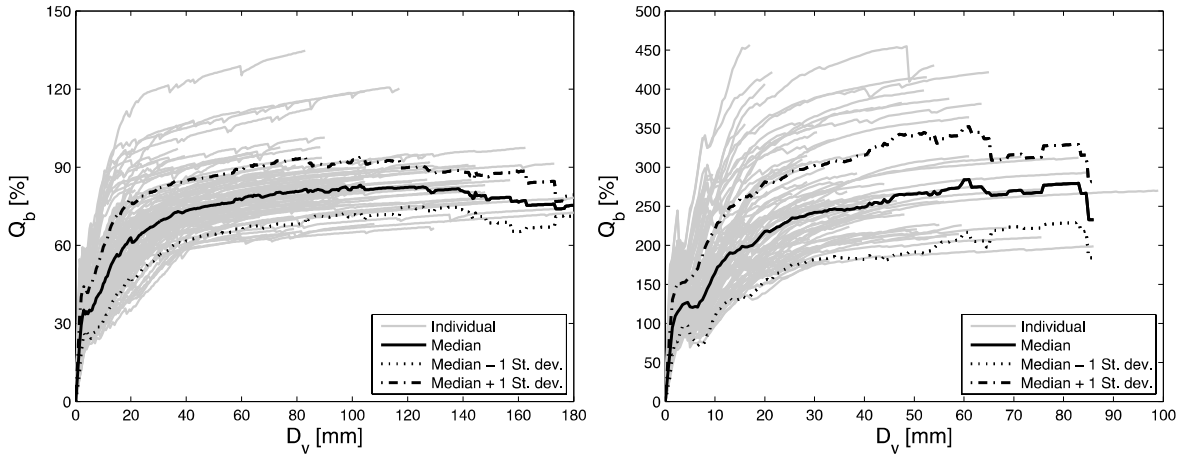

Figure 4: Pushdown (P2) curves of EC2-conforming buildings using 2D models (left) and 3D models (right).

Fig. 4 presents the set of downward load-vertical displacement curves predicted for 2D and 3D models, revealing a maximum progressive collapse capacity of about $1.35Q_b$ in case of the most resistant 2D structure. Peaks of up to $0.83Q_b$ can be observed if the median is considered, and capacities approximately lying within a ± 12% fork were shown when referring to median ± 1 standard deviation. The set of numerical predictions obtained by 3D models confirmed the significant influence of secondary framing beams on progressive collapse potential of the sys-

tem, as they provide a rationally-controlled alternative load path for the unbalanced demand induced by a column loss scenario. Given that one-way slabs were assumed according to construction practice for such buildings, secondary beams were supposed to resist only their self-weight so they were designed to comply with minimum reinforcement requirements by current European standards [42] and, hence, they can be considered as a latent resource of stiffness and strength. The redundancy provided by secondary beams or "secondary-beam effect" visibly improved the robustness of case-study prototypes, being their contribution effective in controlling the overall structural response. As a result, capacities approximately 3 times higher than those shown for 2D models were predicted in this case considering either maximum or median resistance of the EC2-compliant buildings. Slightly more scattered estimates were determined as a wider fork of up to ± 24% resulted when computing median ± 1 standard deviation. As discussed by Brunesi et al. [40], predictions suggested that these secondary members may be actively used to interact with the primary frame systems, resulting in a stiffer, stronger and more stable response under column loss-induced overloads. Due to their visible participation in primary mechanism, vertical displacement peaks more than halved can be shown when 3D and 2D models are compared (Fig. 4).

4.2 Uniform versus non-uniform load distributions: EC2-compliant buildings

In this subsection, the sensitivity of progressive collapse resistance to analysis method was investigated, focusing on gravity-load designed 2D and 3D structural models. In detail, Fig. 5 collects the series of downward load-vertical displacement capacity curves determined for the EC2-conforming population of structures by means of pushdown analysis based on the application of code-compliant [15] non-uniform load distributions able to account for different levels of dynamic amplification in specific portions of the structure. Peculiar behavioral aspects of obtained response (i.e. P1) were examined. In addition, a comparison was provided with those discussed in subsection 4.1 for conventional pushdown analysis approach (i.e. P2).

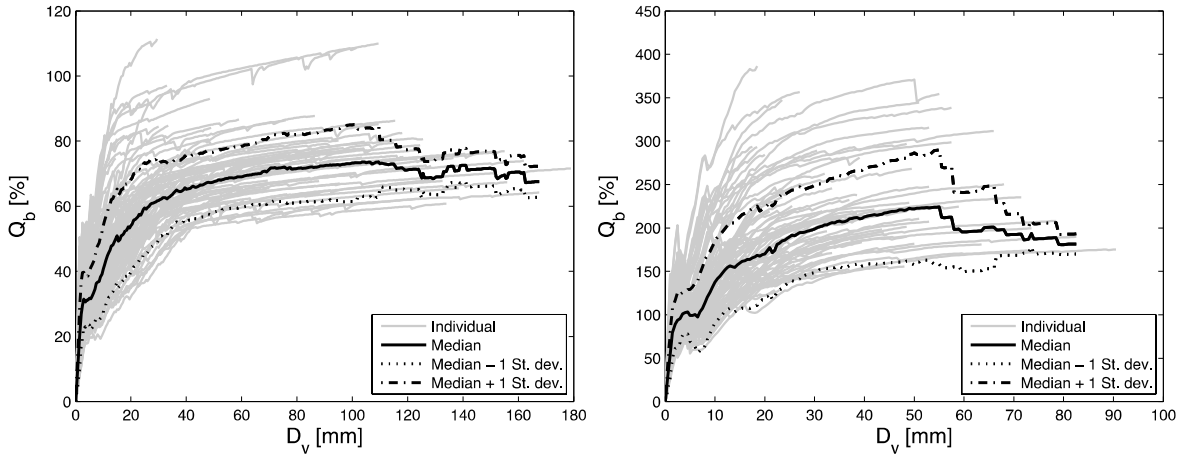

Figure 5: Pushdown (P1) curves of EC2-compliant buildings using 2D models (left) and 3D models (right).

Such an approach explicitly includes dynamic effects in a nonlinear static analysis using an equivalent/global procedure that provides a constant amount of overload dependent on plastic and yielding rotational capacity to be applied to specific structural portions more sensitive to a sudden column removal than others (adjacent spans versus areas away from the removed column). Therefore, predictions more conservative than those resulting from P2 were achieved in this case either for 2D or 3D models. Peaks of about $1.11Q_b$ and $3.86Q_b$ were predicted for the most resistant 2D and 3D structure, respectively. Such an outcome confirms the considerable

contribution provided by secondary frame elements for gravity load redistribution as a consequence of a sudden column-removal condition. As previously mentioned, 3D models resulted in capacities approximately 3 times larger than those determined in case of 2D models. Compared to P2, estimates roughly 10%-20% smaller can be observed as a consequence of equivalent dynamic effects. By contrast, similar considerations can be drawn in terms of median and standard deviation.

4.3 Regression models for DAF estimation: EC2-compliant buildings

DAF can be considered as a mechanical measure that permits one to quantify the inaccuracy of pushdown analysis in comparison with IDA for different design targets beyond the elastic range of the structure. As such, DAF was obtained as the ratio between static and dynamic capacities in terms of vertical peak resistance of the 2D or 3D structural model at a given vertical displacement. Fig. 6 presents the series of force-based DAF versus vertical displacement curves of the population of gravity-load designed structures.

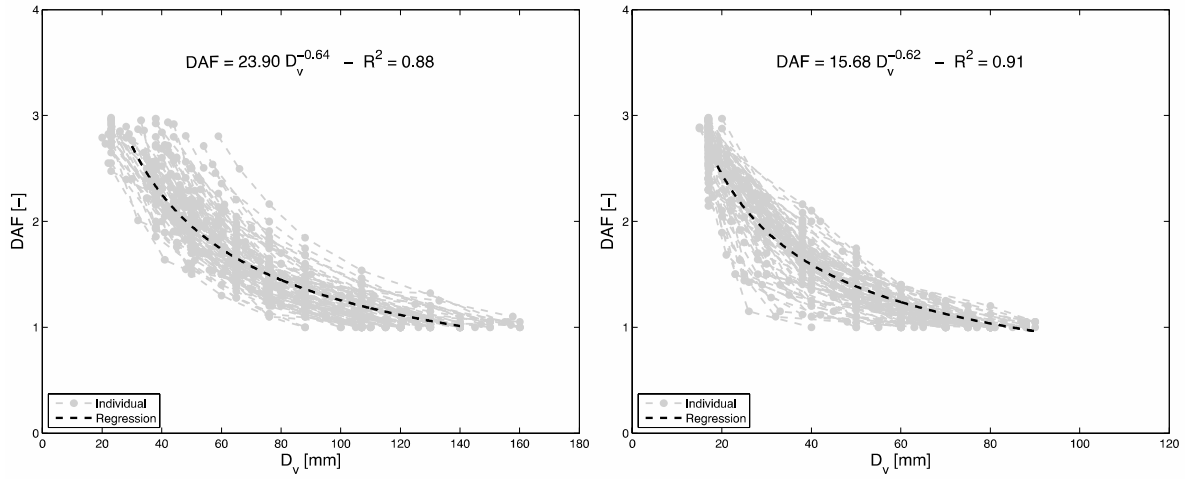

Figure 6: DAF estimates for EC2-conforming building class using 2D models (left) and 3D models (right).

To get a reliable estimate of this quantity, standard pushdown analysis (P2) was used as it is based on the application of a uniform downward load distribution, according to that assumed for nonlinear dynamic simulations [40]. The set of static-to-dynamic capacity ratios of 2D and 3D models collected in Fig. 6 were then used to conduct a regression analysis, which is aimed at providing specific analytical expressions for a quick assessment of DAF at a given vertical displacement/drift target. Accurate predictions were observed for both 2D and 3D models, as the coefficient of determination (R^2) was equal to 0.88 and 0.91, respectively.

5 PUSHDOWN ANALYSIS OF EC8-CONFORMING STRUCTURES

The procedures assumed to perform progressive collapse analysis of EC2-compliant building class were then applied to the population of EC8-compliant structures. As before, numerical simulations were carried out considering either 2D or 3D models. Pushdown analysis with and without consideration of dynamic effects was performed on prototype buildings having the same overall geometry in accordance with MC random sampling of RVs but different detailing as they were separately designed in compliance with EC2 [42] and EC8 [43]. In particular, the population EC8-conforming structures was designed for a medium-high seismicity, assuming the PGA at bedrock to be 0.30g for life safety limit state. A type C ground was selected to perform design in medium ductility class by response spectrum analysis on 3D mod-

els, incorporating accidental eccentricity of the center of mass. Further and more comprehensive details regarding simulated design criteria and related sectional properties/reinforcement layouts may be found in Brunesi et al. [40], while the prevailing numerical observations resulting from the series of pushdown analyses carried out are summarized hereafter, in direct relation to those derived for EC2-conforming case-study buildings.

5.1 Two-dimensional versus three-dimensional models: EC8-compliant buildings

The set of pushdown capacity curves obtained by 2D and 3D models are collected in Fig. 7, and reflected a visible benefit from seismic design/detailing rules. Peak force capacities 50%-70% larger than those observed in case of gravity-load designed structures were predicted for earthquake-resistant framed buildings.

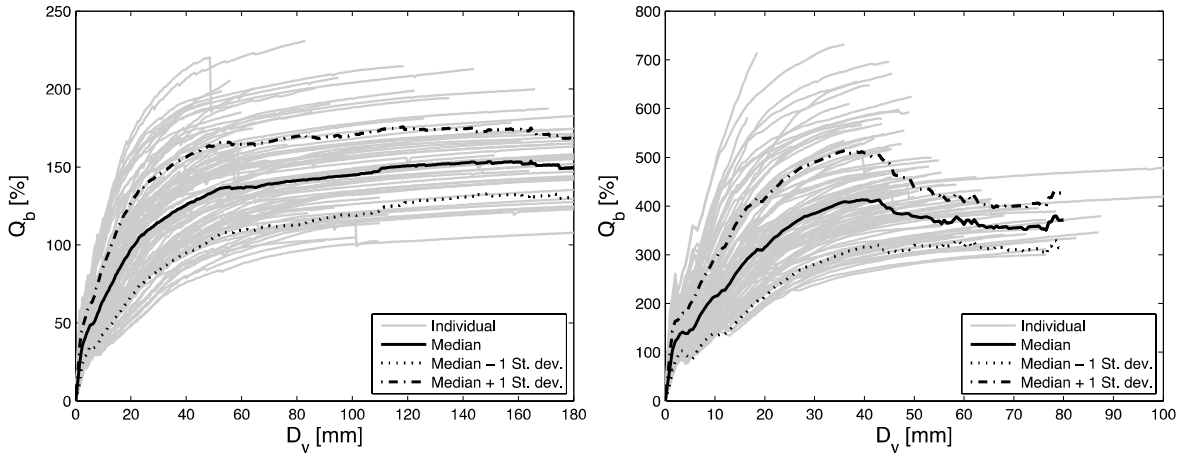

Figure 7: Pushdown (P2) curves of EC8-compliant buildings using 2D models (left) and 3D models (right).

Such an outcome is mostly due to more stable and robust flexural hinging mechanisms and arch effects/catenary actions developed in the critical portions of EC8-compliant structures, as a result of minimum seismic requirements and symmetrical arrangement of longitudinal reinforcement [43]. Compared to EC2-conforming buildings, their collapse modes were characterized by different levels of resistance, robustness, rationale and control. The EC8-conforming prototypes can displace further in the nonlinear regime of their response, or alternatively carry higher loads for a given vertical displacement. Maxima of about $2.31Q_b$ and $7.31Q_b$ were determined using 2D and 3D models, respectively. Hence, the trends emerged by comparing the responses of 2D and 3D gravity-load resistant framed structures were confirmed and corroborated even further by the series of pushdown curves shown in Fig. 7.

5.2 Uniform versus non-uniform load distributions: EC8-compliant buildings

Dynamic effects were included in progressive collapse analysis according to the equivalent procedure proposed in UFC [15], thus permitting one to evaluate their influence on robustness of EC8-conforming building class. In Fig. 8, the downward load-vertical displacement curves predicted by means of 2D models were compared to those obtained using a 3D structural idealization. The peak progressive collapse resistance was found to be equal to $2.09Q_b$ and $6.77Q_b$ in case that the strongest 2D and 3D prototypes are considered, respectively. Compared to Fig. 7, Fig. 8 reveals 10%-15% lower capacities, thus reaffirming the key role played by this code-compliant procedure in controlling the unsafety level of a standard pushdown approach. When considering the median of EC8-compliant buildings, the maximum load carrying capacity was approximately $1.39Q_b$ in case of 2D models and a ± 15% fork was observed whether referring

to median ± 1 standard deviation. On the other hand, a more than doubled peak resistance resulted from the median of 3D models, in combination with a ± 10% wider fork for median ± 1 standard deviation.

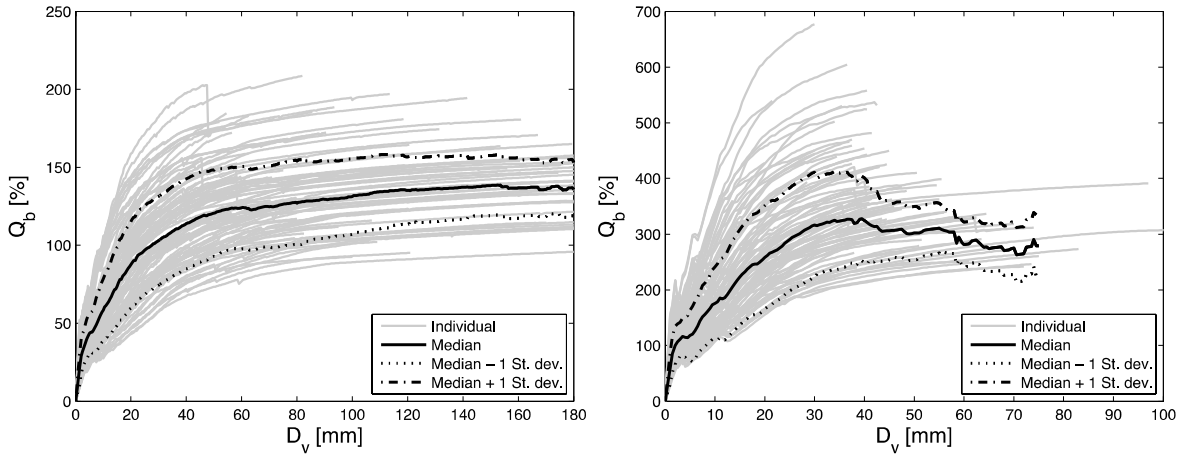

Figure 8: Pushdown (P1) curves of EC8-conforming buildings using 2D models (left) and 3D models (right).

The comparison between pushdown capacity curves of EC2-compliant and EC8-compliant random realizations (i.e. Fig. 5 versus Fig. 8) revealed trends similar to those evidenced when comparing the results of standard pushdown simulations (i.e. Fig. 4 versus Fig. 7). The significant benefit from seismic design/detailing criteria, which was highlighted for either 2D models or 3D models, can be therefore reaffirmed.

5.3 Regression models for DAF estimation: EC8-compliant buildings

Conventional pushdown predictions (i.e. P2) and IDA estimates [40] were used to quantify the discrepancy between the two simulation techniques at different levels of inelastic demand for column loss-induced overloads. As done in case of EC2-conforming prototypes, an exponentially decaying model was fitted to the series of static-to-dynamic capacity ratios obtained by 2D and 3D models (see Fig. 9), thus proposing simplified equations for quick analytical assessment of DAF for earthquake resistant buildings.

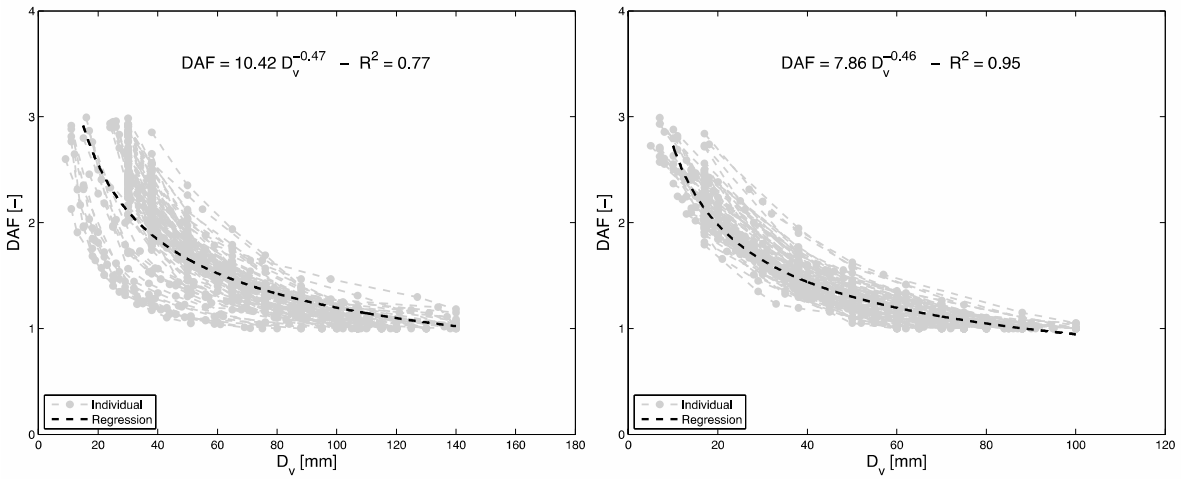

Figure 9: DAF estimates for EC8-compliant building class using 2D models (left) and 3D models (right).

The scatter is very low in case of 3D structural models, as the resulting regression function is characterized by a coefficient of determination equal to 0.95. Conversely, regression analysis provided a less accurate fit using capacities from 2D models (i.e. $R^2 = 0.77$), particularly in the small displacement range, that is when structural performance was characterized by minor or moderate damage.

6 DERIVATION OF FRAGILITY MODELS

To convolve capacity and demand under progressive collapse scenario, the following three criteria were introduced – either at global/structural (i.e. vertical drifts) or local/sectional (i.e. concrete and steel strains) levels – for limit states definition: slight (LS1), significant (LS2) and complete (LS3) damage. As discussed in [40], slight damage limit condition refers to a situation in which the building can be immediately used after an event with minor repair or strengthening only, so it can be regarded as a sort of serviceability limit state. Conversely, complete damage can be considered as an ultimate limit state beyond which the structure is close to collapse, being no longer able to deform and to sustain any further load increment nor the gravity loads for which it has been designed. Significant damage can be regarded as an intermediate case beyond which the building becomes unsafe for its occupants, being the majority of its source of nonlinearity yet fully in use. Therefore, LS2 may be identified as a sort of life safety limit state.

To determine whether a structural element reaches a limit condition, strains and drifts experienced in the critical portion of the skeletal frame where the progressive collapse mechanism was forced to occur were compared with conventionally identified limit capacities [40]:

- LS1 was defined by steel and concrete strains for both EC8- and EC2-compliant building classes. For each randomly generated structure, the yielding strain of steel bars was computed as the ratio between yielding strength and Young's modulus, while concrete strain at peak strength was determined in accordance with Mander et al. [57].
- LS2 was supposed to occur when the vertical drift, obtained as the ratio between the peak displacement above the column removed and the beam span length, exceeded a deterministic threshold. In detail, that drift was assumed to be equal to 0.5% and 1.0% in case of EC2-conforming and EC8-conforming building classes, respectively.
- LS3 was characterized in terms of ultimate steel strain and ultimate concrete strain. For each randomly generated structure, the ultimate concrete strain was calculated according to different material properties and reinforcement arrangement, whereas the buckling/fracture strain of steel bars was set to 4% and 6% in the case of EC2-conforming and EC8-conforming building classes, respectively.

Therefore, a multiplier of Q_b was identified on each pushdown (P1) curve for each damage state, in order to assemble a damage probability matrix. The latter contained fractions of sampled structures in each damage state, for a set of increasing Q_b levels. The cumulative fraction of buildings in each damage state was then computed, summing up the percentages of frames pertaining to each of them according to MC simulation. Finally, a lognormal cumulative distribution function was fitted to fragility points through regression analysis, thus providing the probability of exceeding each damage state in a continuous fashion.

Fragility functions for each structure typology are shown in Figs. 10 and 11, while their parameters, in terms of mean, standard deviation and coefficient of determination, are collected in Table 1. A good match with fragility points from pushdown analysis was observed for each limit state (i.e. LS1, LS2 and LS3), design approach (i.e. EC2- and EC8-compliant structures) and structural idealization (i.e. 2D and 3D models), being R^2 in the range 0.972-0.999.

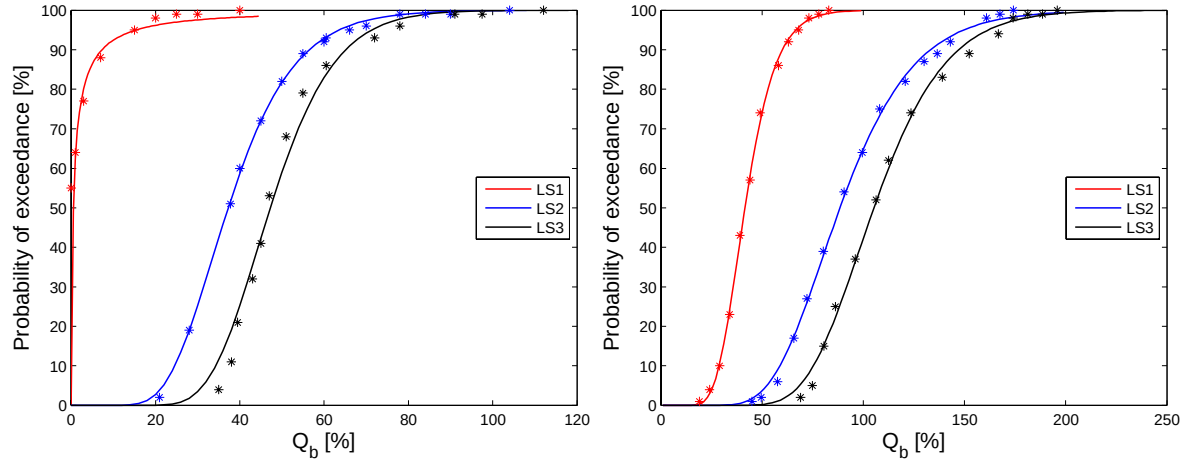

Figure 10: Fragility models of EC2-compliant (left) and EC8-compliant (right) building classes – 2D prototypes.

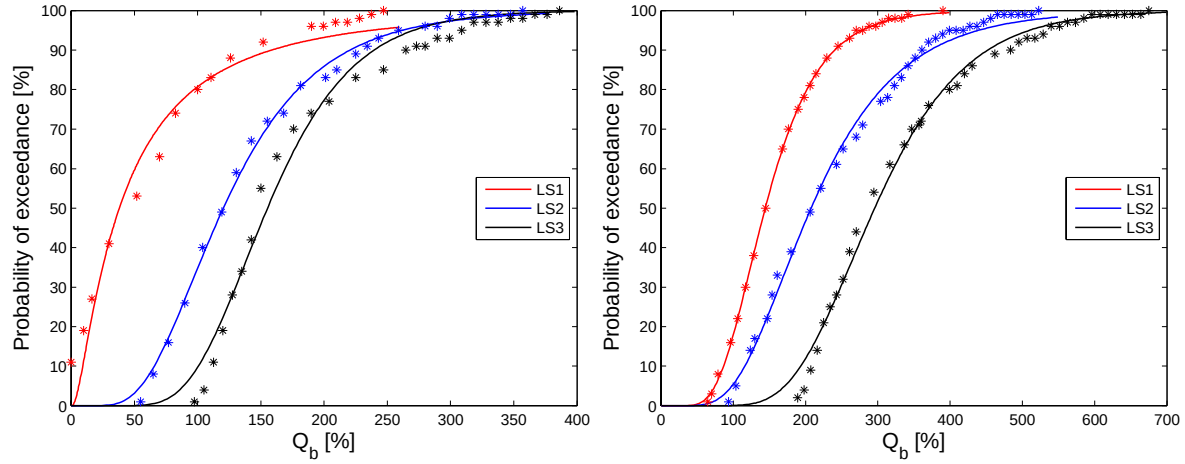

Figure 11: Fragility models of EC2-compliant (left) and EC8-compliant (right) building classes – 3D prototypes.

		LS1			LS2			LS3		
Class	**Model**	μ	σ	R^2	μ	σ	R^2	μ	σ	R^2
EC2-conf.	2D	-5.243	2.053	0.985	-0.987	0.325	0.999	-0.749	0.240	0.985
	3D	-0.964	1.112	0.972	0.186	0.472	0.997	0.440	0.338	0.982
EC8-conf.	2D	-0.880	0.288	0.999	-0.122	0.319	0.998	0.051	0.261	0.996
	3D	0.367	0.399	0.999	0.731	0.456	0.995	1.084	0.332	0.994

Table 1: Pushdown analysis (P1) – μ, σ and R^2 of fragility functions in terms of Q_b.

A very low scatter can be observed in case of EC8-conforming structures, as their fragility models are characterized by a coefficient of determination close to unity ($0.995 < R^2 < 0.999$) for both 2D and 3D models. As far as the EC2-compliant building class is concerned, an identical accuracy was obtained for LS2 and LS3, considering both 2D and 3D models, while the goodness of fit for LS1 was slightly lower as R^2 equals 0.985 and 0.972 for 2D and 3D models, respectively. Nonetheless, that limit state (i.e. slight damage condition) is less crucial than others for progressive collapse applications, in which (i) moderate damage is likely to occur

as a consequence of redistribution of vertical loads from a removed column and (ii) an optimal design target is the life safety or collapse prevention limit state in light of classical performance-based design principles. Moreover, the fragility models proposed in this study reaffirm the key role played by secondary framing beams and seismic design/detailing rules for a cost-effective progressive collapse vulnerability mitigation of RC structures. In fact, a symmetrical reinforcement configuration is effective for the creation of a rationally-controlled primary resisting mechanism, whereas redundancy added by secondary beam systems (designed to satisfy minimum reinforcement requirements prescribed in current code regulations) is crucial to ensure alternative load paths under abnormal loading conditions. In this respect, it can be emphasized that the additional robustness resources provided by secondary frame systems can be predicted at the design stage, for instance through a correlation between the maximum vertical displacement of the 3D model normalized to that of the equivalent 2D model ($D_{max,3D}/D_{max,2D}$) and the maximum demand-to-capacity ratio of beams [19].

Finally, the set of fragility models at multiple damage states derived and commented in this research were compared to the corresponding set of IDA-based functions proposed by Brunesi et al. [40]. Table 2 presents ratios of mean ($\chi_\mu = \mu_{IDA}/\mu_{P1}$) and standard deviation ($\chi_\sigma = \sigma_{IDA}/\sigma_{P1}$) of IDA-based and pushdown-based fragility functions for each damage state, design approach and structural representation of interest.

		LS1		**LS2**		**LS3**	
Class	**Model**	χ_μ	χ_σ	χ_μ	χ_σ	χ_μ	χ_σ

	3D	1.528	1.182	0.232	1.169	0.789	1.073
EC8-conf.	2D	1.321	1.459	2.015	1.225	-0.511	1.075
	3D	0.344	1.208	0.822	1.192	0.909	1.040

Table 2: IDA vs. P1 – ratios of mean ($\chi_\mu = \mu_{IDA}/\mu_{P1}$) and standard deviation ($\chi_\sigma = \sigma_{IDA}/\sigma_{P1}$) of fragility functions.

Pushdown analysis was therefore confirmed to be unconservative for vulnerability assessment of RC framed structures subjected to progressive collapse, as detailed from a deterministic standpoint in past studies [19, 40]. In light of this, ad hoc countermeasures are likely to be implemented in current regulations for progressive collapse scenario loss modeling.

7 CONCLUSIONS

In this work, a modeling procedure for large displacement inelastic pushdown analysis was integrated in a probabilistic framework for the derivation of fragility functions for RC framed structures under extreme loads resulting from a threat-independent sudden column loss. Two low-rise RC building classes were studied, namely gravity-load designed buildings and earthquake resistant buildings. The case-study structures were investigated using two analysis methods, i.e. pushdown analysis with and without consideration of equivalent dynamic effects, and two modeling strategies, i.e. 2D and 3D fiber-based models. The progressive collapse fragility was evaluated for both case-study building classes, considering both structural idealizations as well as uncertainties related to geometry of structural elements, material properties and gravity loads. Classical performance-based assessment principles assumed in earthquake engineering were extended to define demand and capacity at local and global structural levels. A set of fragility models were then derived, allowing the following conclusions to be drawn:

- The fragility models proposed in this study are optimally fitted to discrete fragility estimates provided by pushdown analysis combined with MC simulation, particularly for life safety and total collapse prevention limit states which are crucial for progressive collapse assessment.
- Different fragility levels are associated with multiple damage states, depending on the building class and modeling strategy considered in probabilistic progressive collapse assessment.
- Considerable benefits from seismic design and secondary beams on the actual robustness level of RC bare building structures are confirmed and quantified by the fragility models proposed herein.
- Incremental-mass nonlinear dynamic analysis is suggested to be implemented in progressive collapse-resistant building analysis and design, as pushdown analysis was proven to underestimate the fragility level associated with this type of structures in case of progressive collapse.

Keywords: Robustness, fire induced progressive collapse, S355 structural steel, high strain-rates, high temperatures, Johnson-Cook constitutive law.

Abstract. *With the intention of focusing the attention on the extreme combined effects of temperature and dynamic loadings, the high strain rate behaviour in tension of the widely used S355 structural steel in a wide range of elevated temperatures is presented.*
By means of a Split Hopkinson Tensile Bar (SHTB) equipped with a water-cooled induction heating system, the main mechanical properties as well as different strain energy densities have been evaluated. The reduction factors for the main mechanical properties, in which the novelty of our data is the addition of the strain rate dependency to the temperature, are reported as well. Lastly, a critic review of the Johnson-Cook constitutive law has been reported, highlighting that the use of single averaged thermal softening parameter (m) could lead to considerable errors. These results could be of great interest for the assessment of robustness in structures subjected to fire induced progressive collapse.

1 INTRODUCTION

An extended exposure to high temperatures may severely influence the performance of the steel framed structures triggering for example a fire induced progressive collapse.

Even if the progressive collapse became an important topic after the partial collapse of the Ronan Point Building (UK) in 1968 [1, 2, 3], only after the 9/11 World Trade Center tragedy [4, 5] a significant amount of research has been carried out to assess the fire resistance and to predict the blast response of steel structures. But, only uncorrelated effects of dynamic loadings and high temperatures have been considered [6]. For that reason the mechanical response of steel structures subjected to extreme combined effects has still criticisms open to investigation.

With the intention of fulfilling these criticisms, the mechanical behaviour of a widely used structural steel, namely S355, in a wide range of temperatures (200 °C, 400 °C, 550 °C, 700 °C and 900 °C) and high strain rates will be presented. The results can be of great interest for the assessment of robustness in structures where a progressive collapse is triggered by a coupled effect of fire and dynamic loadings.

2 PROGRESSIVE COLLAPSE: CHOICE OF THE APPROACH

Two approaches are known for studying the progressive collapse, namely the indirect and the direct methods. While for the first, the designers may use an implicit design, in the second the designers need to perform a structural analysis. Two typical used direct methods are the *specific local resistance method* (known also as *key element design*) and the *alternate load path*.

Another approach that should be followed is based on the employment of discrete element method (DEM) models. An extensive research in this field has been performed by Masoero *et al*. [7, 8, 9], that demonstrated the DEM's applicability to progressive collapse by simulating the behaviour of 2D and 3D framed structures after a sudden damage.

Focusing the attention on the direct methods we should not forget the analytical procedure that can be used to model the problem. Although simplified hypotheses are supposed, like *linear static* or *non-linear static* analysis as well as *linear dynamic* analysis, the most rigorous approach for evaluating a progressive collapses is through the use of an explicit *non-linear dynamic* procedure. But, even if the *non-linear dynamic* procedure is the most accurate approach, another fundamental aspect should be taken into consideration: the real mechanical properties of the material subjected to extreme combined loadings [10].

With the intention of evaluating the structural performance in response of a coupled effect of fire and blast loading, one of the most commonly implemented [11, 12, 13] and easy-to-use constitutive relationships in the finite element programs is here considered. This constitutive model has been proposed by Johnson and Cook during the eighties [14] and is widely used to describe the material strength in numerical simulations of dynamic events. The flow stress can be expressed as:

$$\sigma = (A + B \cdot \epsilon_p^n) \cdot (1 + c \cdot ln\frac{\dot{\epsilon}}{\dot{\epsilon}_0}) \cdot (1 - T^{*m}) \tag{1}$$

where ϵ_p is the true plastic strain, $\dot{\epsilon}$ is the considered strain rate, $\dot{\epsilon}_0$ is the reference strain rate (taken as 1 s^{-1}) and T^* is a dimensionless temperature. In order to find the Johnson-Cook parameters A, B and n [15], representing the strain hardening effects of the material in quasi-static conditions, c [15] representing the strain rate sensitivity and m [16] representing the thermal softening sensitivity, a mechanical characterisation in a wide range of temperatures and high strain rates is necessary.

3 MECHANICAL CHARACTERISATION AT HIGH STRAIN-RATES AND HIGH TEMPERATURES

The mechanical characterisation at high strain-rates was carried out by means of a Split Hopkinson Tensile Bar (SHTB) installed at the DynaMat Laboratory [17]. The tests at elevated temperatures were performed by using an Ambrell compact EASYHEAT induction water-cooled heating system (Figure 1). A detailed description of the functioning of the SHTB equipped with the induction water-cooled heating system has been given in [16].

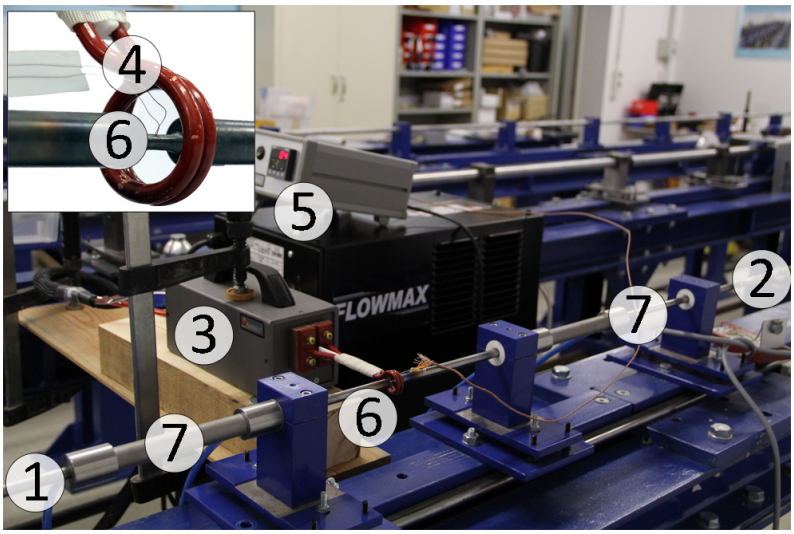

Figure 1: Setup for the high strain rate tests at elevated temperature: (1) the input bar, (2) the output bar, (3) the heating system, (4) the water-cooled induction coil, (6) the sample to be tested connected by means of a thermocouple to a (5) thermal controller and (7) the cooling system for the input and output bars, respectively.

The specimens for the mechanical characterisation were obtained in the longitudinal direction from an hot-rolled wide-flange section HE A [18]. Starting from the initial section geometry, wire electrical discharge machining (WEDM) was used in order to obtain small prismatic samples, that where turned in order to obtain round samples with 3 mm in diameter and 5 mm of gauge length. A full description of the geometry is reported in [19, 20].

In order to understand the effect of the temperature on the dynamic mechanical properties of the S355 structural steel, the high strain rate tests at elevated temperatures were performed with the same testing conditions adopted at room temperature. With these testing conditions and at 20 °C, the obtained averaged strain rates were approximately 300 s^{-1} ($v_1 = 2.30$ m/s), 500 s^{-1} ($v_2 = 2.90$ m/s) and 850 s^{-1} ($v_3 = 4.00$ m/s). The corresponding particle velocities in the input bar, used as a reference for the testing condition, are reported within brackets.

Additional tests were also performed by compensating the preload with the intention of obtaining tests with comparable effective strain rate. This has been helpful for the calibration of the Johnson-Cook thermal softening sensitivity parameter (m).

4 RESULTS

Due to the different mechanical properties of steel at elevated temperatures, an increase of the reflected pulses is noted for increasing temperatures (Figure 2 left). This lead to a noticeable increase in the averaged strain rate at different temperatures (Figure 2 right).

The temperature effect on the mechanical properties of the S355 structural is represented in Figure 3, where the engineering stress versus strain and the true stress versus strain represen-

tative plots are depicted. In Figure 4 the post-mortem images of the samples tested at different temperatures are reported.

Another way of comparing the tensile properties at different temperatures is by means of a reduction factor determined as the ratio of the value at elevated temperatures to the corresponding value at room temperature. The reduction factors for the proof strength and the ultimate tensile strength evaluated at high strain rates are reported in Figure 5. It is possible to observe that the reduction factor proposed by the Eurocode 3 [21] for the proportional limit in quasi-static conditions is not applicable for the high strain-rate tests, while the reduction factors seem not to be strongly different for the three testing conditions. The reduction factors for the other mechanical properties are reported in [16].

5 CONSTITUTIVE MODEL

The Johnson-Cook parameters evaluated by means of tests at room temperature are reported in Table [15], while the experimental data at different temperatures and for a fixed strain rate ($450\,s^{-1}$) were used to determine [16] the thermal softening sensitivity parameters (Table 2).

In a previous study by the current authors [16], a thermal softening factor obtained experimentally at different temperatures was defined (R^*). In Figure 6 a comparison between this

factor and the thermal factor of the Johnson-Cook constitutive law $(1 - T^{*m})$ with fixed single values of m is reported. It is possible to observe that single averaged values of m obtained by comparing only two sets of data from room temperature and a single high temperature, could lead to considerable errors.

6 CONCLUSIONS

In this paper the high strain rate behaviour in tension of the widely used S355 structural steel in a wide range of elevated temperatures has been presented.

- Due to the different mechanical properties of steel at elevated temperatures, a perceptible increase in the effective strain rate was observed.
- The tensile properties were not significantly influenced by the different dynamic testing conditions.
- A remarkable difference between quasi-static and high strain rate reduction factors was highlighted.
- A perceptible variation of the thermal softening parameter (m) was highlighted.
- Using a single averaged value of m could lead to considerable errors.

These findings could be helpful in order to simulate the effect of a dynamic loading, e.g. an explosion, on steel structural elements under different temperatures. As a future development a numerical simulation will be implemented in Ls-Dyna considering the material properties of the structural steel S355 at high temperatures and high loading rates.

Keywords: Robustness, Progressive Damage, Nonlinear FEM, Commercial software.

Abstract. *Different procedures for assessing the robustness of a reinforced concrete (RC) frame under progressive damage are proposed and compared. The removal of a column in a RC frame structure is modeled with a commercial nonlinear finite element software according to three alternative strategies: (i) reduction of mechanical properties of the damaged column, (ii) incremental loading of the structure after total removal of the damaged column, and (iii) incremental unloading of internal forces on the damaged column. Nonlinear analysis is performed under a prescribed load combination on three concrete frames designed with three Italian building codes in force in different periods. Despite the differences in the strategies for damage modeling, similarities between structural response predictions are highlighted. In addition, it is shown that seismic design provisions for RC building structures increase the ductility of the structure but do not guarantee the robustness against the removal of a column.*

1 INTRODUCTION

Structural engineers have been concerned with the resistance of building structures to disproportionate collapse since Ronan Point accident in 1968. In 2001, the catastrophic failures of WTC towers in New York showed the true effects of progressive collapse and raised the public interest on such topic. Specific guidelines have been developed and robustness requirements have been inserted in building codes and laws. Eurocode 0, which is the document at the base of the modern European national regulations on constructions, states that *a localised failure due to accidental actions may be acceptable, provided it will not endanger the stability of the whole structure, and that the overall load-bearing capacity of the structure is maintained and allows necessary emergency measures to be taken*.

In such framework, the researches conducted since the second half of the last century have focused the attention on sudden element removals [1, 2, 3]. Basically, such situations are induced by explosions and impact loads [4]. For ensuring structural robustness in constructions, the modern design philosophies switch from being reliability-based to accounting for consequences of local failure. In this sense, Gudmundsson and Izzuddin [5] argued that the scenario of sudden column loss is an effective and straightforward strategy for integrity assessment. Various design guidelines implement such approach through linear/nonlinear static or nonlinear dynamic analysis [6, 7]. On one side, static analysis with dynamic increase factor may lead to conservative rather than unsafe design depending on the structural behaviour and configuration [8]. On the other, a large computational effort is required for detailed nonlinear dynamic analyses [9].

Despite the previous scenario are the ones that have engendered and still cause many fatalities for building occupants, the attention has recently switched on other sources of degradation and damage [10, 11]. For example, Sun and others dealt with the progressive collapse of steel frames due to fire [12, 13] modifying a FEM code developed at the University of Sheffield. Others used commercial FEA software ABAQUS for investigating the behaviour of steel structures and connections subjected to fire loads, e.g., [14]. Fang and others [15] proposed a simplified energy-based robustness assessment approach in which the maximum temperature is unknown (i.e., this represents an event-independent local damage scenario); they assess the integrity of the steel structure subjected to fire through a multistage procedure implemented on ADAPTIC code.

The robustness of concrete buildings subjected to element removal has been usually assessed through numerical, experimental and analytical strategies (see, for example, [16, 17, 18]). In addition, theoretical [19, 20, 21, 22] and probabilistic approaches [23, 24, 25] as well as scenario analyses have been already formulated and proposed [26].

The aim of the research herein presented is to model in a simple and feasible way a progressive damage acting on concrete frame structure through a commercial software. This is fundamental for assessing the robustness of a construction in such unexpected scenarios [27].

2 METHODS

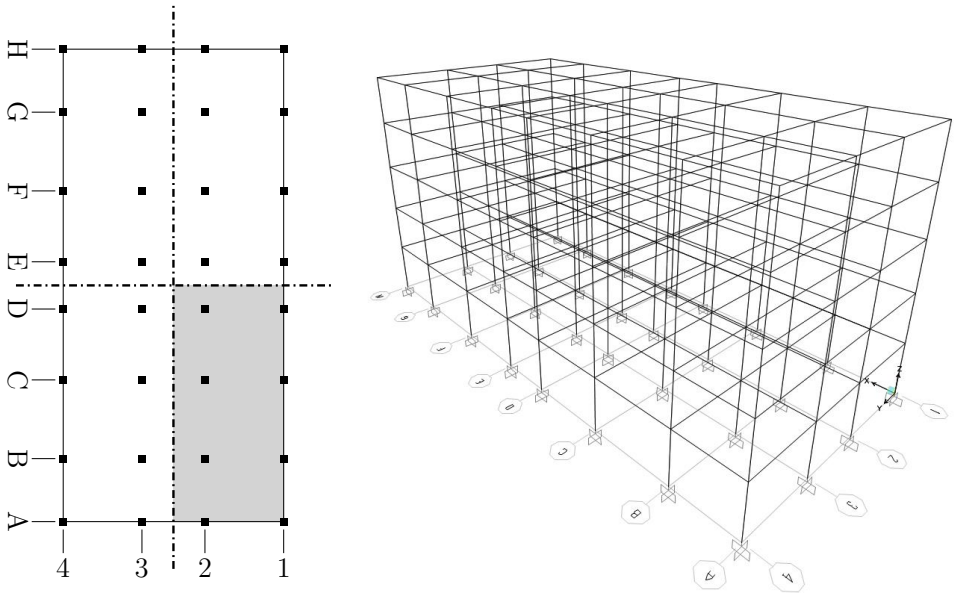
A progressive damage acting on a column of the first level of a reinforced concrete structure is simulated. The structure is subjected to the following load combination

$$1.50\,(DL + 0.25LL)\,, \tag{1}$$

where DL represents the dead load, i.e., the weight of the structural and nonstructural components; LL is the live load, i.e., the moving loads. This load combination is suggested in GSA

[28]; the term 1.50 is the dynamic amplification factor [29].

The test structure is represented by a 14×30 m reinforced concrete frame structure made of 140 beams and 160 columns distributed in five levels. The columns are disposed along the nodes of a grid, as depicted in the schematic of Figure 1(a). The plan position of each column is identified by means of a letter (from A to H) and a number (from 1 to 4) As can be observed in Figure 1(b), at each level, each node is connected with the neighboring ones through an orthogonal mesh of beams (28 beams per level). The levels are labelled by Roman numbers from I (ground level at +0.00 m) to VI (top level at +15.20 m). The interstorey height is 3.20 m for level II and 3.00 m for the remaining levels. The elevation of the levels is reported in Table 1. The bottom nodes, i.e., the foundation nodes, are rigidly constrained.



(a) (b)

Figure 1: (a) Plan view of the schematic of the reinforced concrete frame structure; (b) prospective of the frame structure.

Level	Elevation	Level	Elevation
I	0 m	IV	9.2 m
II	3.2 m	V	12.2 m
III	6.2 m	VI	15.2 m

Table 1: Elevations of the levels of the structure.

In the following, the nodes are identified by the sequence N:[plan position(level)]; for example, the node set at the fourth level at the position identified by letter E and number 3 is written as "N:E3(IV)". The beams are identified by the sequence B:[position of the initial node]:[position of the final node]; in this sense, for example, the beam of the third level (+9.20 m) connecting the nodes N:C2(III) and N:D2(III), is named as "B:C2(III):D2(III)". The columns are identified by the sequence C:[position of the bottom node]:[position of the top node]; for example, the column between the nodes N:F2(II) and N:F2(III) is denoted as "C:F2(II):F2(III)". The structure is doubly symmetrical in plan. Thus, the right-hand side lower quarter is considered in the present paper. The results are replicable to the other corresponding parts of the structure.

Referring to the amount of reinforcement within the elements, the structural safety (of the undamaged structure) has been guaranteed through three different design philosophies. In the first case (named "D+HoR" in the following), ultimate limit state semi-probabilistic approach accounting for ductility and hierarchy of resistances has been implemented; in the second case (named "D" in the following), only ductility requirements are satisfied; in the third case (named "S" in the following), only static design accounting for dead and live loads (with basic seismic design requirements) has been performed. The previous design philosophies correspond to present and early Italian building laws, i.e., [31], [32], [33], respectively. Following the well-known structural mechanics rules, the bending moment-curvature relationships for each of the three structural schemes previously illustrated has been computed and the nonlinear flexure relationships have been implemented in the corresponding Finite Element models.

The effects of progressive column removal have been analyzed through the implementation of three different numerical strategies, described in detail in the following subsections.

In all simulations, eight columns, corresponding to the bottom column of the studied quarter of the construction, are alternatively considered. The identification codes and sizes of the columns are reported in Table 2. The behavior of the structure to the progressive damage is evaluated through the maximum vertical drift of all the beams converging in the top node of the damaged element. In reference to Figure 2 in which two horizontal beams converge in node N, the vertical drift, v_{N}, is

$$v_{\mathrm{N}} = \max\left\{\frac{\Delta_1}{\ell_1}; \frac{\Delta_2}{\ell_2}\right\}. \tag{2}$$

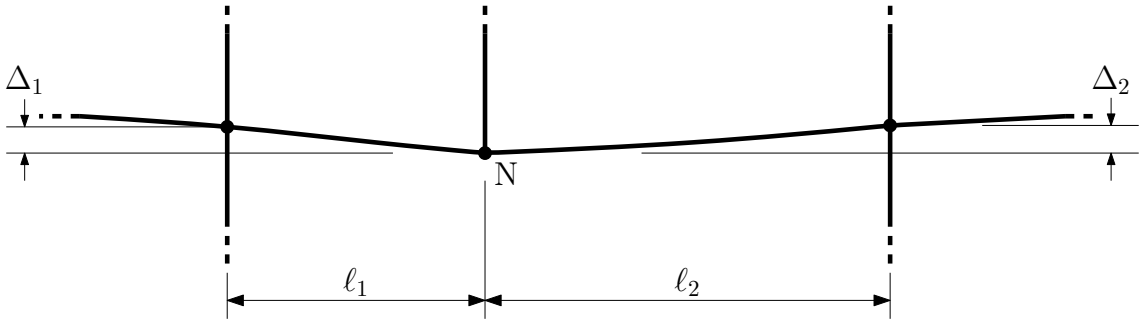


Figure 2: Scheme for the evaluation of vertical drift.

Progressive number	Identification code	Size (cm^2)	Progressive number	Identification code	Size (cm^2)

Table 2: Damaged elements.

The simulations were performed on an Intel i7, 3.60 GHz, 64-bit computer with 16 GB RAM. A specific MATLAB script controlled a SAP2000 solver and stored the displacement of the monitored nodes on a database file. The computation times related to each simulation are evaluated through MATLAB software.

2.1 Damage model A

The damage model A implemented a progressive reduction of the cross-section area and inertia. As implemented by Lematre and Chaboche [30], the degradation of the structural element was controlled by a damage parameter d varying from 0, in case of no damage, to 1, in case of total damage. If $d = 1$ the element is totally removed. The geometrical properties of the i-th element, i.e., the damaged element, of the RC frame were

$$\begin{aligned} A_{id} &= A_{i0}\,(1-d) \\ J_{id} &= J_{i0}\,(1-d)^2\,, \end{aligned} \tag{3}$$

where A_{i0} and J_{i0} are the cross-section area and inertia. The damage model acted on the size of the concrete cross section, not on the area of the rebar.

The eight columns previously identified were alternatively subjected to the damage, and the overall response of the frame structure was monitored. The simulations (21 in total) were performed at the following values of the damage parameter d:

- from d = 0.000 to d = 0.700, with step of 0.100;
- from d = 0.700 to d = 0.850, with step of 0.050;
- from d = 0.850 to d = 0.950, with step of 0.025;
- from d = 0.950 to d = 0.990, with step of 0.010;
- at d = 0.995 and d = 1.000.

For each value of the damage parameter, the reduced geometrical properties, i.e., the ones derived from Eqn. (3), are automatically assigned to the damaged element. For sake of simplicity, a unique undamaged scheme was considered as a basis for all the simulations. The external load was applied to the damaged structure with its nominal value, see load combination detailed in Eqn. (1). SAP2000 solver was set as static nonlinear. Meanwhile, the vertical displacements of the top node of the damaged column (i.e., the node set at level II, i.e., at +3.20 m), as well as the boundary nodes at the same level, were monitored. In addition, the axial force in the damaged element was recorded. This allowed to rapidly estimate the vertical drift of the beams at +3.20 m, assessing the amount of damage on the floor. The results associated with each value of damage parameter were independent one from each other. No previous damage history is considered was each simulation.

2.2 Damage model B

The damage model B considered the total removal of the damaged element and the progressive loading of the structure. Before the incremental loading of the structure, no additional loads were acting on the scheme. The loading process was controlled by the vertical displacement of the top node of the damaged element (i.e., the node set at +3.20 m). Because of that, the loading process might be related to an incremental "pushdown" analysis. In order to monitor the effective load on the structure at each loading step, the total base vertical reaction was considered. The reference base reaction value in the undamaged scheme was determined before the removal of the element and, then, the corresponding values at each loading step were recorded.

2.3 Damage model C

The damage model C considered the substitution of the damaged element with a set of forces that simulate its presence. The forces are then progressively reduced to zero. The simulations accounting for this damage model were implemented as follows, see Figure 3 for visual details. First, (i) the undamaged structure was loaded with the external loads with the load combination into Eqn. (1). A nonlinear solver was considered and the displacements and the forces in the elements were evaluated. In particular, the forces acting in the potentially damaged element were recorded, i.e., the red forces in Figure 3(a). In the present paper, only the forces acting at the top end of the element were considered; the bottom end of the element, being a base column, was restraint. Then, (ii) the damaged element was removed and a set of external forces, F^*, were added to the scheme, black forces in Figure 3(b). Such forces are opposite to the ones of the previous step, i.e., $F^* = -F$. A nonlinear run was made and the nodal displacements were read and it resulted that were approximatively equal to the ones computed at step (i). In the following (iii), a system of forces f opposite to the ones derived in the previous step (ii) was added on the node, as sketched in blue in Figure 3(c). The purpose of the model was to progressively reduce the effects of forces F^*, which means damaging the i-th element. Thus, forces f were progressively increased from zero to F following a displacement controlled incremental scheme (see Damage model B for details on the control node). Therefore, it results

$$\begin{aligned} f &: 0 \to F \\ F^* + f &: F^* \to 0. \end{aligned} \tag{4}$$

It might happen that it was not possible to increment the forces f to their nominal value F because a failure occurs in the loading process. In this case, the ultimate value of f was considered in the analysis.

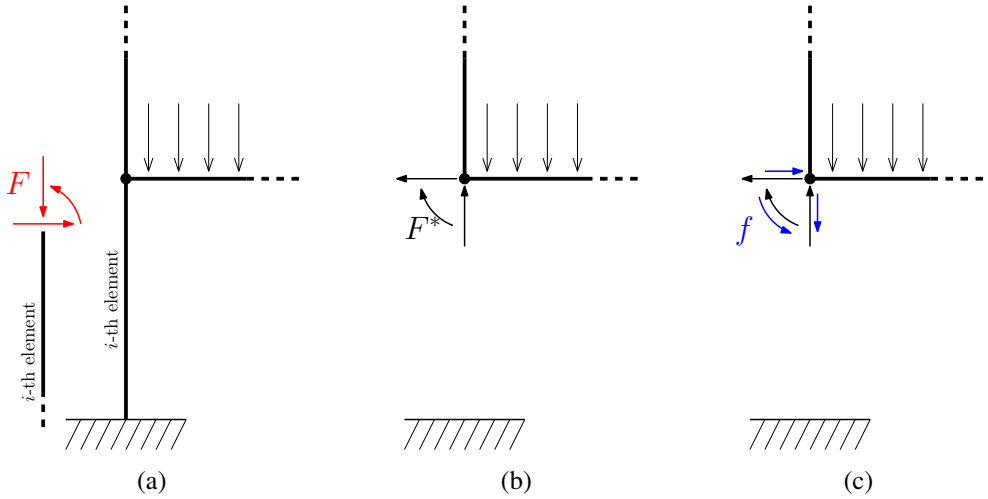

Figure 3: Damage model C. The details are reported in section 2.3.

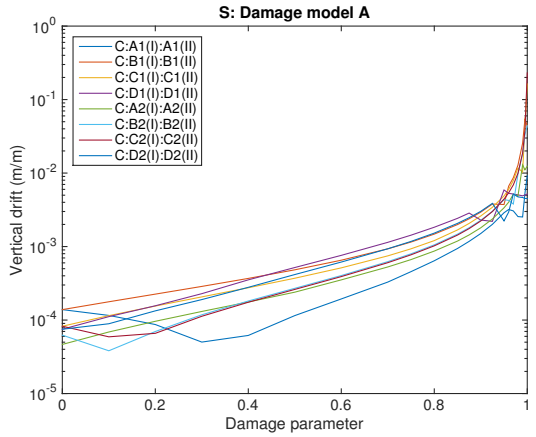
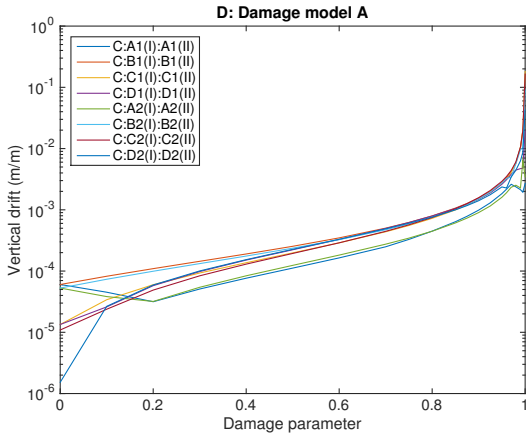
3 RESULTS

The observed behavior modes of the three structures subjected to the three damage models are presented in the following. Figure 4 displays the values of vertical drift as much as the

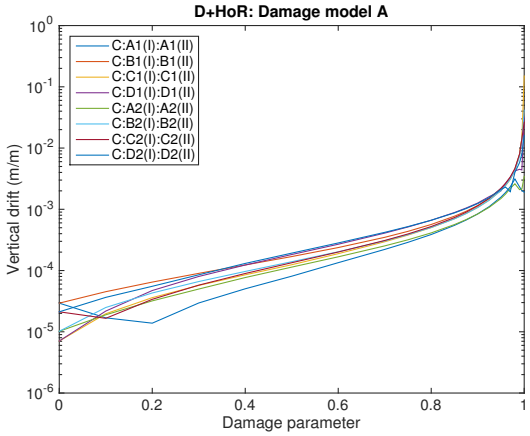
damage parameter d increases. If figure panels are observed, it emerges that the trends obtained for the three structures designed with different standards ("S", "D" or "D+HoR") are similar. The increment of the vertical drift is relatively small for low values of damage parameter, while it sharply increases as much as d tends to unity. The behaviors of the three different structures to damage are compared observing the ranges of the damage parameter at equal vertical drift. For the structure able to support static loads only, see Figure 4(a), a vertical drift of 10^{-3} is given for values of d ranging between 0.65 and 0.85 (depending from the damaged element). A narrow range of values of the damage parameter are found for the same vertical drift in the other two structures: 0.84 – 0.91 in ductile only schemes ("D") and 0.86 – 0.92 in "D+HoR" structures.



(a) "S": static design



(b) "D": ductility design

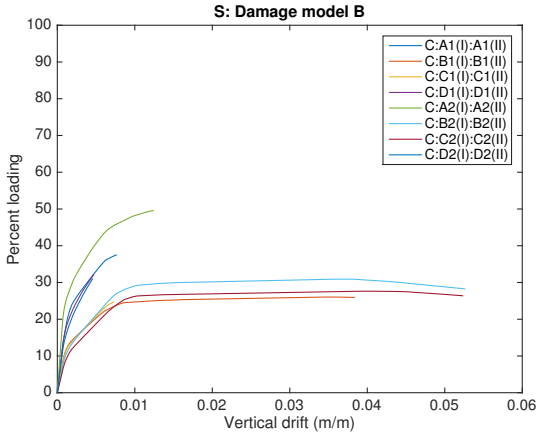


(c) "D+HoR": ductility + hierarchy of resistances design

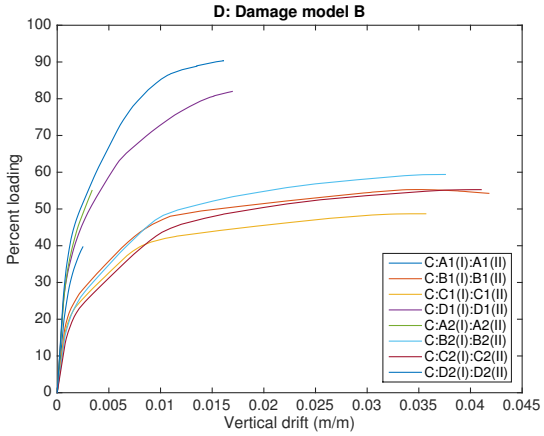
Figure 4: Vertical drifts as functions of the damage parameter d for the Damage model A.

Figure 5 gives the outputs of pushdown analysis illustrated in the framework of Damage model B. The loading percentage is plotted with reference to the vertical drift. It is observed that the overall response varies depending on the structural design and on the damaged element. In none of the considered cases, the values attain 100%, i.e., it is not possible to apply on the structure the loading combination reported in Eqn. (1). The inspection of Figure 5(a) indicates that the response of the structure "S" is variable: the maximum loading allowed on the damaged scheme is about 50% in case of the removal of column C:A2(I):A2(II). Lower values, i.e.,

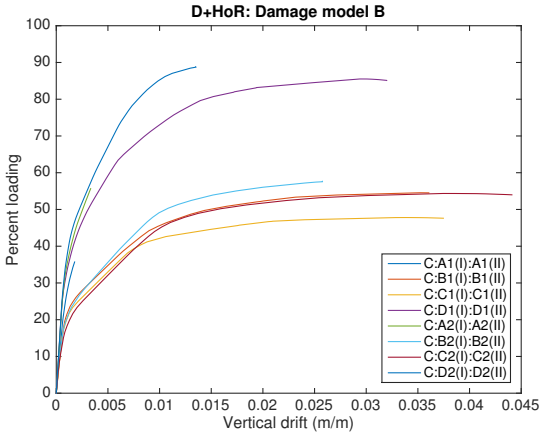
between 25% and 30% of the nominal loading expressed by Eqn. (1), are found in case of damage of the remaining elements. Different trends are observed for the structures designed with ductility. The behaviors of "D" and "D+HoR" schemes under damage are essentially the same. The maximum loading related to the tests performed on columns C:D1(I):D1(II) and C:D2(I):D2(II), i.e., the violet and blue curves in Figures 5(b) and 5(c), is larger than 80% of the nominal value. In the tests performed on the other columns, the maximum load ranges between 40% and 60%. The plateau in some curves on "D" and "D+HoR" structures confirm that, before failure, plastic hinges form and the structure dissipate energy in order to support larger loads.



(a) "S": static design



(b) "D": ductility design

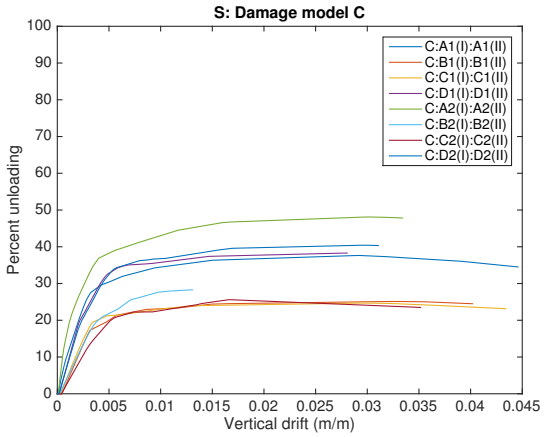


(c) "D+HoR": ductility + hierarchy of resistances design

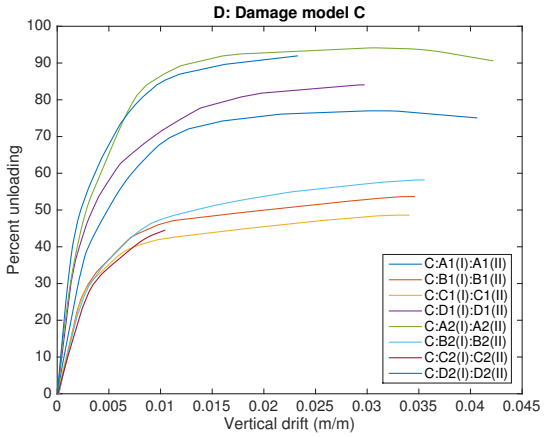
Figure 5: Vertical drifts and percentage of unloading for Damage model B.

Consistent results are found if Damage model C (Figure 6) is considered. Despite the loading on the structure is different from the previous damage model, the results are quite similar. The tests conducted on the structure designed to support static loads show that the unloading ranges between 20% and 50%, as displayed in Figure 6(a). Meanwhile, the remaining schemes confirm that it is not possible to add the nominal value of f in order to set to cancel the force F^*. Ranges between 40% and 90% are observed in Figures 6(b) and 6(c).

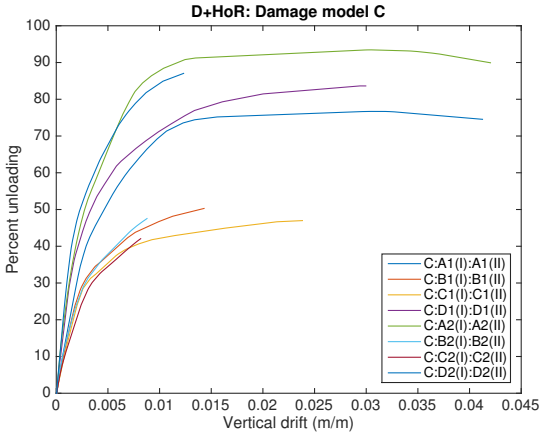
Both Damage model B and C identify the behavior of the damaged structure through values of vertical drift and loading/unloading percentages. Therefore, a relationship between the two



(a) "S": static design



(b) "D": ductility design



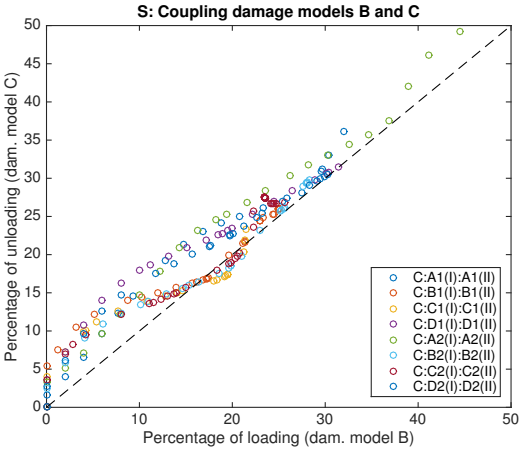
(c) "D+HoR": ductility + hierarchy of resistances design

Figure 6: Vertical drifts and percentage of loading for Damage model C.

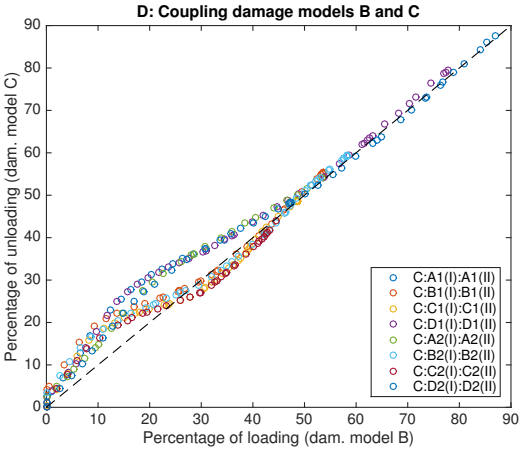
different approaches is investigated. The coupling between the results of the two damage models is made through the value of the vertical drift. The loading percentages of Damage model B are interpolated at the values of the drifts corresponding to the computed unloading percentages of Damage model C. In Figure 7 the correlation points are plot. It results that at 0% in Damage model B, positive percentages are evaluated in Damage model C. This is due to the fact that at the beginning of the simulation in Damage model B the structure is unloaded, i.e., no vertical drift is recorded, while it is loaded (and, thus, deformed) at the initial step of the simulations with Damage model C.

Fair correlation is seen in any of the considered structures for loading/unloading percentages smaller than roughly 35%. In the schemes designed with ductility requirements (i.e., both "D" and "D+HoR") better results are observed in some tests for percentages larger than 50%.

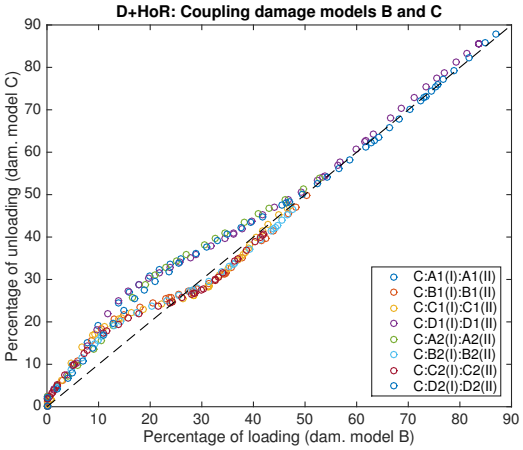
In order to assess the computational effort for performing the simulations, the computation times needed for getting the results herein presented have been recorded. As emerges in Table 3, the time needed for the calculations related to Damage model A is one order of magnitude larger than the one necessary to perform the robustness analysis on Damage models B and C.



(a) "S": static design



(b) "D": ductility design



(c) "D+HoR": ductility + hierarchy of resistances design

Figure 7: Coupling between Damage model B and Damage model C. The dashed line is the bisector of the quarter, identifying the perfect correlation between the two damage models.

4 DISCUSSION AND CONCLUSIONS

A literature overview has highlighted that no detailed researches were conducted on the ways to implement a damage condition in a commercial FEM software in order to assess the structural robustness of a construction. The present approach deals with three different strategies that do not expressly consider the damage from a local (microscopic effects on the damaged element) to a global (the whole construction) scale. The first damage model evaluates the response of the structure for various levels of cross-section reduction in selected damaged elements. The second damage model presupposes that selected elements are removed and the structure is incrementally loaded. In the last damage model, the damaged element is replaced by an additional system of forces equivalent to the ones that it experiences in the undamaged structure; then, forces are progressively reduced. In real situations, the external loads (gravity + dead load) are always present throughout all the duration of the damage process. Because of that, we think that Damage model C can provide a good representation of what might happen on a real damaged structure. Meanwhile, we observe that a damage on a column is monitored through geometrical and mechanical data (carbonation depth, spalling, aging): in this case, there are no clear connec-

Scheme	Dam. model A	Dam. model B	Dam. model C
S	6h 12m	0h 24m	0h 31m
D	5h 52m	0h 38m	0h 37m
D+HoR	3h 40m	0h 27m	0h 17m

Table 3: Computation times.

tions between the percentage of unloading and the amount of damage on the element. Although Damage model A tries to overcome this problem through the damage parameter, its inadequacy is highlighted by the fact that at the beginning of each simulation the structure is unloaded. Damage model B does not consider neither the presence of the element during the damage process nor the loads acting on the structure. However, it is the simplest to be implemented in the analysis since no iterative calculations or advanced modeling are required.

We believe that the Damage model C can be the most accurate among the three proposed strategies for assessing the structural robustness of a structure. However, at present, its implementation in a commercial code is not simple because programming abilities are required. Usually, softwares does not allow to control single loadcases, except those related to seismic horizontal force in push-over analyses. The implementation of Damage model C in the commercial softwares would require a specific plug-in able to perform such kind of analyses.

Anyway, the results of Damage models B and C are comparable, as found in Figure 7. That is why we believe that Damage model B, which is the simplest and the quickest to be implemented among the three proposed strategies, can give insights on the structural robustness of a scheme. This choice is supported by the fact that there are no substantial differences in the computational effort in choosing Damage model B or C for assessing the robustness of the structure.

In general, we found that none of the three structures designed with different standard requirements are safe in case of the removal of a column at the bottom level. This confirms that seismic design guidelines and principles do not necessarily ensure the structural robustness of a building.

Future developments of the research would deal with the correlation between the physical damage and the parameters to be used in the numerical simulation. This would permit to assess the reliability of a structure onto which a progressive damage is acting.

Keywords: Framed structures, Exceptional actions, Fire damage, Seismic response, Residual capacity, Theoretical model.

Abstract. *The effect of natural or man-made disasters, especially when they assume exceptional character, on the urban habitat (buildings, infrastructures, etc.) can result in damages and losses for billions of dollars. In case of cascading events, the residual capacity of a construction damaged from a first threat is not evaluated through suitable calculation procedures neither well codified in actual standards.*

In this framework and with reference to framed structure buildings, the current research activity has the task to provide a tool which helps structural engineers to make a fast evaluation of the buildings performance after exceptional loading actions. Specifically, a theoretical formulation based on the results provided by pushover analyses for the assessment of the residual seismic capacity of buildings after damage produced by exceptional actions is herein presented. The theoretical method presented is basically applied to some case studies of steel framed buildings aiming at showing its effectiveness. To this purpose, a general analysis methodology, with the aim to show the procedure for the practical application of the theoretical formulation, is shown. Such a methodology has been applied to two steel framed buildings designed according to both the old and the new seismic Italian codes. After these frames have been subjected to a fire analysis at different temperatures, non-liner static analyses including P-Δ effects have been carried out with the aim to estimating both the force-displacement curves and the plasticity distribution in the structures. The analyses have provided the tangible application of the procedure, giving the structural parameters accounting for the structure damage status at the end of the exceptional loading action.

1 INTRODUCTION

Disasters occur under many different forms and have duration ranging from a hourly disruption to days or weeks of ongoing destruction. They can be either natural [1] or produced by people, both of them having a great impact on the community.

Hurricanes [2, 3] and tropical storms are among the most powerful natural disasters because of their size and destructive potential. Tornadoes are relatively brief but violent and, together with earthquakes, strike suddenly without warning. Flooding is the most common of natural hazards and requires an understanding of the environment natural systems.

Disasters can also be caused by humans. Hazardous materials emergencies include chemical spills and groundwater contamination. Workplace fires are more common and can cause significant property damage and loss of life. Communities are also vulnerable to threats posed by extremist groups, who use violence against both people and property. High-risk targets include military and civilian government facilities, international airports, large cities and high-profile landmarks. Cyber-terrorism involves attacks against computers and networks done to intimidate or coerce a government or its people for political or social objectives.

After constructions are subjected to a first extreme event, the structural performance evaluation should be related to the building response under gravity loads. After this step, the structure should be checked with reference to the seismic actions used in the design phase.

For example, considering fire exposure as a damage event, few studies have been developed and implemented to assess the residual seismic capacity of framed structures after the above exceptional action.

Among the limited researches available in literature, it was found that Mostafei et al. provided a study on the seismic resistance of fire-damaged reinforced concrete columns [4]. Analytical results show that the main seismic resistance properties of two reinforced concrete columns, namely the lateral load capacity and ductility, decreased substantially due to fire exposure. Mostafei also performed a structural test for evaluating the residual lateral load resistance of a reinforced concrete structure after fire damage [5]. Results of this test showed a reduction of both residual lateral stiffness and lateral load capacity of the structure after fire damage.

In the framework of this research activity, in the first part of this study, a theoretical formulation (based on pushover curves) for the assessment of seismic residual capacity of framed structure after extreme load action has been proposed. Instead, in the second part, related to the numerical investigation on moment resisting steel frames after fire damage, an analysis methodology able to validate the equations given in the first part has been proposed.

More in detail, based on the results provided in first part of this paper, with the aim to show a numerical procedure able to evaluate the functions $k_\delta(\phi)$, $k_F(\phi)$ used to measure the reduction of structural performance after an exceptional action, numerical non-linear seismic analyses on two steel structures, before subjected to fire and designed according to both the old [6] and the new [7] seismic Italian codes, have been performed.

2 THEORETICAL PREDICTION OF THE SEISMIC RESPONSE OF DAMAGED FRAMED STRUCTURES

In the last few decades, with the development of Performance-Based Design procedures, the need of simplified methods to estimate with an adequate confidence level the seismic demand for structures is increased. Non-linear static procedures appear as one of the most attractive analysis tool due to both their ease of use and also for the simple and effective graphical representation of the structural response by means of the so-called pushover curve.

The procedure of a conventional pushover analysis [8] is an incremental-iterative solution of the static equilibrium equations. The forcing function is a set of displacements or forces that are necessarily kept constant during the analysis. During an increment of displacement or force, the resistance of the structure is evaluated from the internal equilibrium conditions and the stiffness matrix is updated under certain conditions dependent on the iterative scheme adopted. The unbalanced forces are re-applied if they are deemed large until a convergence criterion is satisfied. At convergence, the stiffness matrix is reorganised and another increment of displacements or forces is applied.

In order to evaluate the seismic capacity of a framed structure before damaged by extreme actions, a theoretical formulation based on the *F*-δ pushover curve is herein proposed. The proposed formulation allows to evaluate the seismic response by determining three significant points of the cited response curve.

With reference to the Figure 1, which schematically illustrates the results provided by a push-over analysis carried out on a generic undamaged framed structure, it is possible to identify the following points:

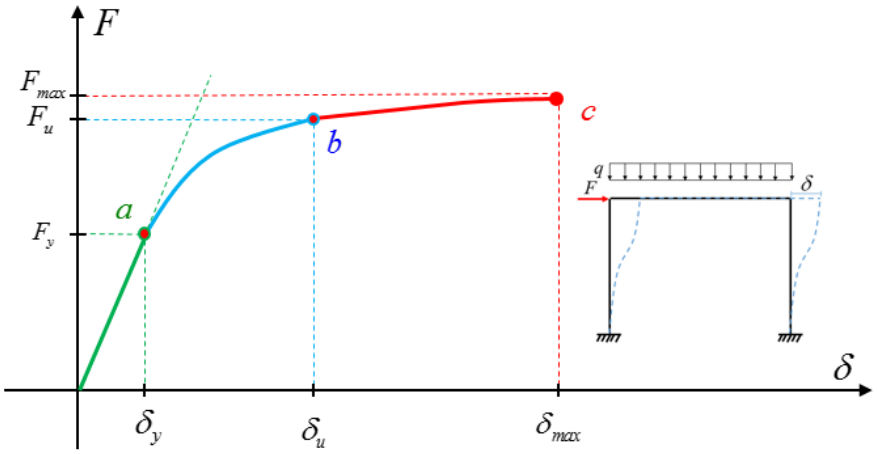

Figure 1: General force-displacement curve.

- Point a (F_y; δ_y) = seismic base shear and top horizontal displacement values corresponding to the first yielding;
- Point b (F_u; δ_u) = seismic base shear and top horizontal displacement values corresponding to the structure excursion in the elasto-plastic field;
- Point c (F_{max}; δ_{max}) = seismic base shear and top horizontal displacement values corresponding to the collapse.

So, when the following conditions are met:

$$\begin{aligned} F &\in \left[0; F_y\right] \\ \delta &\in \left[0; \delta_y\right] \end{aligned} \tag{1}$$

the structure is in the elastic range.

Instead, when:

$$\begin{aligned} F &\in \left[F_y; F_u\right] \\ \delta &\in \left[\delta_y; \delta_u\right] \end{aligned} \tag{2}$$

the structure is in the elastic-plastic range and, finally, when:

$$\begin{aligned} F &\in \left[F_u ; F_{max}\right] \\ \delta &\in \left[\delta_u ; \delta_{max}\right] \end{aligned} \tag{3}$$

the structure is in the plastic range up to the collapse condition (robustness field).

The quantities shown in Figure 1, useful for the assessment of seismic capacity of undamaged framed structure, can also be used to determine the residual capacity of buildings damaged by exceptional loading actions.

To this purpose, the mentioned quantities must be corrected to take into account the damage produced by an extreme load acting before the earthquake. In particular, in order to determine the seismic capacity of a framed structure damaged by an exceptional action, it is necessary to calculate the points *a*, *b* and *c* of the *F*-δ curve corresponding to each damage level induced by external (natural or man-made) actions. Consequently, the following relationships have to be considered:

$$\begin{cases} F_y \rightarrow F_y\left(\phi\right) \\ F_u \rightarrow F_u\left(\phi\right) \\ F_{max} \rightarrow F_{max}\left(\phi\right) \end{cases} \tag{4}$$

$$\begin{cases} \delta_y \rightarrow \delta_y(\phi) \\ \delta_u \rightarrow \delta_u(\phi) \\ \delta_{max} \rightarrow \delta_{max}(\phi) \end{cases} \tag{5}$$

where (F_y, F_u, F_{max}) and (δ_y, δ_u, δ_{max}) are parameters representative of the seismic behaviour of the original structure (without damage), while the corresponding ($F_y(\phi)$, $F_u(\phi)$, $F_{max}(\phi)$) and ($\delta_y(\phi)$, $\delta_u(\phi)$, $\delta_{max}(\phi)$) are indicative of the structural seismic behaviour after induced damage. The parameter ϕ has to be seen as "the value of a generic parameter correlated to a specific damage state produced by an assigned external action acting before the seismic event". Table 1 shows some meanings assumed by the damage parameter ϕ corresponding to different types of exceptional actions considered.

Exceptional Load	**Φ**
Fire	Temperature, Exposure time [4], [5], [9]
Hurricane, Tornado	Wind speed [2]
Blast load, Explosion	Wave front speed; Peck static overpressure; Maximum dynamic pressure [10], [11], [12]
Volcanic Ash Fall	Ash thickness; Ash density; Ash temperature [13]
Volcanic Pyroclastic Flow	Flow temperature; Flow dynamic pressure; Flow speed [13]
Volcanic Lahar	Lahar speed; Lahar hydrodynamic pressure [13]
Volcanic Earthquake	Earthquake Peak Ground Acceleration (PGA) [13]

Table 1: Examples of damage parameters corresponding to various types of exceptional actions.

Once ϕ is defined and assuming known the values of the following functions:

$$\begin{aligned}\alpha_y(\phi) &= \left[F_y(\phi)/F_y\right] \\ \alpha_u(\phi) &= \left[F_u(\phi)/F_u\right] \\ \alpha_{max}(\phi) &= \left[F_{max}(\phi)/F_{max}\right]\end{aligned} \tag{6}$$

$$\begin{aligned}\xi_y(\phi) &= \left[\delta_y(\phi)/\delta_y\right] \\ \xi_u(\phi) &= \left[\delta_u(\phi)/\delta_u\right] \\ \xi_{max}(\phi) &= \left[\delta_{max}(\phi)/\delta_{max}\right]\end{aligned} \tag{7}$$

the values of displacements and forces after damage can be expressed in the following way:

$$\begin{aligned}\delta_y(\phi) &= \delta_y \cdot \xi_y(\phi) \\ \delta_u(\phi) &= \delta_u \cdot \xi_u(\phi) \\ \delta_{max}(\phi) &= \delta_{max} \cdot \xi_{max}(\phi)\end{aligned} \tag{8}$$

$$\begin{aligned}F_y(\phi) &= F_y \cdot \alpha_y(\phi) \\ F_u(\phi) &= F_u \cdot \alpha_u(\phi) \\ F_{max}(\phi) &= F_{max} \cdot \alpha_{max}(\phi)\end{aligned} \tag{9}$$

From these general relationships it is possible to extrapolate a more compact formulation, thereby expressing the six constants (F_y, F_u, F_{max}, δ_y, δ_u, δ_{max}) as a function of only two maximum parameters (F_{max}, δ_{max}) of the curve. This is shown in Figure 2, where the dimensionless pushover curve obtained for a generic ϕ parameter is plotted.

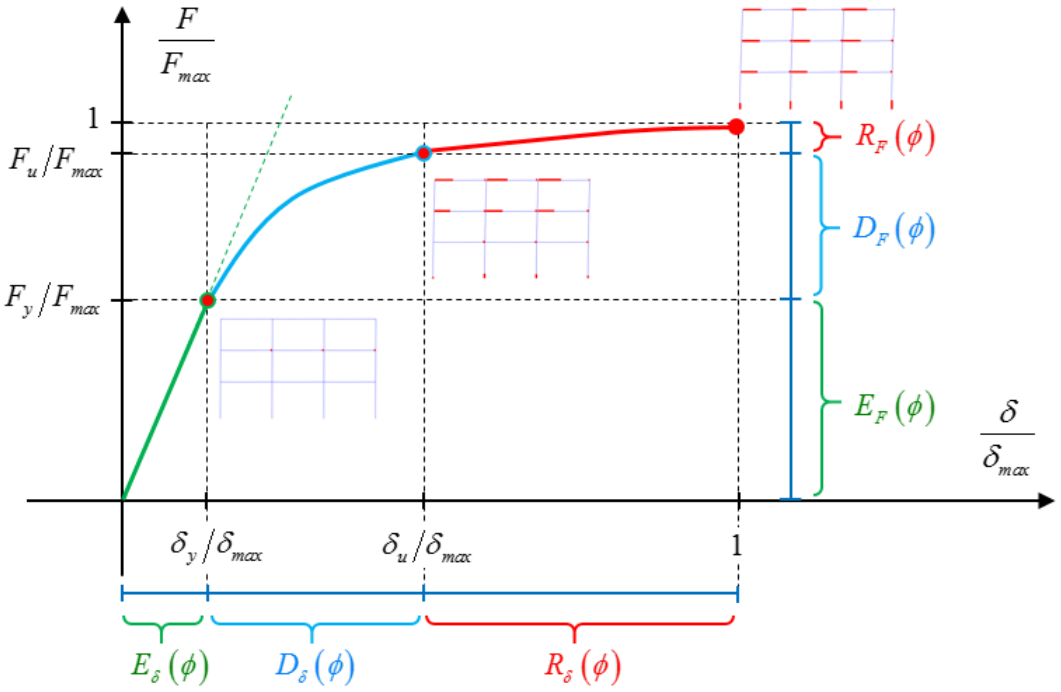

Figure 2: Dimensionless pushover curve.

Assuming once again known the functions described in equations (6) and (7), it is possible to write:

$$E_\delta(\phi) = \left[\frac{\delta_y}{\delta_{max}} \cdot \frac{\xi_y(\phi)}{\xi_{max}(\phi)} \right] \tag{10}$$

$$D_\delta(\phi) = \left\{ \left[\frac{\delta_u}{\delta_{max}} \cdot \frac{\xi_u(\phi)}{\xi_{max}(\phi)} \right] - \left[\frac{\delta_y}{\delta_{max}} \cdot \frac{\xi_y(\phi)}{\xi_{max}(\phi)} \right] \right\} \tag{11}$$

$$R_\delta(\phi) = \left\{ 1 - \left[\frac{\delta_u}{\delta_{max}} \cdot \frac{\xi_u(\phi)}{\xi_{max}(\phi)} \right] \right\} \tag{12}$$

These functions must satisfy the following conditions:

$$\begin{cases} E_\delta(\phi) \\ D_\delta(\phi) \in [0;1] :\rightarrow E_\delta(\phi) + D_\delta(\phi) + R_\delta(\phi) = 1 \\ R_\delta(\phi) \end{cases} \tag{13}$$

$E_\delta(\phi)$, $D_\delta(\phi)$ and $R_\delta(\phi)$ are parameters that can be seen as distribution coefficients of the seismic capacity of structures in terms of horizontal displacement. In particular, $E_\delta(\phi)$ refers to the elastic field, $D_\delta(\phi)$ to the ductile field and $R_\delta(\phi)$ to the robustness field.

Multiplying the expressions (10), (11) and (12) for the quantity ($\delta_{max} \cdot \xi_{max,}$), the following equations can be derived:

$$\delta_{max} \cdot \xi_{max}(\phi) \cdot E_\delta(\phi) = \Delta\delta_y(\phi) \tag{14}$$

$$\delta_{max} \cdot \xi_{max}(\phi) \cdot D_\delta(\phi) = \Delta\delta_u(\phi) \tag{15}$$

$$\delta_{max} \cdot \xi_{max}(\phi) \cdot R_\delta(\phi) = \Delta\delta_{max}(\phi) \tag{16}$$

where $\Delta\delta_i(\phi)$ (i=y, u, max) are the displacement increment necessary for the transition from a behavioural phase to the following one.

Through the equations (14), (15) and (16), it is possible to write:

$$\delta_y(\phi) = 0 + \Delta\delta_y(\phi) \tag{17}$$

$$\delta_u(\phi) = \delta_y(\phi) + \Delta\delta_u(\phi) \tag{18}$$

$$\delta_{max}(\phi) = \delta_u(\phi) + \Delta\delta_{max}(\phi) \tag{19}$$

where $\delta_i(\phi)$ (i=y,u,max) are the basic displacements required to determine the seismic response in the displacement field.

Placing the equations (14), (15), (16) in the equations (17), (18), (19), it is possible to write:

$$\delta_y(\phi) = 0 + \delta_{max} \cdot \xi_{max}(\phi) \cdot E_\delta(\phi) \tag{20}$$

$$\delta_u(\phi) = \left[\delta_{max} \cdot \xi_{max}(\phi) \cdot E_\delta(\phi) \right] + \left[\delta_{max} \cdot \xi_{max}(\phi) \cdot D_\delta(\phi) \right] \tag{21}$$

$$\delta_{max}(\phi) = \left[\delta_{max} \cdot \xi_{max}(\phi) \cdot E_\delta(\phi) \right] + \left[\delta_{max} \cdot \xi_{max}(\phi) \cdot D_\delta(\phi) \right] + \left[\delta_{max} \cdot \xi_{max}(\phi) \cdot R_\delta(\phi) \right] \tag{22}$$

Grouping the equations (20), (21) and (22) with respect to (δ_{max} . $\xi_{max}(\phi)$), the following relationships are achieved:

$$k_{y,\delta}(\phi) = \xi_{max}(\phi) \cdot E_{\delta}(\phi) \tag{23}$$

$$k_{u,\delta}(\phi) = \xi_{max}(\phi) \cdot \left[E_{\delta}(\phi) + D_{\delta}(\phi) \right] \tag{24}$$

$$k_{max,\delta}(\phi) = \xi_{max}(\phi) \cdot \left[E_{\delta}(\phi) + D_{\delta}(\phi) + R_{\delta}(\phi) \right] = \xi_{max}(\phi) \tag{25}$$

where $k_{i,\delta}(\phi)$ (i= y, u, max) are the reduction factors of seismic performance of the structure in the displacement field, which take implicitly into account the repartition of the capacity itself.

Definetively, it is possible to write:

$$\delta_{y}(\phi) = \left[\delta_{max} \cdot k_{y,\delta}(\phi) \right] \tag{26}$$

$$\delta_{u}(\phi) = \left[\delta_{max} \cdot k_{u,\delta}(\phi) \right] \tag{27}$$

$$\delta_{max}(\phi) = \left[\delta_{max} \cdot k_{max,\delta}(\phi) \right] \tag{28}$$

Instead the equations (26), (27) and (28) show that the basic displacements $\delta_{y}(\phi)$, $\delta_{u}(\phi)$ and $\delta_{max}(\phi)$ belonging to the $F(\phi)$–$\delta(\phi)$ curve can be calculated starting from the displacement value δ_{max} only, therefore neglecting the δ_{u} and δ_{y} values.

Equivalently, the trends of $F_{y}(\phi)$, $F_{u}(\phi)$ and $F_{max}(\phi)$ can be expressed as a function of the F_{max} value only by considering the $k_{F,y}(\phi)$, $k_{F,u}(\phi)$ and $k_{F,max}(\phi)$ parameters as follows:

$$F_{y}(\phi) = \left[F_{max} \cdot k_{y,F}(\phi) \right] \tag{29}$$

$$F_{u}(\phi) = \left[F_{max} \cdot k_{u,F}(\phi) \right] \tag{30}$$

$$F_{max}(\phi) = \left[F_{max} \cdot k_{max,F}(\phi) \right] \tag{31}$$

where:

$$k_{y,F}(\phi) = \alpha_{max}(\phi) \cdot E_{F}(\phi) \tag{32}$$

$$k_{u,F}(\phi) = \alpha_{max}(\phi) \cdot \left[E_{F}(\phi) + D_{F}(\phi) \right] \tag{33}$$

$$k_{max,F}(\phi) = \alpha_{max}(\phi) \cdot \left[E_{F}(\phi) + D_{F}(\phi) + R_{F}(\phi) \right] = \alpha_{max}(\phi) \tag{34}$$

Definitively, all the previous relationships provide a theoretical formulation for the calculation of the seismic response of a framed structure previously damaged by an extreme event.

Unfortunately, into equations (8), (9), (26), (27), (28), (29), (30) and (31), the values of the functions $\alpha(\phi)$, $\xi(\phi)$, $k_{\delta}(\phi)$ and $k_{F}(\phi)$ are not known a priori (see respectively equations (6), (7), (23), (24), (25), (32), (33), (34)) .

Basically, the main issue consists on the determination of the structure damage status at the end of the exceptional loading action. In this framework, Table 2 shows some of the variables, other than the building properties, which influence the structural response.

Exceptional Load	Influential variables
Fire	Fire scenario, Fire model, Fire Proofing
Hurricane, Tornado	Wind speed
Blast load, Explosion	Explosive characteristic, Detonation scenario, Blast Proofing
Volcanic Ash Fall	Ash thickness, Ash density, Ash temperature , Roof configuration
Volcanic Pyroclastic Flow	Flow dynamic pressure, Building shape, Topographical configuration of the site
Volcanic Lahar	Structural typology, Impact Angle with structure, Lahar temperature, Impact surface, Flow density
Volcanic Earthquake	Earthquake Response Spectrum, Soil-Structure Interaction.

Table 2: List of various variables influencing different types of exceptional actions.

The variables listed into the above table must be considered in order to provide useful values of the functions $\alpha(\phi)$ and $\xi(\phi)$ and, consequently, of the functions $k_\delta(\phi)$ and $k_F(\phi)$ for design purposes. This aim can be accomplished through a comprehensive numerical and experimental investigation campaign by taking into account at least the variability of the above mentioned influential variables.

Once known these functions and the undamaged structure capacity (F_{max}; δ_{max}), a simplified check of the seismic capacity of a given framed structure after an exceptional loading action can be executed without performing sequential non-linear analyses.

3 THE CASE STUDIES

In order to show the effectiveness of the theoretical method presented above, starting from the general equations described in Section 2, it can be possible to replace the dependence of the functions from "ϕ" with the specified damage parameter that, in the specific case, consists on the temperature value "θ" inside the structural members.

Practically, starting from the following general equations:

$$\begin{aligned} F(\phi) &= F_{max} \cdot k_F(\phi) \\ \delta(\phi) &= \delta_{max} \cdot k_\delta(\phi) \end{aligned} \tag{35}$$

it is possible to express the study significant parameters as a function of the parameter θ as follows:

$$\begin{aligned} \alpha(\phi) &\rightarrow \alpha(\theta) \\ \xi(\phi) &\rightarrow \xi(\theta) \end{aligned} \tag{36}$$

$$\begin{aligned} k_F(\phi) &\rightarrow k_F(\theta) \\ k_\delta(\phi) &\rightarrow k_\delta(\theta) \end{aligned} \tag{37}$$

which give rise to the following relationships:

$$F(\phi) = F_{max} \cdot k_F(\theta)$$
$$\delta(\phi) = \delta_{max} \cdot k_\delta(\theta) \tag{38}$$

that are used to examine the structural seismic behaviour of steel MRF after fire.

3.1 Geometrical and mechanical features

In this study, two different types of steel framed structures have been analysed aiming at evaluating their seismic capacity after fire actions. The choice of the frame types has been done according to a previous study performed by the first Author [14, 15, 16].

The first framed structure has been designed according to the old Seismic Italian Code (M.D., 1996), while the second one has been designed according to the new Seismic Italian Code (M.D., 2008). Both structures are subjected to permanent and variable loads of 5.15 kNm^{-2} and 2 kNm^{-2}, respectively.

Both framed structures have the same geometric configuration with three 5m bays and three levels (H=3.50 m at 1st floor; H=3.00 m at 2nd and 3rd floor).

Figure 3 shows the geometrical properties of the steel framed structures inspected.

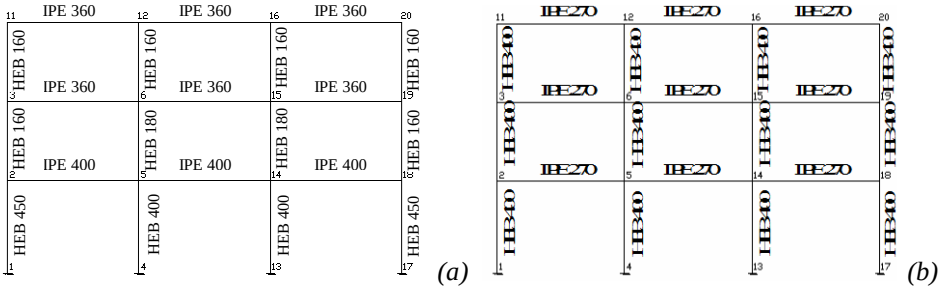

Figure 3: The examined steel framed structures designed according to M.D. 1996 (a) and M.D. 2008 (b).

The selected framed buildings are made of S275JR steel profiles.

Figure 4a shows the stress-strain relationships of the steel material used in this study, while figure 4b shows the reduction factors of the material mechanical properties at elevated temperatures [17].

In particular, six uniform temperature fields (θ= 20°C, 100°C, 200°C, 300°C, 400°C, 500°C) have been applied to the structures before seismic loads have been considered.

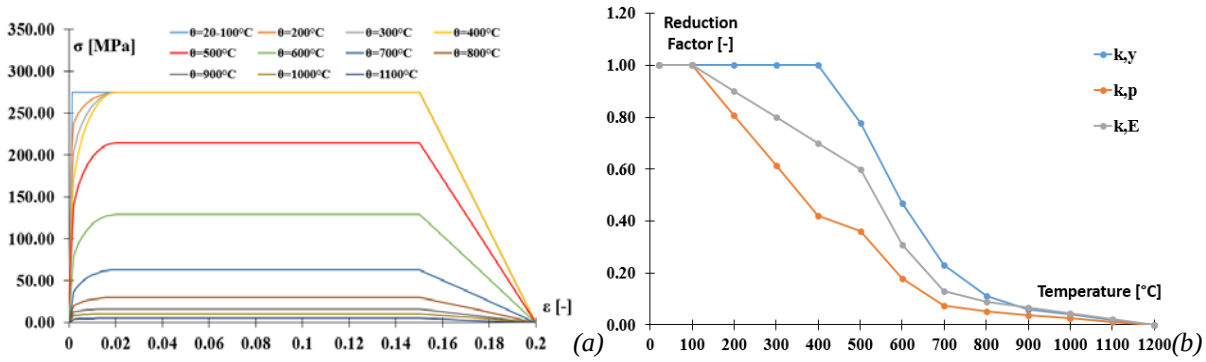

Figure 4: Mechanical properties of S275JR steel: constitutive laws (a) and reduction factors (b) at different temperatures.

3.2 The FEM models

Non-linear static analyses including *P-Δ* effects have been performed by means of the FE software "ABAQUS v.6.10-1" [18] in order to estimate both the force-displacements pushover curves and the plasticity distribution in the inspected structures.

Figure 5a and b show the details of the typical finite element model based on beam elements used for modelling the generic frame. In particular, columns and beams have been modelled by using into a 2D model the beam elements type B21. Second-order elements, like B22 ones, have been avoided owing to the so-called 'volumetric locking' problem, which is induced by the large strains in the frame deformed configuration. Firstly, the effect of different number of constitutive elements for columns and beams has been investigated in order to provide accurate results with a reduced computational time. It was found that 80 elements are sufficient for a reliable analysis of the 2D plane frame model.

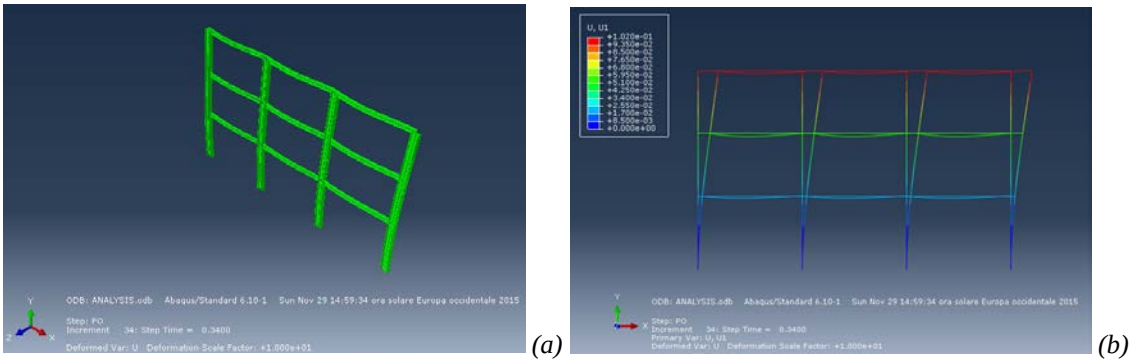

Figure 5: Deformed FEM model under gravity loads of one of the tested frames (a) and horizontal displacements under seismic actions (b).

The column bases of the steel framed structures are fixed (fully rigid column bases). For the sake of simplicity, rotational stiffness of beam-column joints have not been modelled, but the full continuity between beams and columns at their intersections has been considered. In the Abaqus numerical models, the non-linear stress-strain material curves have been modelled. Since the analysis involves large inelastic strains, the engineering stress-strain curves have been converted into true stresses vs. logaritmic plastic strains at different temperatures. In fact, in order to simulate the effect of fire, a simplified hypothesis has been done: only the mechanical property variation has been considered, neglecting thermal expansions and the related phenomena. So, mechanical properties change due to temperature has been considered constant through the cross-sections and applied to all structural members.

3.3 Numerical results at θ = 20 - 100°C

The analyses performed with the Abaqus software on the examined structures at the environment condition (θ = 20°C) have shown that their behaviour is analogous to that of the same structures at θ = 100°C. The numerical analysis results in the non-linear field on the case studies in terms of diplacements and force-displacement pushover curves are illustrated in Figures 6a and b, respectively.

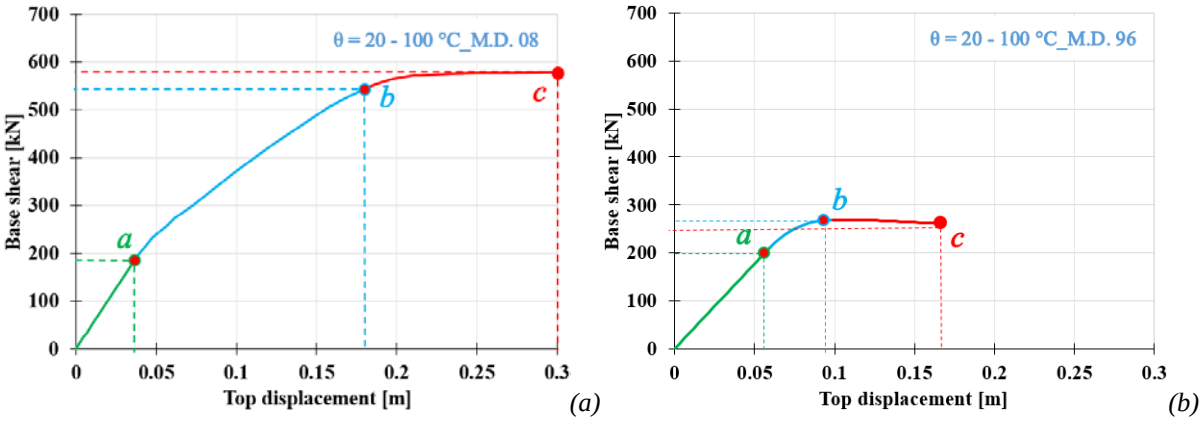

Figure 6: Force-displacement pushover curves at θ = 20 – 100°C for frames designed with M.D. 08 (a) and M.D. 96 (b) codes.

The points highlighted in Figure 6 have been determined starting from the study of plasticity distribution within the structures subjected to horizontal incremental loads [19, 20]. In order to better understand this aspect, firstly reference is made to the Figures 7a and 8a, where the damage state corresponding to the first yelding phenomena due to horizontal loads in the structures designed according to M.D. 08 and M.D. 96, respectively, is plotted. This plasticity distribution corresponds to the points “a” of the force-displacement curves of Figures 6a and 6b.

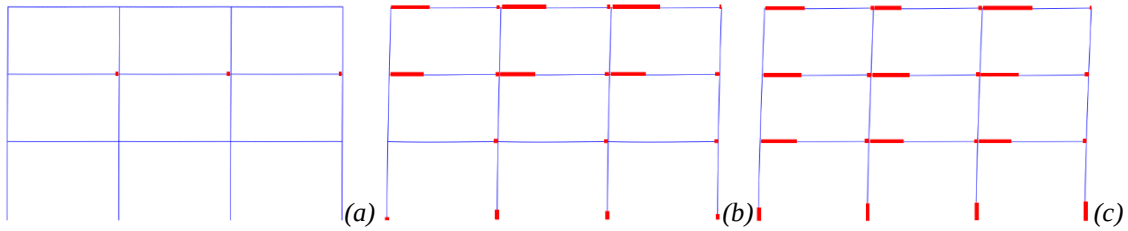

Figure 7: Plasticity distribution at θ = 20 – 100°C for the M.D. 08 frame: (a) first yielding; (b) mechanism activation; (c) collapse.

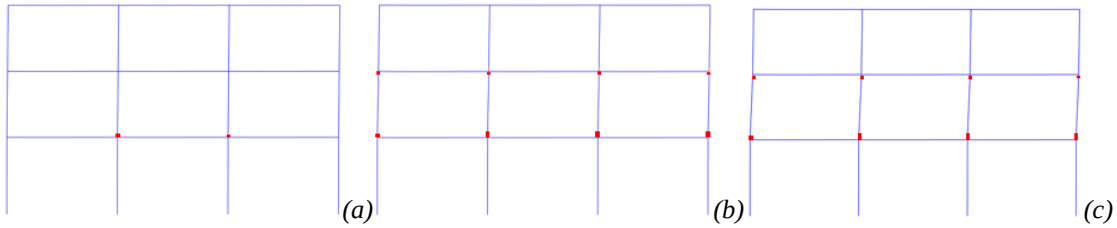

Figure 8: Plasticity distribution at θ = 20 – 100°C for the M.D. 06 frame: (a) first yielding; (b) mechanism activation; (c) collapse.

Figures 7b and 8b provide a snapshot of the plasticity distribution at the time of the mechanism activation for M.D. 08 frame and M.D. 96 one, respectively. This condition is reached when a quasi-global collapse mechanism for M.D. 08 frame and a soft-storey mechanism for M.D. 96 frame are attained. In this condition, the points "b" of the curves in Figures 6a and 6b are reached.

Finally, Figures 7c and 8c show the distribution and the extension of the yielded zone at collapse for the examined structures. This condition occurs when the extension of the plastic zones in the columns is equal to the cross-section height. Therefore, the parameters F_{max} and δ_{max} are attained, they providing the points "c" of the curves in Figures 6a and 6b.

3.4 Numerical results at high temperatures

Following the procedure described in the previous section and considering different temperature values up to 500°C, the non-linear force-displacement curves of the investigated frames have been obtained. These curves, which are representative of the seismic capacity of the Italian frames under examination, are shown in Figures 9a and 9b.

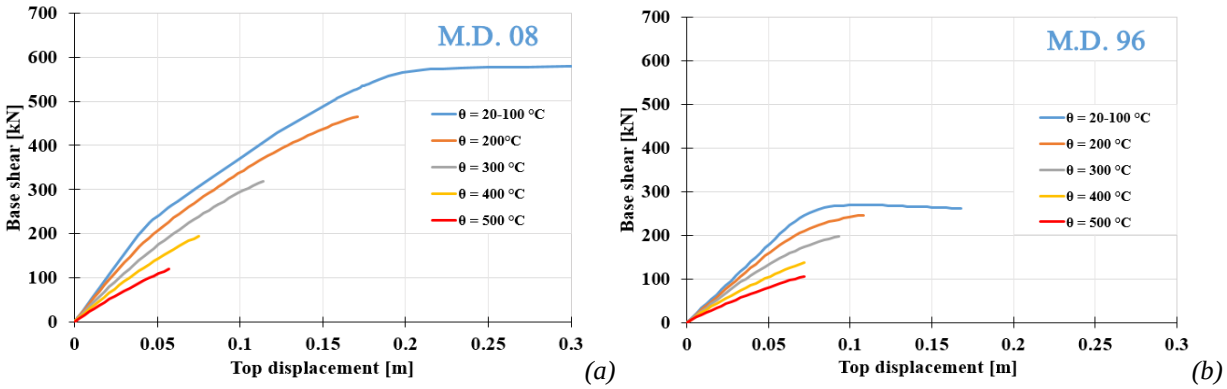

Figure 9: Force-displacement curves obtained from non-linear analyses on M.D. 08 (a) and M.D. 96 (b) frames.

The analysis of results describing the plasticity evolution within the study framed structures has allowed to redact the Tables 3 and 4, where the lists of variables describing the seismic response curves are plotted. In such tables, the zero values are indicative of the incapacity of structures to withstand seismic actions after fire.

From the analysis of results, it is highlighted that, at the same value of temperature, a substantial behavioural difference between the framed structure designed according to the new Seismic Italian Code (M.D., 2008) and the one designed according to the old Seismic Italian Code (M.D., 1996) exists.

500	0	103.13	108.80	0	0.066	0.072

Table 4: Numerical results obtained from analyses on the structure designed according to the M.D. 96 code.

In order to quantify the above detected differences, the pictures reported in Figures 10a and 10b need to be considered.

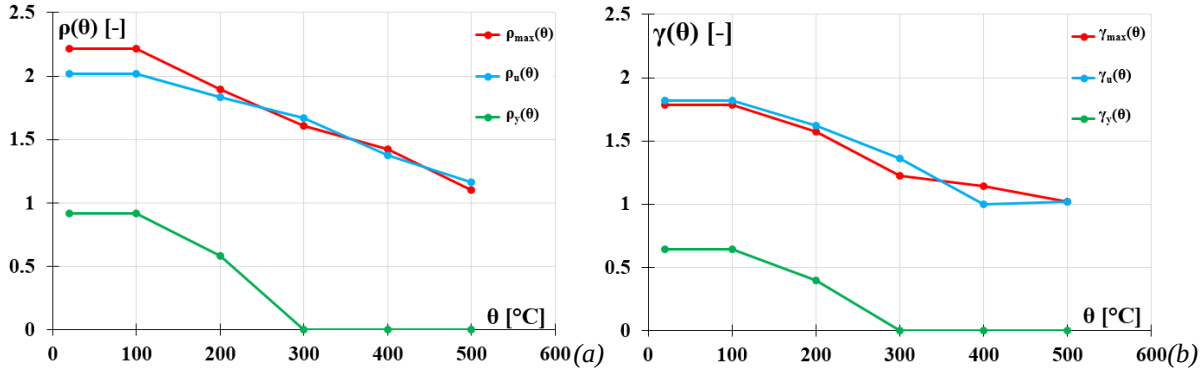

Figure 10: Behavioural trends of the $\rho - \theta$ (a) and $\gamma - \theta$ (b) curves.

The above graphs are representative of the following functions:

$$\begin{aligned}
\rho_y(\theta) &= \left[F_y(\theta)_{M.D.08} / F_y(\theta)_{M.D.96}\right] \\
\rho_u(\theta) &= \left[F_u(\theta)_{M.D.08} / F_u(\theta)_{M.D.96}\right] \\
\rho_{max}(\theta) &= \left[F_{max}(\theta)_{M.D.08} / F_{max}(\theta)_{M.D.96}\right]
\end{aligned} \tag{39}$$

$$\begin{aligned}
\gamma_y(\theta) &= \left[\delta_y(\theta)_{M.D.08} / \delta_y(\theta)_{M.D.96}\right] \\
\gamma_u(\theta) &= \left[\delta_u(\theta)_{M.D.08} / \delta_u(\theta)_{M.D.96}\right] \\
\gamma_{max}(\theta) &= \left[\delta_{max}(\theta)_{M.D.08} / \delta_{max}(\theta)_{M.D.96}\right]
\end{aligned} \tag{40}$$

From the reported trends it can be observed that, at the same temperature, structure designed according to the M.D. 08 code always shows a seismic performance in the elastic-plastic and plastic ranges greater than that of the frame designed according to the M.D. 96 code. This occurs in terms of both forces and displacements up to 400 °C.

Analogously to the design philosophy at basis of the two codes, the detected situation changes in the elastic range. In fact, it can be noted that the M.D. 96 frame, being designed to remain mainly in the elastic range under applied loads, has shown an elastic performance better than that of the M.D. 08 frame, which is designed particularly to dissipate the amount of the seismic energy input in the elastic-plastic range, showing greater excursions in the plastic field. To confirm this, it can be observed that, starting from a temperature of 300 °C, the formation of plastic zones in the M.D. 08 structure occurs already for vertical loads, while this condition for the other structure happens at a temperature of 500 °C.

Regarding the degradation of forces and displacements with the temperature, reference is made to the trends shown in Figures 11a and 11b, which represent the functions described in the equation (6), for M.D.08 frame and M.D. 96 one, respectively. On the other hand, the variation of the parameter ξ with temperature θ is shown in Figures 12a and 12b.

As it can be observed, at the same temperature, force and displacement parameters undergo significant reductions, particularly in the elastic field, for the structure designed according to the M.D. 08 code.

This condition can be explained considering the reduced seismic capacity of the old structure compared to the new one, as well as the different collapse mechanisms attributable to the two structures analysed (floor mechanism for the M.D. 96 frame and column

mechanism at their base for the M.D. 08 frame, neglecting in both cases the beam mechanisms).

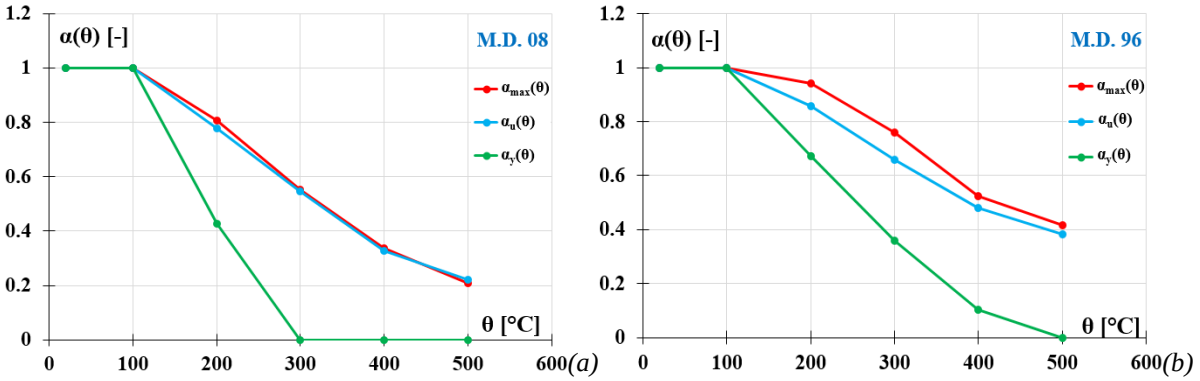

Figure 11: $\alpha - \theta$ curves for M.D. 08 (a) and M.D. 96 (b) frames.

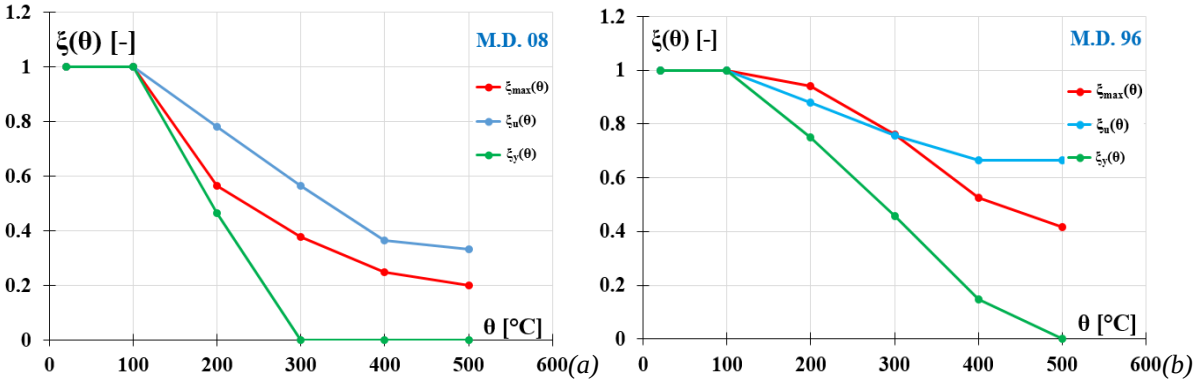

Figure 12: $\xi - \theta$ curves for M.D. 08 (a) and M.D. 96 (b) frames.

3.5 Calculation of $k_F(\theta)$ and $k_\delta(\theta)$ functions

Starting from the results provided by the numerical analyses performed on the two steel frames, the functions described by equations (6) and (7) in Section 2 have been calculated.

Once evaluated the pushover response parameters at θ=20°C, combining them with the functions cited above, the $k_F(\theta)$ and $k_\delta(\theta)$ functions are achieved.

Figures 13, 14 and 15 show the trends of the functions described above for the two frames designed with different seismic design codes.

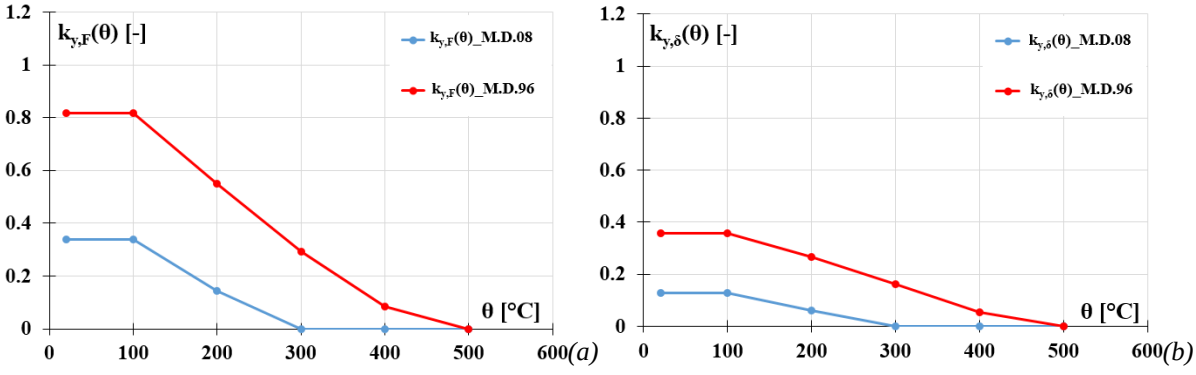

Figure 13: $k_{y,F} - \theta$ (a) and $k_{y,\delta} - \theta$ (b) curves of the inspected framed structures.

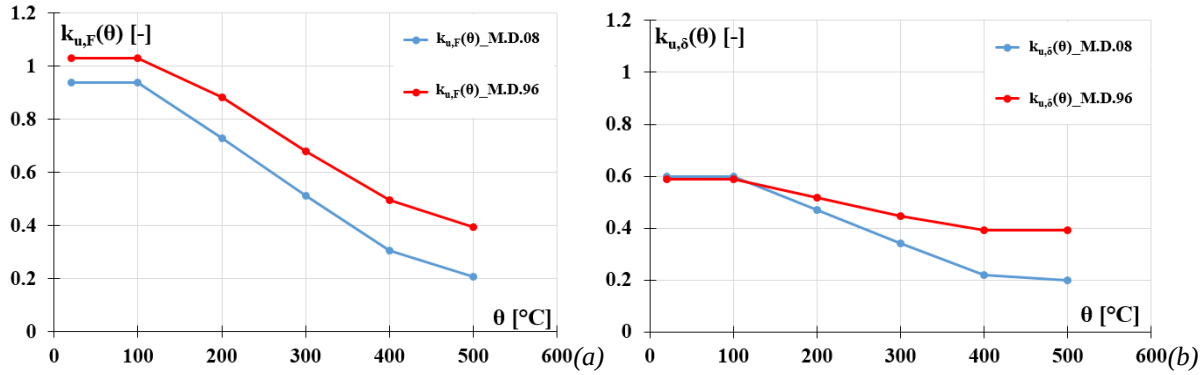

Figure 14: $k_{u,F} - \theta$ (a) and $k_{u,\delta} - \theta$ (b) curves of the inspected framed structures.

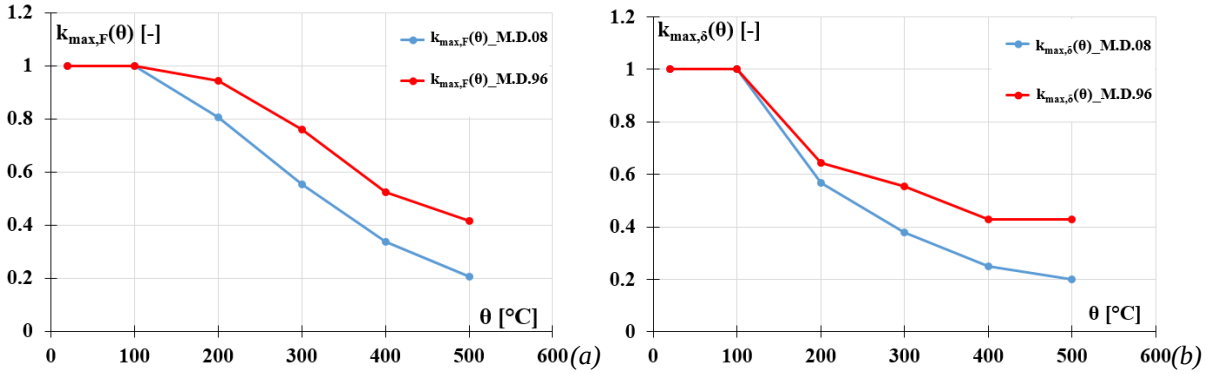

Figure 15: $k_{max,F} - \theta$ (a) and $k_{max,\delta} - \theta$ (b) curves of the inspected framed structures.

As already detected in the previous section for the functions $\xi(\theta)$ and $\alpha(\theta)$, at the same temperature, the most significant reduction of the functions k_δ and k_F with the temperature θ, especially in the elastic field, is detected for the M.D. 08 frame.

Finally, it should be noted that, by multiplying the values of F_{max} and δ_{max} at 20°C for the appropriate values of the above functions, it is possible to fully reconstruct the values of Tables 3 and 4.

4 CONCLUSIVE REMARKS AND FURTHER DEVELOPMENTS

In this study, a research activity concerning the seismic behaviour of framed structures after damages deriving from application of an exceptional load has been carried out.

Based on the results of a pushover analysis, a theoretical formulation to evaluate a simplified force-displacement curve for seismic appraisement of a structure damaged from an extreme event is reported.

However, after the basic non-linear behaviour of the undamaged structure is estimated, the concrete application of the method requires the *a priori* knowledge of some functions depending on the structure damage status at the end of the exceptional loading action. This can be attained by means of a widespread experimental-numerical examination campaign for evaluating the damages deriving from some variables influencing the effects of a given exceptional action.

An effective and practical way to apply the proposed method is provided in the Section 3 of the paper, where the residual seismic capacity of steel Moment Resisting Frames (designed according to both the new and the old seismic Italian codes) subjected to a preliminary fire action is estimated.

Numerical analysis results have shown that the reduction of mechanical properties of steel material due to fire can drastically affect the seismic response of investigated structures.

Results of this numerical investigation have shown that the structure designed according to the M.D. 08 code shows a seismic capacity in the post-elastic range greater than that designed according to the M.D. 96 code. Contrary, in the elastic field, the old frame behaves better than the new one. This is mainly due to the different design approaches used for the inspected frames. In fact the M.D. 96 structure is mainly designed to withstand applied loads without energy dissipation in the post-elastic range (no "capacity design" approach). This means that the first yielding in the old structure develops for base shear values greater than the new frame ones.

Finally, it is perceived that at the room temperature, the base shear capacity of the M.D. 08 frame is at least two times greater than the M.D. 96 structure one. Starting from this condition, the difference between the base shears drastically decreases after fire action. However, it can be noted that the force reduction trend shows a linear gradient with temperature, reaching its lower value at the temperature of 500 °C. The same behaviour is also observed for displacements. These trends are mainly due to the different distribution of damage under seismic loads, which appears to be more distribuited for the M.D. 08 frame, while it is localised at a certain storey for the M.D. 96 structure.

As a further development of the research activity, in order to both better understand the seismic behaviour of steel MRF before and after fire and validate the theoretical formulations given, an exhaustive campaign of numerical and experimental investigations is strongly needed. Some of the aspects that need to be more investigated are:

- The influence of the structure seismic response before fire damage, taking into account different geometrical configurations and any structural irregularities.
- The influence of the fire model and location.
- The influence of structural response at high temperatures, i.e. thermal expansions and related phenomena, as well as the actual temperature distribution in the cross-sections and along the structural elements.

Keywords: Masonry block structures, Non-smooth contact dynamics, Rigid blocks, Mathematical programming.

Abstract. *In this paper a variational formulation for dynamic analysis is adopted to investigate rocking behaviour of masonry block structures under lateral loads. The model is composed of rigid bodies interacting at potential contact points located at the vertexes of the bock interfaces. A no-tension and associative frictional behaviour with infinite compressive strength is assumed at contact interfaces. The contact dynamic problem is governed by equilibrium equations, which relate external, inertial and contact forces, and by kinematic equations, which ensure compatibility between contact displacement rates and block degrees of freedom. Mathematical programming is used to solve the optimization problem arising from the formulation of the variational problem associated to dynamics of the block assemblages. To evaluate the accuracy and computational efficiency of the implemented formulation, a validation study is presented for rigid blocks subjected to rocking behaviour under different acceleration pulse types and for an in-plane wall panel problem from the literature. A good agreement in terms of failure mechanism and response time histories was observed. The computational efficiency and the stability of the implemented procedure were found to be encouraging, thus suggesting that the proposed model may be used to model dynamic behaviour of masonry block assemblages with a large number of rigid bodies.*

1 INTRODUCTION

In case of seismic events, the response of masonry structures, such as historical monuments made of stone blocks or facades in masonry buildings subjected to local failure mechanism, is typically characterized by rocking behaviour [1-3].

Different modelling approaches are available in the literature to investigate the dynamic response of masonry block structures subjected to rocking. Among those, non-smooth contact dynamics (NSCD) represents an alternative modelling approach to discontinuous finite element modelling as well as to the discrete element method (DEM) [4-8].

The NSCD method has been applied to masonry block structures since the beginning of its development and it is now receiving a growing attention in the research community on masonry structures [9-11]. This is due to different reasons, also including the availability of fast and accurate algorithm for the numerical solution of the formulations which have been proposed in the literature for the mathematical programming problem arising from the conditions governing the contact dynamics [12-15].

In this paper a simple formulation for dynamic analysis of masonry block structures is adopted to investigate rocking behaviour of masonry block structures. The aim of the study was to evaluate its accuracy and computational efficiency when applied to in-plane loaded wall panels. The adopted modelling approach for contact interfaces represents an extension to dynamics of the point-based formulation used in the rigid block model which has been developed for limit analysis of masonry block structures in [16-18].

The static and kinematic variables as well as the relationships governing the behaviour of the rigid block model and the limit analysis formulation are presented in Sections 2 and 3. In Section 4 we present a validation study on single rigid block subjected to free rocking motion and to different acceleration pulse types. Finally, an application to a numerical case study of an in-plane wall panel considered in the literature is illustrated to show the ability of the implemented formulation to capture rocking behaviour of multi-block assemblages.

2 THE RIGID BLOCK DYNAMIC MODEL

We consider a multi-body assemblage made of rectangular rigid blocks *i* interacting at potential contact points *k* located at the vertexes of the interface *j* (Fig. 1).

A no-tension and associative frictional behaviour with infinite compressive strength is assumed at contact interfaces.

The dynamic model is formulated following the approach proposed in [19, 20] for granular materials, though now detailed for two-dimensional assemblages of rectangular blocks.

The contact variables are the internal forces acting at each contact point *k*, which are located at a vertex of interface *j* of block *i* (Fig. 2a). These variables are collected in vector **c** and include the shear force component t_k and the normal force n_k along the local coordinate axes.

The kinematic variables associated in a virtual work sense to the contact forces are the relative displacement rates at the contact points, namely the tangential and normal displacement rates Δu_{tk} and Δu_{nk} (Fig. 2b), which are collected in the vector $\Delta \boldsymbol{u}$.

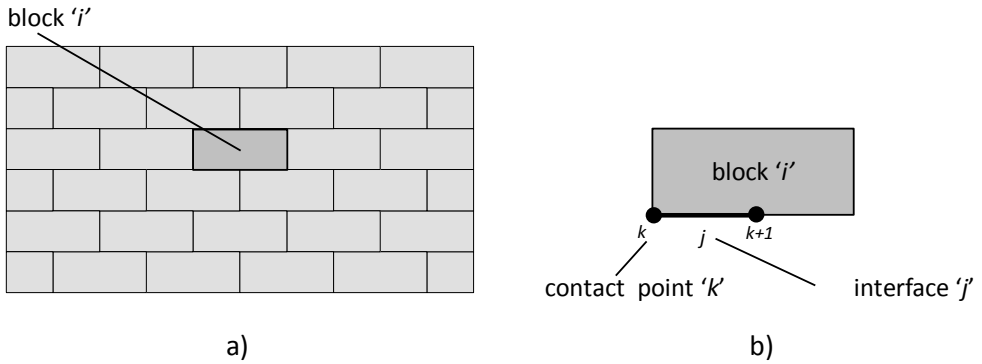

Figure 1: a) Rigid block assemblage; b) Rigid block *i* , interface *j* and contact point *k*.

External loads applied to the centroid of rigid block *i* are collected in vector of external forces $\boldsymbol{f}_{ext}$ (Fig. 2a).
The position at the centroid of block *i* is collected in the vector $\boldsymbol{x}_i$:

$$\boldsymbol{x}_i(t) = \left[x_i(t) \quad z_i(t) \quad \alpha_i(t) \right]^{\mathrm{T}} \tag{1}$$

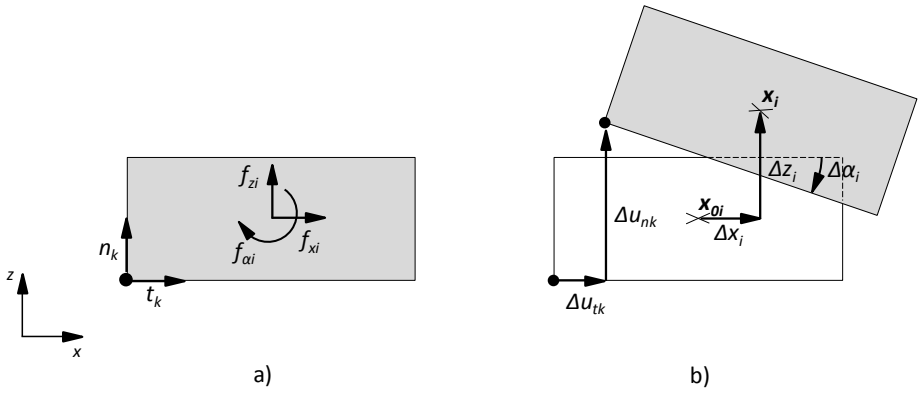

Figure 2: a) Contact forces and b) kinematic variables at block centroid *i*, and contact point *k*.

The equations of motions are discretized with respect to time using the θ-method and assuming:

$$\dot{\boldsymbol{x}}(t) = \frac{1}{\theta}\left[\frac{\Delta \boldsymbol{x}}{\Delta t} - (1-\theta)\,\dot{\boldsymbol{x}}_0 \right] \tag{2}$$

where $\Delta \boldsymbol{x} = \boldsymbol{x} - \boldsymbol{x}_0$ is the displacement vector, $\boldsymbol{x}_0$ and $\dot{\boldsymbol{x}}_0$ are the known position and velocity at time t_0 and $\theta \geq 0.5$.

On the basis of the incremental expression (2), the equations of motion of the rigid block assemblage interacting at potential contact points can be posed as follows:

$$\bar{\boldsymbol{M}} \Delta \boldsymbol{x} + \boldsymbol{A}_0 \boldsymbol{c} = \bar{\boldsymbol{f}}_0 \tag{3}$$

where $\boldsymbol{A}_0$ is the equilibrium matrix corresponding to contact forces;

$\bar{\boldsymbol{M}} = \dfrac{1}{\theta \Delta t^2} \boldsymbol{M}$;

$\boldsymbol{M}$ is the mass matrix collecting the mass m_i and the mass moment of inertia J_i of each block*;*

$\bar{\boldsymbol{f}}_0 = \boldsymbol{f}_{ext} + \bar{\boldsymbol{M}}\dot{\boldsymbol{x}}_0 \Delta t$.

The non-penetration condition at potential contact point *k* is formulated in a linearized explicit form, that is assuming that the geometry is the same for two subsequent time steps.

In matrix form, the condition can be expressed imposing that the normal component of the relative displacement at a contact point *k* has not to be greater than the initial gap g_{0k}, as follows:

$$\boldsymbol{N}_0^{\mathrm{T}} \Delta \boldsymbol{u} \le \boldsymbol{g}_0 \tag{4}$$

where $\boldsymbol{N}_0^{\mathrm{T}}$ is the matrix collecting the initial normal associated with surfaces *j* and $\boldsymbol{g}_0$ is the vector of initial gaps.

For contact interactions, a complementarity condition is also included which ensures that contact forces are positive only if the gap is closed otherwise are zero:

$$\begin{aligned} &\boldsymbol{n} \ge \boldsymbol{0} \\ &\mathrm{diag}(\boldsymbol{n})\left(\boldsymbol{N}_0^{\mathrm{T}} \Delta \boldsymbol{u} - \boldsymbol{g}_0 \right) = \boldsymbol{0} \end{aligned} \tag{5}$$

The behaviour at contact interfaces undergoing sliding failure is governed by failure conditions which are expressed according to the Coulomb friction law.

In vector notation, the limit conditions for sliding failure can be written as:

$$\pm \boldsymbol{t} \le \mu \boldsymbol{n} \tag{6}$$

where μ is the friction coefficient.

3 FORMULATION AND IMPLEMENTATION OF THE VARIATIONAL PROBLEM OF RIGID BLOCK DYNAMICS

Under the assumption of associative flow rule for displacement rates, the equilibrium equations (3), kinematic conditions (4-5) and sliding friction conditions (6) are equivalent to the following discrete mixed force–displacement problem [19, 20]:

$$\begin{aligned} &\min_{\Delta x} \ \max_{c} \ \frac{1}{2} \Delta \boldsymbol{x}^{\mathrm{T}} \bar{\boldsymbol{M}} \Delta \boldsymbol{x} - \Delta \boldsymbol{x}^{\mathrm{T}} \bar{\boldsymbol{f}}_0 + \Delta \boldsymbol{x}^{\mathrm{T}} \boldsymbol{A}_0 \boldsymbol{c} - \boldsymbol{g}_0 \\ &\text{subject to} \quad \pm \boldsymbol{t} - \mu \boldsymbol{n} \le \boldsymbol{0} \qquad \boldsymbol{n} \ge \boldsymbol{0} \end{aligned} \tag{7}$$

The problem (7) can be uncoupled into two dual quadratic programming problems, corresponding to the kinematic and force-based formulation of the contact dynamic problem.

To calculate and update positions of the blocks and contact gaps, an iterative procedure was implemented to solve the mathematical program (7).

The procedure was implemented in a computer code, *DynoBlock_2D*, which provides as outputs the time histories of contact forces and kinematic variables as well as the plots of the failure mechanisms at different time steps.

The quadratic programming problems associated to (7) were solved using the primal–dual interior-point solver in MOSEK [23].

The analyses were carried out using a PC containing a 3.3GHz Intel Xeon E3-1245 processor with 8 GB of RAM. The value of algorithm parameter θ for time discretization was set equal to 0.7 and time increment was set equal to 0.002 s.

4 DYNAMICS OF THE SINGLE RIGID BLOCK

To validate the proposed formulation, the case study of a single rigid block subjected to free rocking motion and to ground acceleration pulses was considered.

The rigid block dimensions are 0.20×1.00m and the unit weight is 18.0 kN/m^3 (Fig. 3). The friction coefficient μ adopted at the contact interface is equal to 0.7.

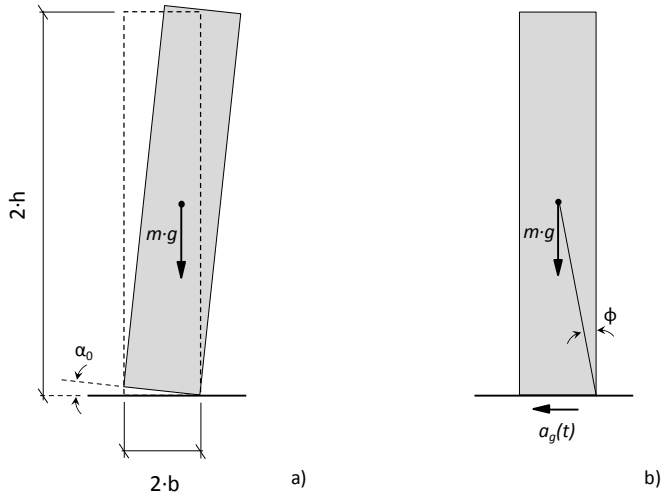

Figure 3: Rigid block subjected to free rocking motion and to ground acceleration pulses.

To analyze the free rocking motion response of the block subjected to gravity acceleration g an initial angle α_0=0.01 rad was considered.

The rotation time history of rigid block obtained from the proposed formulation is shown in Fig. 4. The comparison with closed form solution, which is referred to a value of the coefficient of restitution $\sqrt{r} = 0.925$ relating the reduction of the angular velocity before and after the impact, shows a good agreement [21].

The response obtained for the rigid block resting on the base and subjected to a constant horizontal ground acceleration a_g was investigated as well for validation. The objective of this set of simulations was to test the accuracy of the formulation in predicting the minimum value of the horizontal acceleration for the motion to be initiated and the magnitudes of rectangular pulse excitations with duration of 1.0s needed for overturning.

The numerical simulations showed that the minimum value of the horizontal acceleration a_g to begin tilting of the block was 0.20g. As expected, this value is in accordance with the condition $a_g / g \geq \varphi$, corresponding to the simple condition that the overturning moment induced by the lateral force on the contact has to be greater than the corresponding resistant moment related to the weight.

The rotation time histories for different values of ground accelerations in the case of rectangular pulse excitations are shown in Figure 5.

Case study	Model size ($b \times c$)	a_g (g)					
		Acceleration value for rocking initiation		Overturning acceleration amplitude for constant pulse with duration 1.0 s		Overturning acceleration amplitude for a sinusoidal pulse with duration 1.0 s	
		Differential equations	Proposed	Differential equations	Proposed	Differential equations	Proposed
Single block	1 × 2	0.200	0.201	0.204	0.204	0.237	0.237

Table 1: Single rigid block: acceleration values for overturning and CPU times.

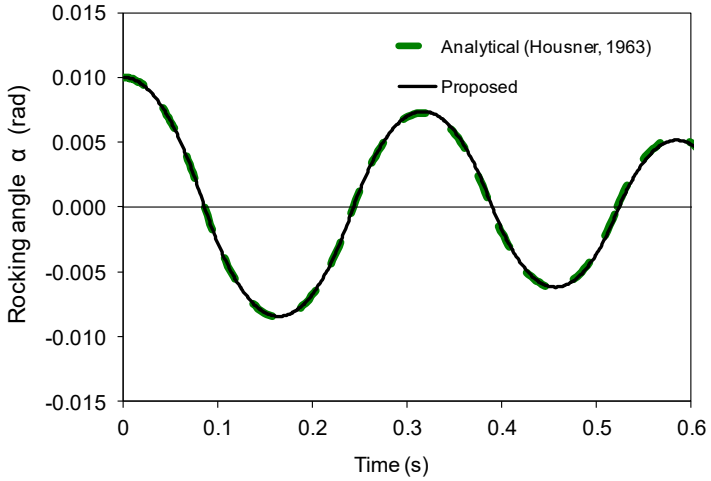

Figure 4: Rotation time history of the rigid block subjected to free rocking motion: comparison of proposed and analytical formulations.

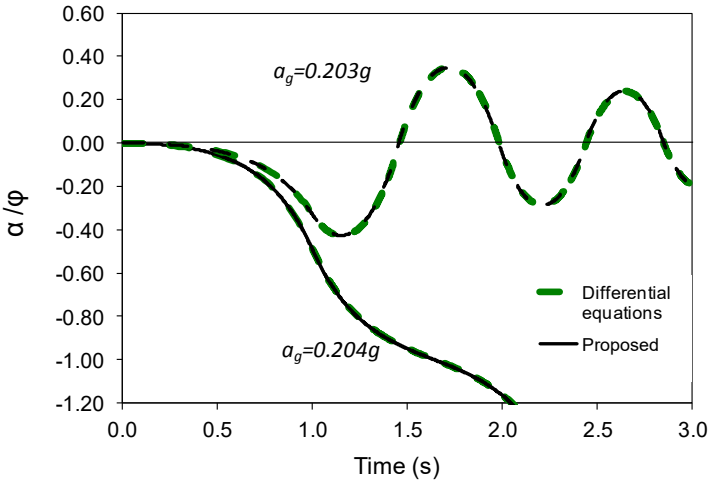

Figure 5: Rotation time histories of the rigid block subjected to constant (rectangular) acceleration pulses with duration of 1.0 s.

A similar study was carried out for sinusoidal pulse excitation. Also in this case the results are in good agreement with the response obtained from numerical integration of the differential equation of motion (see Table 1).

5 APPLICATION TO IN-PLANE LOADED MASONRY WALL

In this section we consider for validation a block panel analysed by Ferris and Tin-Loi [22] using mathematical programming with equilibrium constraints (MPEC) for computational limit analysis and subsequently investigated in [16] using a second order cone programming formulation (SOCP) .

The main goal of this study was to compare results from the present QP dynamic formulation with those obtained from previously developed limit equilibrium analysis (LA) procedures and to illustrate the ability of the proposed formulation in capturing the rocking response in case of rectangular pulse excitation.

The wall panel under investigation is illustrated in Figure 6 (example no.3 in [22]). The size of a full block is 0.4×0.175m, the friction coefficient is 0.65 and the unit weight is 1.0kN/m^3. To simulate the load cases of the limit analysis formulation, in the contact dynamic QP formulation the blocks are subject to a constant value of horizontal acceleration and to the gravity acceleration. The analysis is repeated increasing the horizontal acceleration by step of 0.001g until rocking motion is initiated. Once the minimum value of acceleration is obtained, a constant acceleration pulse with duration of 1.1 seconds is applied to the panel to analyze the evolution of the failure mechanism over time.

The sizes of the numerical model, expressed as the number of blocks b and contact points c, are reported in Table 2, together with the numerical results in terms of accelerations and ultimate load factors obtained from limit equilibrium analysis, as well as CPU times.

The computed acceleration magnitude to initiate rocking motion is in good agreement with the load factors obtained using previously presented limit equilibrium formulations (Table 2). Indeed, the computed acceleration values are comprised in the range of associative and non-associative solutions from limit analysis problems.

Case study	Model size ($b \times c$)	Limit equilibrium analysis using SOCP [16]				Dynamic analysis using QP (proposed)	
		Associative friction solutions		Non-associative friction solutions			
		λ	CPU Time (s)	λ	CPU Time (s)	a_g (g)	CPU Time* (s)
Example no. 3 [22]	46 × 240	0.404	0.1	0.356	0.9	0.387	97.5

*Referred to 3.3GHz CPU, per unit time duration of dynamic analysis (second) in the case of QP formulation.

Table 2. In-plane loaded masonry wall: comparison of collapse load factors from LA formulations and acceleration obtained from CD-QP problems.

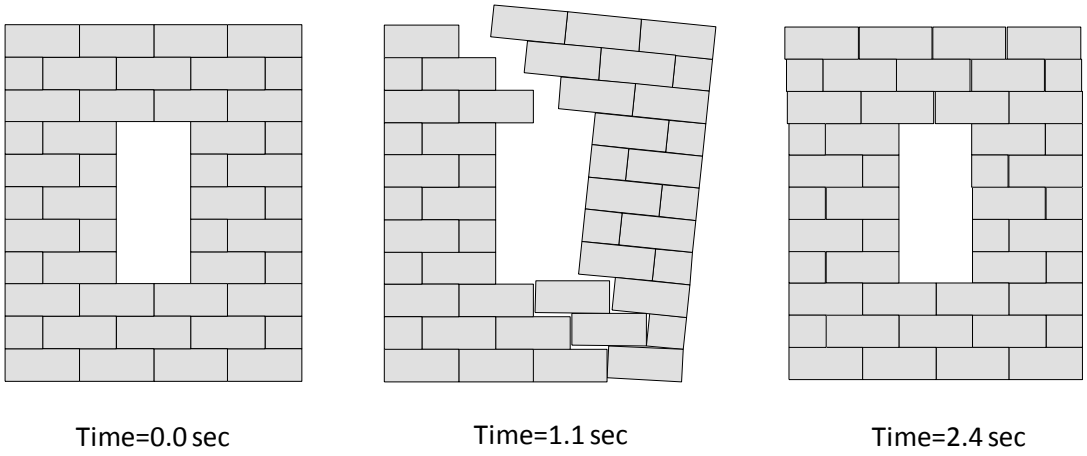

Figure 6: Wall sample n.3 [22]: failure mechanism time history obtained from the contact dynamic formulation under a rectangular pulse excitation of 0.387g with duration of 1.1s.

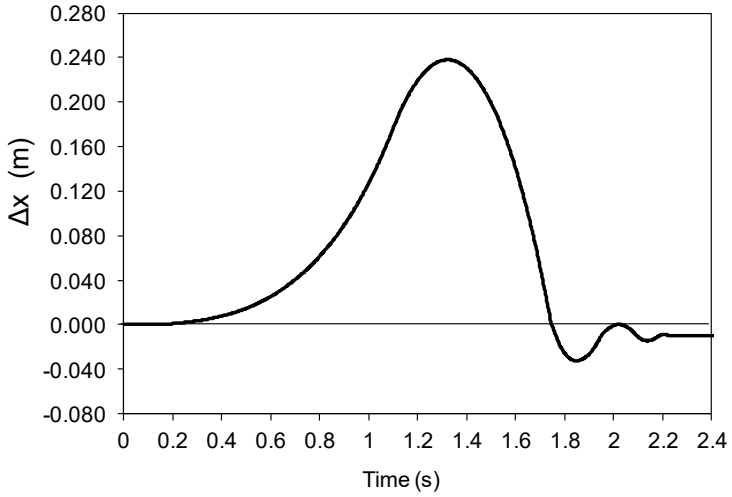

Figure 7: Time history of the top drift displacement.

The time history of the failure mechanism and the drift displacement at the top for the rectangular pulse excitation with duration of 1.1 s are shown in Figures 6 and 7.

It is interesting to point out the residual drift after pulse excitation and the stability of the predicted response, which shows no chattering effect and is only slightly affected by the few mechanical and algorithm parameters inherent the numerical model, namely the friction coefficient, the θ factor and the size of time step.

6 CONCLUSIONS

- A 2D formulation for contact dynamic analysis of block masonry structures with no-tension and associative frictional joints and infinite compressive strength was presented. The formulation is based on the contact point model for interfaces and uses QP programming to solve the discretized equation of motion under kinematic and static constraints.

- The model was validated against numerical case studies from the literature involving single and multi-block assemblages and a good agreement in terms of failure mechanism and response time histories was observed.
- The computational efficiency and the convergence stability of the implemented procedure were found to be encouraging, also considering the small number of mechanical and algorithm parameters associated to the adopted formulation.

CONTROLLED ROCKING, DISSIPATIVE CONTROLLED ROCKING AND MULTI-HIERARCHICAL ACTIVATION: NUMERICAL ANALYSIS AND EXPERIMENTAL TESTING

Royce Liu & Alessandro Palermo

Keywords: pier, bridge, experimental, unbonded post-tensioning, controlled rocking, PRESSS.

Abstract. *The earliest modern work on rocking focussed on pure rocking structures. That is, structures that are able to uplift and where the tendency to self-centre is purely provided by self-weight. Since then, free rocking has evolved into a multitude of new design strategies due to the addition of elements such as post-tensioning (controlled rocking) or having multiple interfaces in a single element where uplift can occur (segmental rocking). Although these new design strategies evolved from free rocking, there is little clarity in current literature about the differences in dynamic behaviour which is important in seismic design. A specific example of this, is that, the PRESSS system also known as DCR (dissipative controlled rocking: the combination of post-tensioning, dissipative devices and free rocking) and free rocking are usually mistaken to reduce damage to a structure through the same mechanism of gap opening and hence that the dynamic behaviours are the same. This paper looks to give a short modern history of the evolution the rocking structure and argue that design strategies based on rocking may not have the same dynamic response as pure rocking through comparison of the results of non-linear response history analyses of a SDOF structure utilizing pure rocking, controlled rocking, and dissipative controlled rocking strategies. Following on the theme of the evolution of the rocking structure, at the University of Canterbury, unidirectional, quasi-static, cyclic, tests were conducted on a 1/3 scale two span bridge utilising a single cantilever controlled rocking pier which was designed to operate in three different configurations: without dissipative devices, with one set of hysteretic dissipative devices, and with two sets of hysteretic dissipative devices. The very last configuration is a new design strategy proposed by the authors as "hierarchical DCR" where there are two sets of dissipative devices across the rocking interface and where one set is activated at a later pier displacement to the other. The concept behind this idea is to increase structural robustness of the DCR system as a means of collapse prevention due to subsequent or unusually rare events such as the maximum credible earthquake. This paper will also present the results of this testing.*

1 INTRODUCTION

Past major earthquakes have shown significant drawbacks related to bridges using conventionally designed RC piers. These include: residual drift, which affects post-earthquake functionality and speed of reinstatement; physical damage from non-linear material behaviour, which not only affects post-earthquake functionality and the speed of reinstatement, but also, the remaining life of the bridge; and major indirect losses, from down time of the bridge caused by the aforementioned consequences of allowing non-linear material behaviour within the pier member. An alternative to conventional RC design, whose aim is to minimise and or eliminate the aforementioned performance issues related to member plastic hinging, are a family of design strategies based on rocking. These include free rocking, controlled rocking and dissipative controlled rocking (DCR) also known as hybrid PRESSS [1] and are all shown in Figure 1. Controlled rocking is free rocking with the addition of unbonded post-tensioning (Fig. 1b). Instead of wholly relying on self-weight to provide self-centering, where the tendency to self-centre reduces with displacement (Fig. 1a), controlled rocking also relies upon both the initial post-tensioning force and elongation of the tendons to provide self-centering. The name of this design strategy was coined from the fact that there is greater control over the tendency to self-centre due to the adjustable nature of the post-tensioning. This combination results in a bilinear elastic force-displacement plot with positive stiffness after uplift initiates (Fig. 1b).

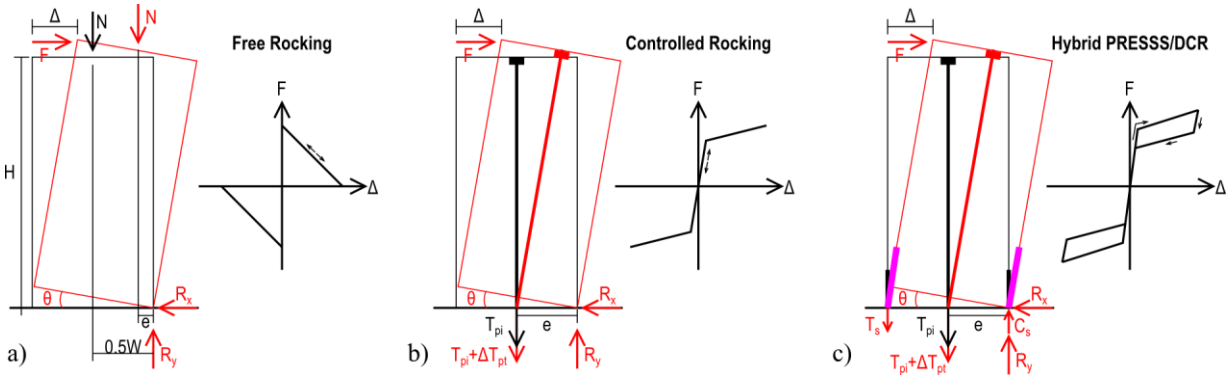

Figure 1: Free body diagrams and force displacement plots for a rigid block on rigid foundation utilising: **a)** free rocking; **b)** controlled rocking; and **c)** hybrid PRESSS/DCR.

The further addition of dissipative devices (usually metal hysteretic) across the rocking interface (internal or external to the member) results in the design strategy of dissipative controlled rocking (Fig. 1c). The dissipative devices add to the moment capacity and or damping of the structure resulting in a flag shaped hysteresis loop (Fig. 1c).

This contribution focusses on rocking bridge structures and has three main aims. The first is to elaborate more on the variety and development of rocking solutions in order to show the evolution of the rocking structure and the reasoning associated with it. The second is to argue that not all design strategies based on rocking exhibit the same dynamic behaviour which is a common misconception. And the third is to present the concepts for a new design strategy called Multi-Performance DCR (MDCR) developed by the authors, in addition to results from experimental testing as proof of concept.

2 LITERATURE REVIEW: EVOLUTION OF ROCKING APPLIED TO BRIDGES

Two main streams of design strategies for bridges based on rocking have evolved in parallel, namely, uplifting and jointed structures. Major interest in the use of rocking as a seismic design strategy stems from Housner [2] where he observed that water towers which were able to rock

on their foundations during the May 1960 Chilean Earthquake survived relatively undamaged compared to their monolithic counterparts.

Uplifting structures encompass two types of foundation rocking: uplifting shallow foundation (Fig. 2a, right) and pile cap rocking on supporting piles (Fig. 2a, left); and stepping (Fig. 2b). These types of structures are the closest to classical free rocking structures due to their reliance on self-weight for self-centering. Of the uplifting structures, the rocking shallow foundation [3–6] and stepping structures were the first to be investigated [7,8]. While the rocking pile foundation was investigated later on [9,10] but more as a solution to geotechnical constraints imposed by poor soil conditions.

Uplifting is a form of seismic isolation because seismic demands are reduced to the supported structure through period elongation [2,3,6,11–14]. However, the amount of period elongation is dependent on the amplitude of rocking displacement [2,6]. In addition to this, soil–structure interaction effects for foundation rocking structures also contribute to reducing seismic demands [15].

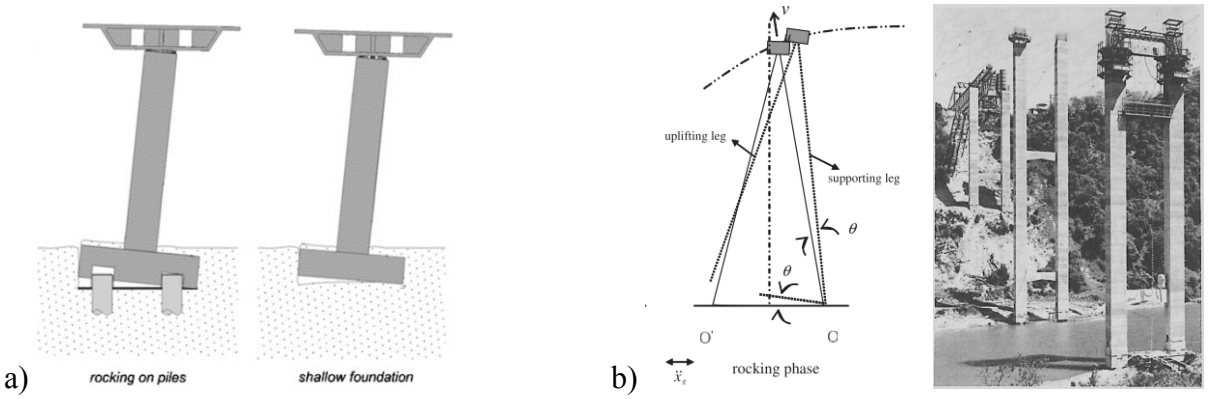

Figure 2: a) Examples of foundation rocking structures [9]. Left, rocking on piles and right, rocking shallow foundation. **b)** Examples of stepping structures. Left, displaced structure showing mode of movement [11]. Right, Rangitikei viaduct NZ a bridge using stepping piers [16].

The other stream of design strategies based on rocking are jointed structures, where, locations of plastic hinges are replaced with rocking joints as a means of reducing seismically induced damage. This type of design strategy was initially developed for precast concrete buildings under the US PRESSS program where both a crude controlled rocking solution [17] and the present day hybrid PRESSS/ dissipative controlled rocking (DCR) [1] solution were developed. The first application of a jointed rocking structure to bridges was proposed by [18]. Mander and Cheng [18] envisioned both free and controlled rocking bridge piers (cantilever and pier bent) with steel armouring at the rocking interfaces to prevent damage to the edges of the rocking sections (Fig. 3a).

The proposed application of the hybrid PRESSS system to bridges (Fig. 3b) was only made some years later by Palermo et al. [19] as a means of achieving improved seismic performance compared to monolithic construction. Initially the PRESSS system in bridges used internal dissipative devices in the form of debonded mild steel reinforcement [20] (Fig. 3c). This then changed into the use of external dissipative devices [21] to facilitate easy observation and replacement (Fig 4a). Then Kam et al. [22] proposed improvement of the response of the DCR connection to both near and far field earthquakes through combining velocity (fluid viscous dampers) and displacement dependent dissipators (metal hysteretic) to produce an advanced flag shape hysteresis curve (Figs. 4b & c).

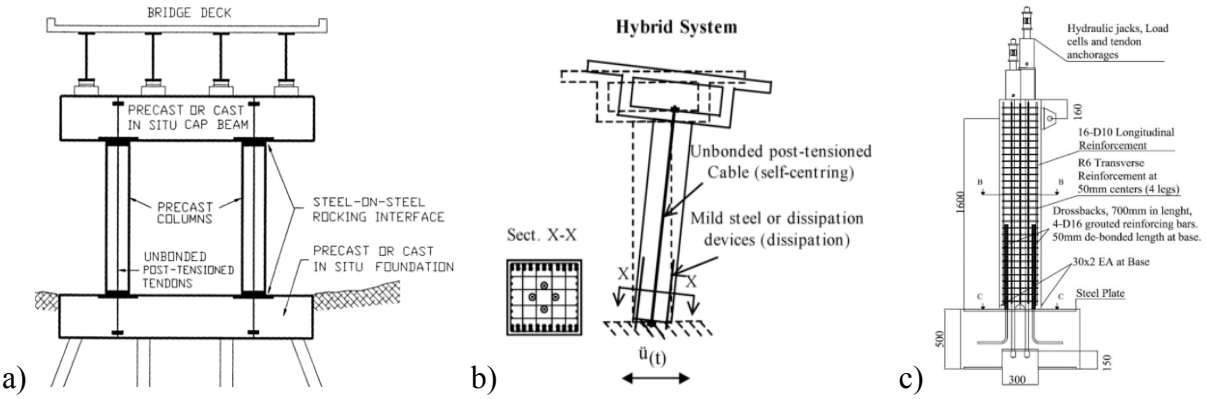

Figure 3: a) Controlled rocking pier bent [18]. **b)** Proposed application of PRESSS to bridges showing possible design [19]. **c)** Design schematic of a cantilever PRESSS column used in experimental testing [20].

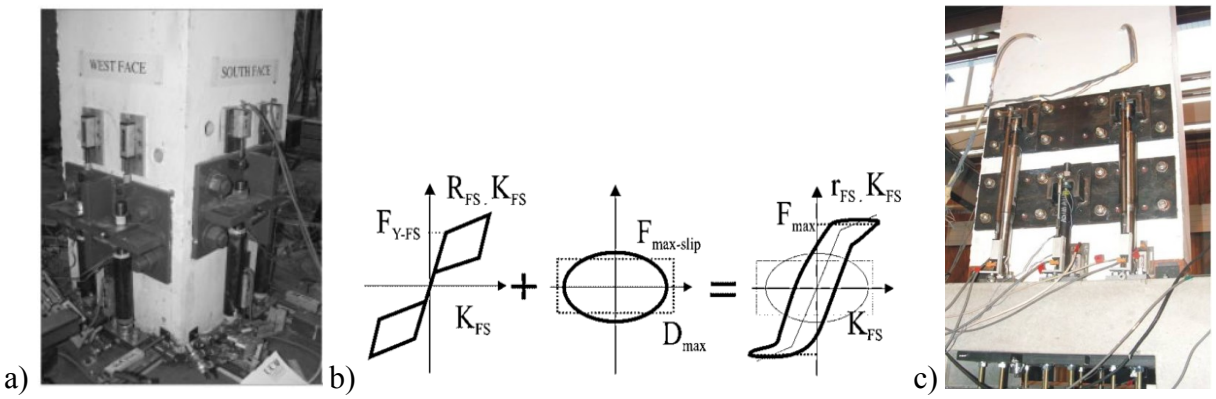

Figure 4: a) PRESSS/DCR column using external dissipators [21]. **b)** Advanced flag shape (AFS) hysteresis [22]. **c)** Experimental testing of the AFS concept showing the combination of viscous and metal hysteretic devices to achieve the advanced flag shape [23].

Most of the previously described developments on DCR applied to bridges were made at the University of Canterbury, New Zealand. Outside this institution, research has been more focussed on applying low damage technologies to accelerated bridge construction (especially in the US) and the application of DCR to tall segmental concrete bridge piers (Fig. 5) as a means of increasing the dissipative capacity of the pier [24–26].

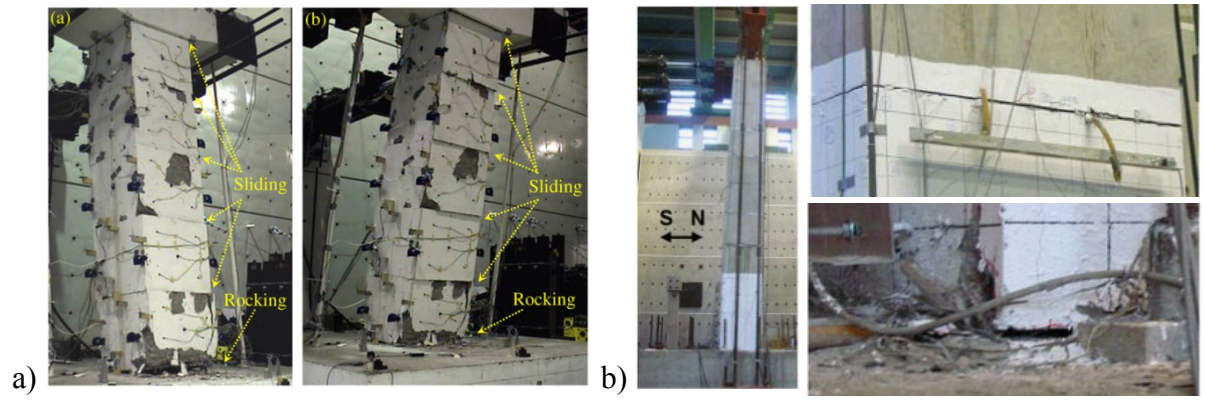

Figure 5: a) Segmental pier combining controlled rocking with frictional means of energy dissipation from sliding [27]. **b)** Segmental pier tested by Wang [24] using internal debonded reinforcement for energy dissipation.

Today, the authors of this paper see the DCR solution evolve into "Multi-Performance Dissipative Controlled Rocking" (MDCR) [28]. Further explanation of this concept is given later in this paper.

3 DISCUSSION: WHY FREE ROCKING AND HYBRID PRESSS ROCKING DO NOT WORK IN THE SAME WAY

There is a common misconception that Dissipative Controlled Rocking (DCR) and free rocking have similar dynamic behaviours and that their treatment in design can be considered similar. This misconception arises from the assumption that the addition of post tensioning, and dissipative devices to a free rocking structure does not change the dynamic behaviour of the free rocking structure. However, other than the obvious similarities, these two design strategies exhibit very different dynamic behaviours which is an extremely important consideration for design.

Consider for example the free vibration (Fig.7) and ground motion response (Fig. 8) of the HBD5/PT2 pier specimen (Fig. 6, right) taken from Marriott [29] and modelled in OpenSees using a simple 2 spring SDOF (Fig. 6, left) in three different configurations: free rocking of the pier, post-tensioning only (controlled rocking), and post-tensioning with metal hysteretic dissipators (DCR).

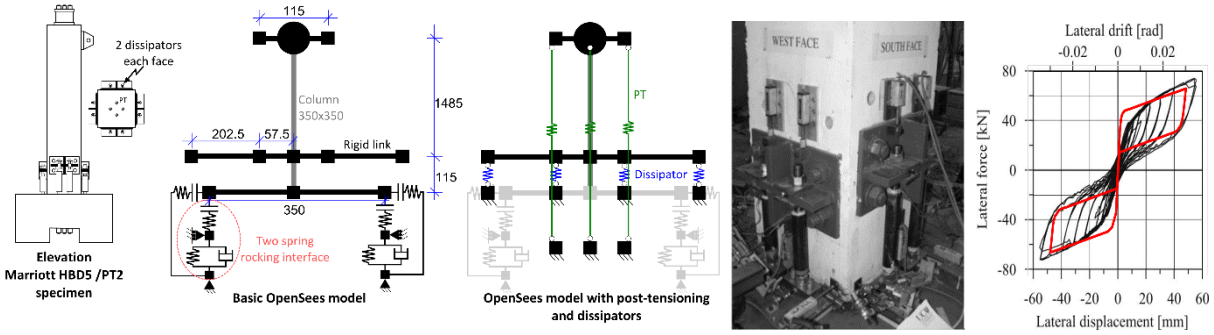

Figure 6: Left, OpenSees models of test specimens HBD5/PT2 taken from [29]. Middle, photo of HBD5 specimen from [29] with external buckling restrained fuse dissipators, and concrete to steel rocking interface. Right, comparison of the model and experimental flag shaped hysteresis curves.

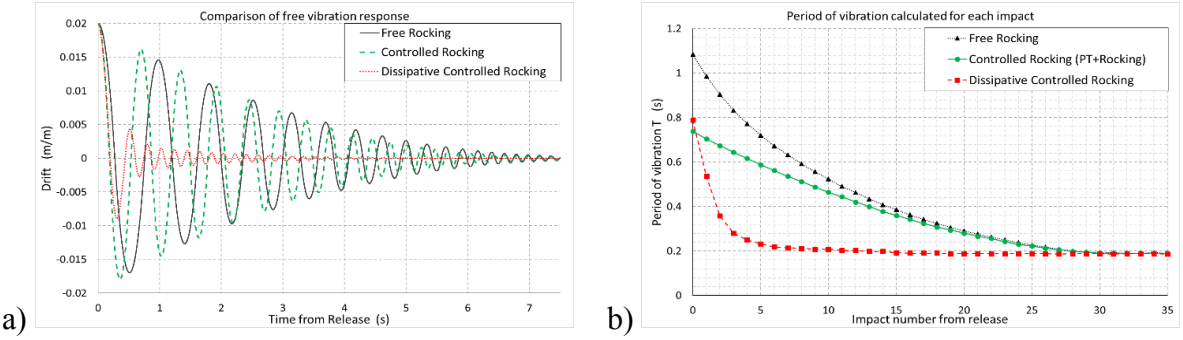

Figure 7: a) Free vibration response since release from 2% drift. **b)** Variation in the period of vibration as a function of the number of rocking impacts since release.

It can be seen in Figure 7a that the addition of post-tensioning immediately reduces the initial period of vibration due to the additional restoring force provided by tendon elongation. Figure 7b shows that the addition of post-tensioning has little effect on the damping of the system which is expected due to it behaving in the elastic range. This means that controlled rocking

mainly relies on contact damping for energy dissipation. Finally, with the further addition of metal hysteretic dissipators, the pier will tend to behave as a fixed base structure. This is due to the continuous supplemental damping provided by the dissipators quickly reducing the amplitude of vibration so that the displacements of the dissipators are below yield and the pier no longer rocks due to the high elastic stiffness of the dissipators (Fig's. 7a &b).

Inspecting the response history (Fig. 8) of the same pier, in the same three configurations, subject to seven different ground motions (Fig. 8, top left) scaled to have the same PGA (0.365g) as the design spectrum, a similar trend in behaviour is apparent. The displacement response of the different configurations (Fig. 8) clearly shows the period elongation effects of free rocking which are not observed for the controlled rocking (post-tensioning plus rocking) or DCR configurations. Hence, controlled rocking and DCR do not display seismic isolation properties and should therefore be treated more like fixed base structures in terms of seismic design.

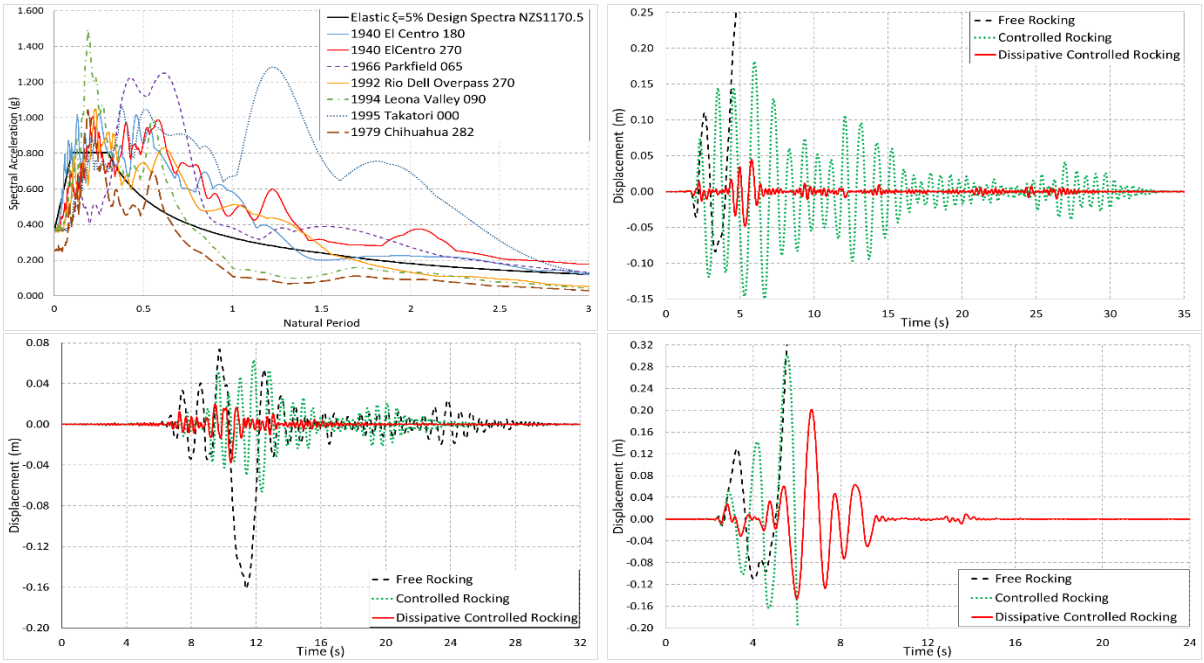

Figure 8: Top left, 5% damped elastic acceleration spectra used for nonlinear response history analysis. Top right, bottom left, and bottom right, displacement response of the three pier configurations subject to the 1940 ElCentro 180, 1994 Leona Valley 090, and 1995 Takatori 000 records respectively. The 1994 Leona Valley 090 record was the only record which did not result in overturning of the free rocking configuration.

4 IMPROVING THE STRUCTURAL REDUNDANCY OF DCR: MULTI-PERFORMANCE DISSIPATIVE CONTROLLED ROCKING (MDCR)

In the context of cantilever bridge piers, the plastic hinging mechanism is of column sway, where, collapse prevention is dependent upon the ductility capacity of the plastic hinge at the base. In DCR cantilever bridge piers the rotational ductility against overturning is dependent upon the dissipators and post-tensioning. Currently, all the dissipators are designed to activate at a set level of earthquake loading and all have the same ultimate capacities. Hence, currently the robustness of DCR is purely provided by multiplicity in the number of dissipators and post-tensioning. Once rupture of a few dissipators and yielding of the post-tensioning occurs, the pier would lose significant stiffness and would be prone to P-Δ effects which would eventuate in collapse of the structure (Fig. 9a).

To mitigate this issue, research is being conducted by the authors on a new design strategy based on dissipative controlled rocking called "Multi-Performance Dissipative Controlled

Rocking" (MDCR). The concept is to delay the onset of collapse through discretizing the capacity of the structure provided by dissipative devices and or mechanisms (rocking), such that, the devices and or mechanisms are activated in a hierarchical manner under increasing levels of shaking. The authors have proposed three methods of achieving this [28], however, only one is explained in detail here due to its relation to the experimental results being presented

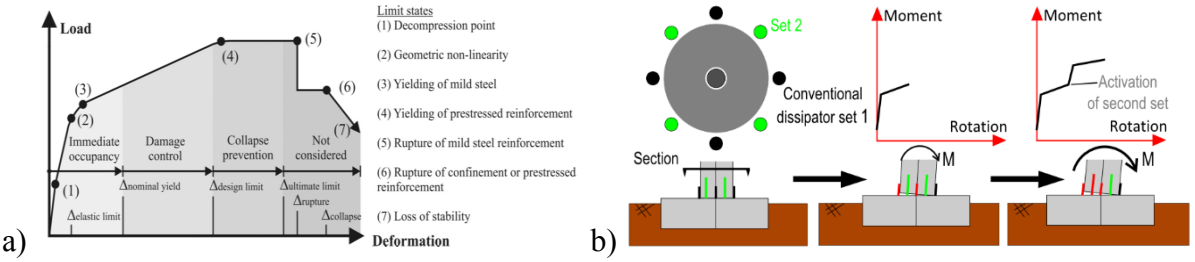

Figure 9: a) Performance objectives and limits for a DCR pier [29]. **b)** Example of hierarchical activation used.

The method of achieving hierarchical activation focussed on in this paper, is to have two sets of dissipators across one rocking interface (Fig. 9b). One set, is directly attached to the members either side of the rocking interface, while, the other is attached in such a way that it is only engaged when uplift at the rocking interface exceeds a specified value. The purpose of this arrangement, is that under frequent seismic loading (return period less than ULS) only one set of dissipative devices is relied upon and if the intensity of the ground motion exceeds that of the ULS ground motion then the second set of dissipative devices is activated in addition to the first set. In this way, after a ULS ground motion, even though one set of dissipators may be spent, the vulnerability of a DCR pier to a sequential significant ground motion (if the first set is not immediately replaced) is lessened due to the presence of the second unused set on standby. In addition to this, in extreme events where both sets contribute to resisting the ground motion, the onset of yielding of the post-tensioning and major P-Δ effects are delayed due to the activation of the second set reducing overall displacements.

5 EXPERIMENTAL INVESTIGATION INTO MDCR

Experimental testing was carried out on a 1/3 scale precast concrete bridge with single cantilever, post-tensioned, rocking pier designed to operate in controlled rocking, DCR, and MDCR configurations. The same pier was also tested in isolation after removal of the decks in DCR and MDCR configurations. The aim of the testing was to physically test the MDCR concept and compare it to a conventional DCR benchmark.

5.1 Specimen overview

The specimen is based on a prototype structure (Fig. 10) typical of a two lane, short-span, reinforced concrete, New Zealand Highway Bridge. The prototype consists of two, 13m simple spans; a single, 1.5m diameter circular pier; and hammer head type cap beam, supporting, a precast superstructure made of standard design double hollow core units. The test specimen, is a fully precast concrete structure (design f'c = 40MPa) and is 1:3 scale. Like the prototype, it is a two span simply supported bridge (Fig. 11). The decks are hollow core slabs each nominally 4222mm long by 2400mm wide and rest on rectangular UHMWPE bearings.

The pier is 500mm in diameter, and has a clear length of 2140mm. The armouring at the base of the pier is a custom made, 500 x 10 CHS with an annular steel ring welded to the base (Fig. 12c).Shear studs welded to the inside of the CHS ensure composite action with the pier. Shear and torsion restraint of the pier base is provided by external shear and torsion keys (Fig.

12b). Pier post-tensioning is provided by a single 26.5mm diameter Macalloy bar of 3182mm unbonded length. Grooved type dissipators were used. The dissipators had 4 grooves, are 16mm in diameter, have a design fuse length of 185mm, a design fuse area of 135mm^2 and are made from mild steel (Fig. 12e) The pier base accommodates a maximum of 8 dissipators (Fig. 12a) which are evenly distributed around the pier (Fig. 9b): 4 for conventional PRESSS hybrid configuration and 4 for hierarchical activation ($\theta_{engagement}$ =2.5% so that yielding would occur prior to θ_{MCE} =2.75%). The dissipator to dissipator circle diameter is 570mm.

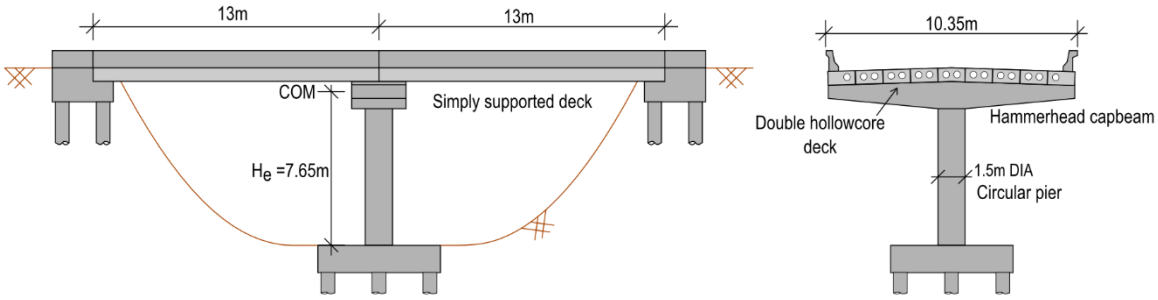

Figure 10: Prototype bridge.

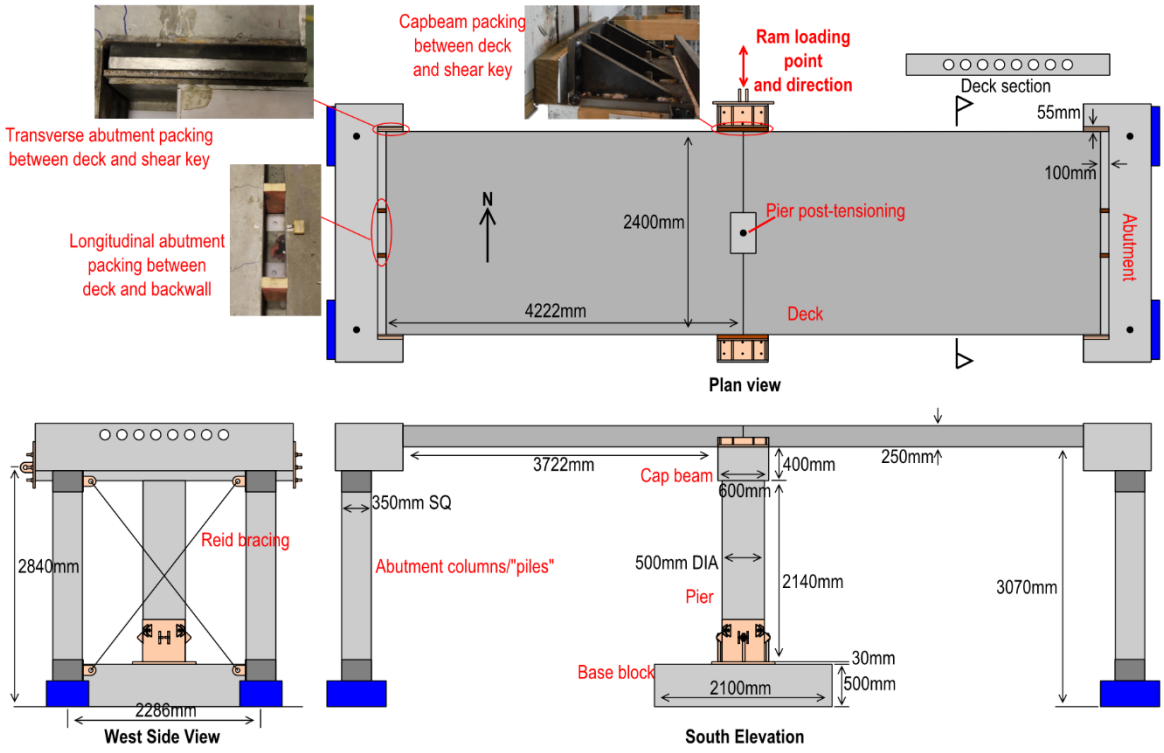

Figure 11: Overall specimen dimensions and detail regarding the boundary conditions around the decks.

5.2 Pier details: hierarchical activation of two sets of dissipators

In the experimental testing shown here, hierarchical activation, involved two sets of dissipators, where, one set is engaged at a later pier displacement to the other. Many options for achieving this were investigated, however, most were either infeasible or impractical. The final option chosen, consists of dissipators being connected by pins to the foundation and pier (Fig. 12a), but where, the pinned bracket connecting the dissipator to the pier has a slotted hole (Fig. 12d).

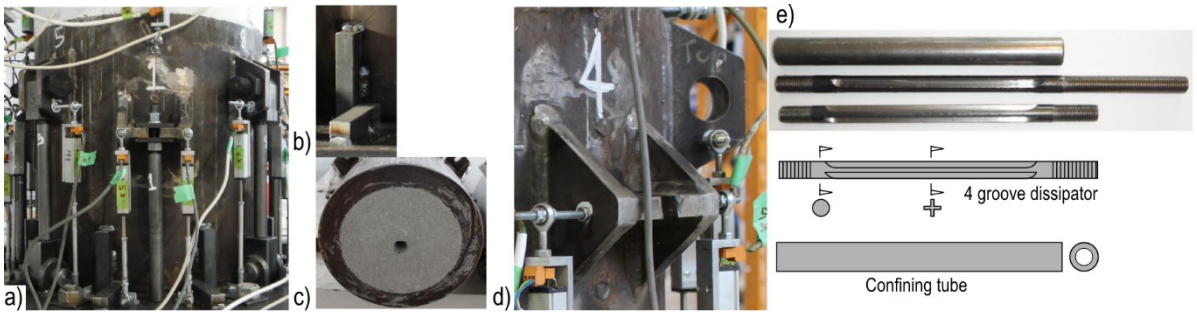

Figure 12: a) Pier with all dissipators attached; **b)** Shear and torsion keys; **c)** Pier base rocking interface; **d)** Dissipator bracket detail, pinned dissipator bracket in background; **e)** Groove type dissipator and confining tube.

At zero lateral pier displacement, the pin in the slotted hole is designed to sit at the top of the slot. Then as the pier uplifts, the dissipator bracket with slotted hole moves upwards and relative to this the pin approaches the bottom of the slot. Only when the uplift is sufficient for the pin to engage with the bottom of the slot, is the dissipator pulled upon. This option for producing hierarchical activation was chosen for three reasons: the pins allow the dissipator to be pulled on axially, despite, the arced uplift movement of the pier; the slotted hole allows the dissipator to undergo compression once it has been extended, whilst, also providing vertical and horizontal restraint of the dissipator ends; and this option was reasonably practical to implement, along with the spent dissipators being accessible for replacement.

5.3 Specimen design

In terms of seismic action design parameters, the prototype was assumed to be of importance level 2; sited in Christchurch, with a hazard factor of 0.3; constructed on non-liquefiable soil of class C; and not subject to near fault effects. Seismic design was only conducted in the transverse direction due to this direction of loading being the governing load case for the pier. Displacement based design was used to determine the seismic design parameters for the prototype pier which were then scaled for specimen design. Table 1 below summarizes the salient pier seismic design parameters calculated.

Table 1: Summary of specimen seismic design parameters from displacement based design.

Specimen ULS design actions and dimensions	**Units**	**Value**
Design gravity load, W_{scaled}	kN	195
Design lateral load, V_{scaled}	kN	42.9
Effective height of equivalent SDOF, $H_{e,\ scaled}$	mm	2550
Pier diameter, D_{scaled}	mm	500

5.4 Test setup and loading regime

The test set up consisted of a single 300kN ram, loading the bridge transversely at the cap beam level 2310mm above the base of the pier (Fig. 13). The position and direction of loading were chosen to simulate transverse seismic loading of the bridge and to allow later pier only tests to be conducted. Loading of the bridge was cyclic, displacement controlled, and quasi-static. The loading protocol used for testing was derived from ACI T1.1-01 [30]: three fully reversed cycles are applied at each drift ratio; the first drift ratio is within the linear elastic

response range; subsequent drift ratios are between 1.25 and 1.5 times the previous value. Lateral drifts of 0.1%, 0.125%, 0.175%, 0.25%, 0.35%, 0.5%, 0.75%, 1.0%, 1.5%, 2.0% 2.75% 3.5%, and 4.5% were imposed. However, only during testing of the pier in isolation were all of the drift ratios imposed. During bridge testing, the maximum applied drift ratio was 2.75% due to safety reasons and the load capacity of the ram to cap beam loading attachment.

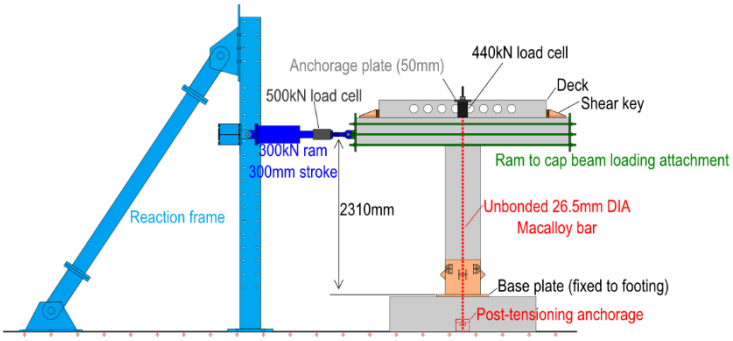

Figure 13: Experimental test set up showing that the bridge was loaded by a single ram at the cap beam level

5.5 Testing schedule

The bridge and pier only test configurations relevant for comparing the performance of DCR and MDCR are summarized in Table 2 below.

Table 2: Selected bridge and pier test schedules. No deck post-tensioning or deck dissipators were used in tests 1,3 and 4.

Test	Pier post-tensioning kN	Conventional pier dissipators	Pinned dissipators
1: Bridge, no pier dissipators	89.2	-	-
3: Bridge, 8 pier dissipators (MDCR)	91.37	4	4
4: Bridge, 4 pier dissipators (PRESSS)	92.3	4	0
12: Pier only (decks removed), $\lambda(\theta=2\%)$ =1.33	154.7	4	0
13: Pier only (decks removed), $\lambda(\theta=2\%)$ =0.75	155.3	4	4

5.6 Experimental results and analysis

In the very first test of the bridge system (Test 1), energy dissipation was found to be significant despite the source only being from friction (Fig. 14a). The self-centering characteristic of the pier combined with the frictional hysteresis produced a flag shaped response. The addition of 4 dissipators in Test 4 so the pier would be in a conventional PRESSS hybrid configuration increased both the stiffness and damping of the entire system (Fig. 14a). In Test 3, the bridge was tested with the pier utilising hierarchical activation. However, due to the activation drift being just over 2% and the maximum drift applied being 2.75% the contribution made was small (Fig. 14a). In tests 3 and 4 no failure of the dissipators occurred.

Testing of the pier in isolation, allowed the full effect of hierarchical activation (Test 13) to be observed (Fig. 14b). Compared to the conventional PRESSS arrangement (Test 12), the activation of the second set of dissipators increased the amount of energy able to dissipated (Fig. 15) in addition to the pier stiffness. In test 12, during unloading from the peak positive displacement of the second cycle at 3.5% drift, failure of one dissipator on the extreme tension side of

the pier occurred. The dissipator failed due to shear failure of the dissipator threads engaged with the nut below the dissipator bracket. This caused that particular dissipator to work in tension only for the following load cycles resulting in pinching of the hysteresis loops.

Further evaluation of the changes in damping between tests 12 and 13 was undertaken through evaluation and comparison of the area based hysteretic damping from these two tests (Fig. 16a).The area based hysteretic damping was computed using equation 1. Where: ED is the area enclosed in one cycle of a hysteresis loop; F_{pp} and F_{pn} are the signed peak positive and negative forces measured during that cycle; U_{pp} and U_{pn} are the signed peak positive and negative displacements for the same cycle; K_{eff}, is the effective secant stiffness; and U_o is the average peak displacement.

$$\xi_A = \frac{ED}{2\pi K_{eff} U_o^2} \quad where, \quad K_{eff} = \frac{F_{PP}-F_{PN}}{U_{PP}-U_{pn}} \; and \; U_o = \frac{U_{pp}-U_{pn}}{2} \tag{1}$$

Figure 16a compares the area based damping averaged over the repeated cycles for each drift level for tests 12 (conventional PRESSS) and 13 (MDCR). It can be seen that past a drift of 1.5% for test 13, that the hysteretic damping is less than that for test 12 until failure of the thread on one dissipator occurred. This reduced hysteretic damping can be explained as follows: because the experiment was displacement controlled U_o is very much the same for both tests 12 and 13, therefore, comparing the difference between the two tests in terms of the area based damping is effectively the average ratio of the energy dissipated per cycle (ED) to the effective stiffness K_{eff}. Although, ED for test 13 is larger than the corresponding cycle in test 12 once activation occurs (Fig. 15), this increase in ED is not as large as the increase in Keff therefore resulting in a reduced value of area based damping when compared to test 12. The implications of this reduced area based hysteretic damping combined with increased secant stiffness with respect to transient seismic response is currently unknown and further work will be conducted to numerically assess such impacts.

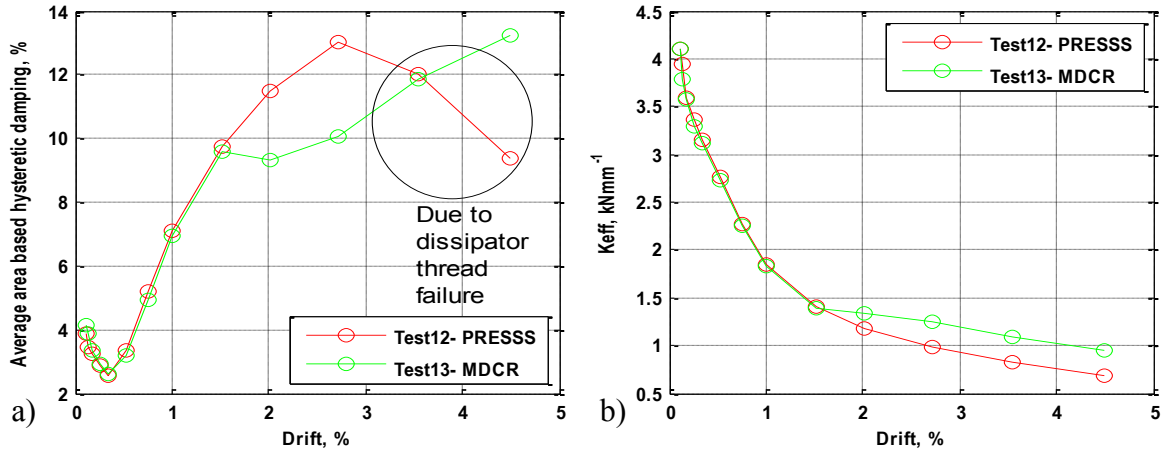

Figure 16: a) Comparison of the average corrected hysteretic damping for tests 12 and 13 as a function of ductility. **b)** Average effective stiffness for each drift level of tests 12 and 13. Activation of the second set of dissipators increases the effective stiffness.

6 CONCLUSION

In conclusion, a brief literature review was given outlining the family of rocking structures and their relation to one another. The literature review showed the progressive development and changes of rocking structures with time. The distinction in dynamic behaviour between free rocking, controlled rocking, and DCR was shown through the results of preliminary numerical analysis in OpenSees. A possible future evolution of PRESSS hybrid rocking was suggested in the form of hierarchical activation (MDCR) and description of this new design strategy given. Finally, results from experimental testing, focussing, on the comparison of DCR against MDCR were given. The results prove the concept of MDCR, however, the unexpected effect on area based hysteretic damping will require further investigation to ascertain whether this is detrimental to transient response.

Keywords: rocking bridges, flag-shaped hysteretic behavior, self-centering, prestressed tendons.

Abstract. *Allowing structural members to uplift and rotate around pre-defined pivot points isolates and relieves the structure from deformation and damage during strong earthquakes. Such rocking behavior has been examined as damage avoidance seismic design for bridges. Rocking structures, either freestanding or hybrid (supplemented with energy dissipation and re-centering devices), have been proposed by several researchers as high-performance systems that can survive major earthquakes without substantial damage. This paper investigates, analytically and numerically, the seismic performance of a hybrid rocking bridge bent which exhibits flag-shaped hysteretic behavior. The rocking frame is enhanced with elastic prestressed central tendons to provide re-centering capacity and hysteretic buckling restrained braces to dissipate energy. The present study examines its seismic behavior under both pulse-type and non-pulse-type ground motions. The focus of the present analysis is on the role of the prestressing force on the seismic performance. The results reveal the diverse influence of prestress. Specifically, prestress is beneficial for small rocking rotations, but could become detrimental when the frame sustains large rotations and as the size of the columns increases. Finally, the results reveal the sensitivity of the different rocking design solutions to the characteristics of the considered ground motion. As a consequence, none of the examined rocking frames can be considered as the optimal design solution under all ground motions.*

1 INTRODUCTION

Rocking as a means of seismic isolation is attracting the interest of researchers for almost a century (see [18, 16, 29, 6, 13, 9, 10, 30, 8, 39, 34] and references therein). Recently, there is an increasing need to examine the dynamics of progressively more complicated and realistic structures ([1, 2, 40, 38] among others). Of particular interest for bridge engineering is the rocking frame configuration of Fig. 1 proposed originally by [22] as a "damage avoidance design" for bridges. The existing bridges designed to rock remain scarce (see [11] and references therein), even though, an increasing number of studies illustrate their high seismic performance. In particular, [7, 33, 35, 36] revealed that rocking piers can exhibit large drifts (around 6% to 10%) with minor damage and/or residual displacements. Recent experimental studies [37, 27] showed that the residual drifts of posttensioned rocking columns are negligible (0.4%) compared to the pertinent drifts of conventional monolithic columns (6.8%) with the same peak drift ratios; in accordance with [32]. Further, [19, 20] showed that the stability of the rigid rocking frame is enhanced, the more heavy its cap-beam is, regardless of the rise of its center of mass; a counter-intuitive behavior.

Such self-centering systems aim to eliminate residual drifts after strong earthquakes. Many researchers [25, 26, 28, 23, 17, 43] combine the use of additional re-centering with energy dissipation devices, to propose "hybrid rocking systems" which exhibit flag-shaped hysteretic behavior (FSHB). In this context [26, 23, 17] compared numerically and experimentally the seismic performance of rocking versus conventionally designed monolithic piers. The rocking piers showed higher self-centering capacity and lower residual displacements compared to the monolithic solution. [11] examined a hybrid rocking frame with asymmetric configuration (with columns unequal in height), and compared its stability with the pertinent symmetric configuration. That study unveiled the marginal influence of the asymmetry on the stability despite the very different kinematics between the two configurations. Building on previous work on hybrid rocking structures [17, 21, 11], the present work investigates the effect of the prestressing force on the seismic performance of hybrid FSHB rocking frames, and compares different rocking design solutions.

2 ANALYTICAL MODELLING

This section examines (analytically) a rocking bridge bent which exhibits flag-shaped hysteretic behavior. The present study considers structures designed to exhibit planar rocking and it assumes no sliding between the contacting bodies takes place [5]. Consider the rocking frame of Fig. 1 enhanced with central (linear-elastic) prestressed tendons and (nonlinear-hysteretic) buckling restrained braces (BRBs) at the bottom of the piers. Note that, this study ignores the fracture of the tendons and the dissipaters, which is discussed in [11]. To describe the hysteretic behavior of the BRBs, the Bouc-Wen model [4, 42] is adopted. The restoring dissipating force is expressed as:

$$F_D = \varepsilon k_d u\left(t\right) + \left(1-\varepsilon\right) k_d u_y z\left(t\right) \tag{1}$$

where ε is the post-yield to pre-yield elastic stiffness (k_d) ratio, $u\left(t\right)$ is the axial deformation of the brace, u_y is the yield displacement equal with $u_y = 4b\sin\left(\phi_y/2\right)$ with $2b$ the width of the base of the column of the frame and ϕ_y the yield rotation (Fig. 1). $z\left(t\right)$ is a dimensionless hysteretic parameter that is governed by:

$$\dot{z}(t) = \frac{1}{u_y}\left[\dot{u}(t) - \gamma\left|\dot{u}(t)\right| z\cdot\left|z\right|^{n-1} - \beta\dot{u}(t)\left|z\right|^{n}\right] \tag{2}$$

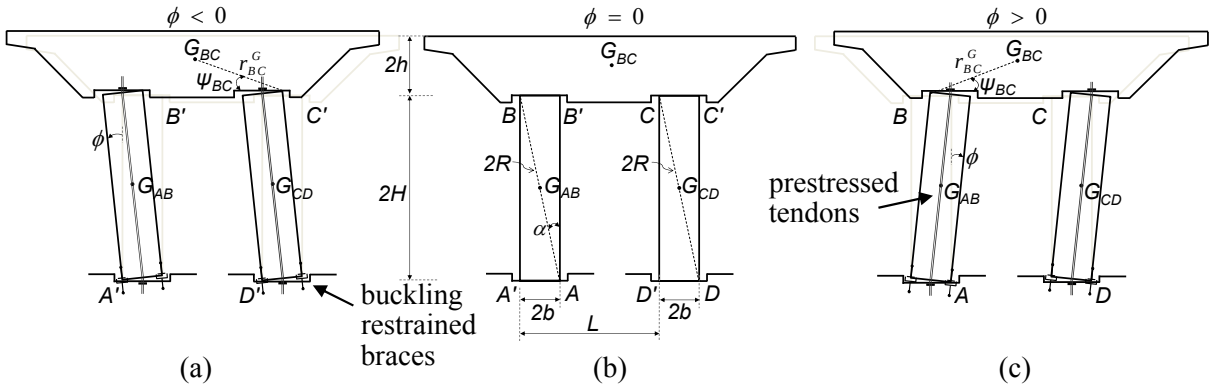

Figure 1: The examined hybrid rocking bridge bent (a) during counter-clockwise rotation, (b) at rest position and (c) during clockwise rotation.

Parameters β, γ and n control the shape of the hysteretic loop. Following [3], $\beta = 0.55$, $\gamma = 0.45$, $n = 1$, $\varepsilon = 0.025$ and $u_y = 3.5\,mm$.

2.1 Flag-shaped hysteretic behavior (FSHB)

Assuming positive (clockwise) rotations, the restoring moment offered by the weight of the two columns and the cap-beam is equal with:

$$\frac{M_R^{gr}}{2\left(m_{AB}+m_{BC}\right)gR} = \sin\left(\alpha-\phi\right) \tag{3}$$

where m_{AB} and m_{BC} are the masses of the column AB and the cap-beam BC respectively, R is the half diagonal of the column of the frame, g is the gravitational acceleration, and α is the slenderness of the column. ϕ is the generalized coordinate which describes the rocking motion of the frame (Fig. 1). The additional re-centering and energy dissipation devices offer a total restoring moment M_R^{hyb}:

$$\begin{aligned}\frac{M_R^{hyb}}{2(m_{AB}+m_{BC})gR} &= 4\left(\rho_t+\varepsilon\rho_d\right)\sin\phi + 2\sin\alpha p_{str}\cos\tfrac{\phi}{2} \\ &+8\left(1-\varepsilon\right)\rho_d\sin\tfrac{\phi_y}{2}\cos\tfrac{\phi}{2}z(t)\end{aligned} \tag{4}$$

The dimensionless parameters ρ_d, ρ_t and p_{str} control the stiffness of the dissipaters k_d, of the tendons k_t and the initial prestressing force P_0 respectively:

$$\rho_d = \frac{k_d b^2}{\left(m_{AB}+m_{BC}\right)gR},\quad \rho_t = \frac{k_t b^2}{\left(m_{AB}+m_{BC}\right)gR},\quad p_{str} = \frac{P_0}{\left(m_{AB}+m_{BC}\right)g} \tag{5}$$

The present study assumes that the design parameters ρ_d, ρ_t and p_{str} vary within $0 \le \rho_d \le 5.0$, $0 \le \rho_t \le 0.7$ and $0 \le p_{str} \le 0.1$ respectively. The total restoring moment becomes:

$$\begin{aligned}\frac{M_R}{2(m_{AB}+m_{BC})gR} &= \sin\left(\alpha-\phi\right) + 4\left(\rho_t+\varepsilon\rho_d\right)\sin\phi + 2\sin\alpha p_{str}\cos\tfrac{\phi}{2} \\ &+8\left(1-\varepsilon\right)\rho_d\sin\tfrac{\phi_y}{2}\cos\tfrac{\phi}{2}z(t)\end{aligned} \tag{6}$$

On the other hand, the overturning moment induced by the ground excitation ($\ddot{u}_g$) becomes:

$$\frac{M_{OT}}{2\left(m_{AB}+m_{BC}\right)\ddot{u}_g R} = \cos\left(\alpha-\phi\right) \tag{7}$$

Rocking initiates when the overturning moment of Eq. (7) becomes equal with the total restoring moment of Eq. (6). This equality yields the minimum ground acceleration necessary for rocking initiation:

$$\ddot{u}_{g,\min} = g \tan\alpha \, (1 + 2p_{str}) \tag{8}$$

Eq. (8) shows that increase of the prestressing force, causes increase in the ground acceleration necessary to initiate rocking. During rocking, the motion of the frame is interrupted by non-smooth impacts. At each impact, a part of the total kinetic energy is lost and the frame continues its motion with a ratio between the angular velocity after and before the impact (coefficient of restitution) equal with [11]:

$$\eta = \frac{\dot{\phi}^{+}}{\dot{\phi}^{-}} = \frac{1 - \frac{3}{2}\sin^2\alpha + 3\gamma_m \cos 2\alpha}{1 + 3\gamma_m} \tag{9}$$

The present study assumes the coefficient of restitution η to be 0.92.

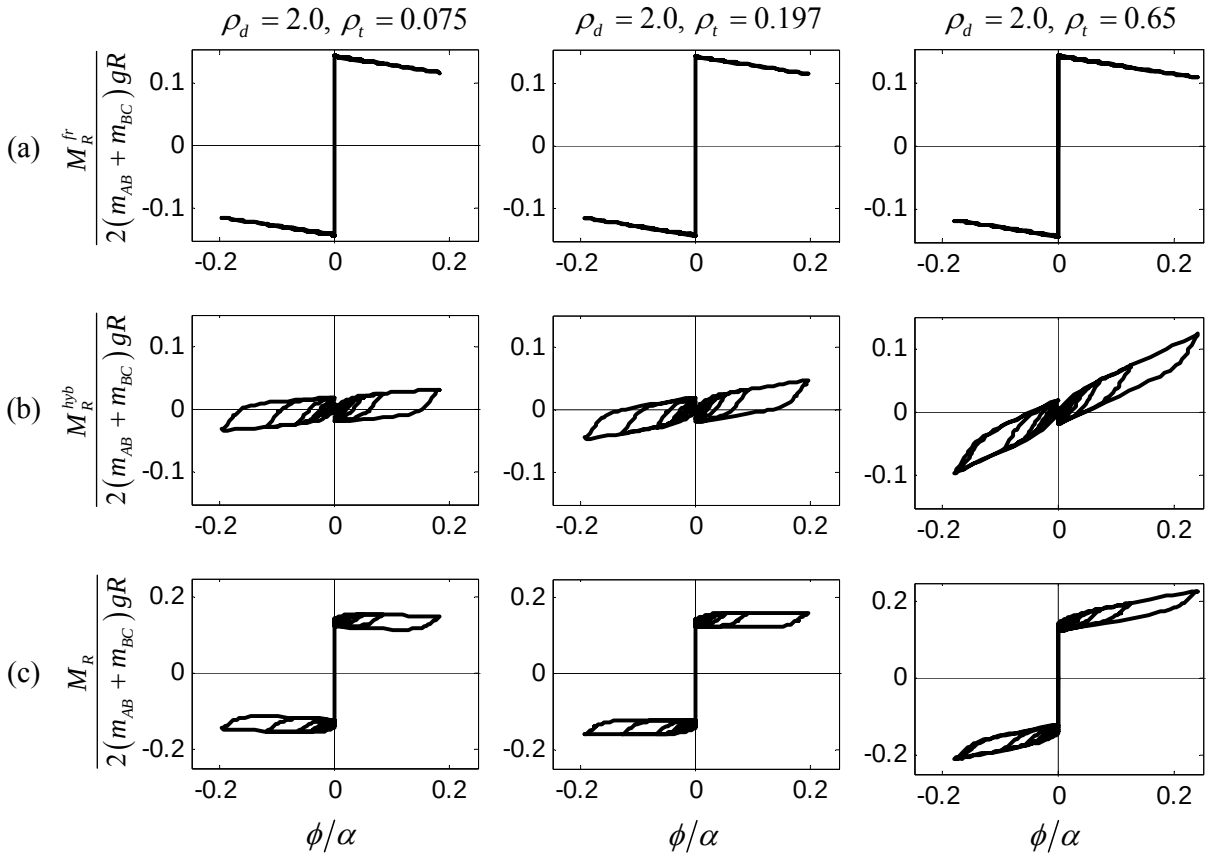

Figure 2: Restoring moments due to (a) gravitational forces, (b) the presence of tendon and dissipater and (c) total restoring moment for the rocking frame subjected to M&P pulse with $\nu_g = 45°$, $\gamma_g = 2.0$, $\alpha_g = 0.6g$ and $\omega_g = 6.09\, rad/s$.

The moment-rotation relationship follows the curves shown in Fig. 2. Observe that, the restoring moment due to the gravitational forces of the columns and the cap-beam do not enclose any area under the moment-rotation curve (Fig. 2(a)) since energy is dissipated only during impact. The presence of buckling restrained braces provides additional energy dissipation, equal with the enclosed area in Fig. 2(b). When tendons and dissipaters are combined, the hysteretic

behavior of the rocking bridge bent becomes flag-shaped (Fig. 2(c)). Note that, increase in the tendon's and the dissipater's stiffness causes increase in the overall lateral stiffness of the structure. For positive stiffness systems, it holds:

$$\rho_t + \varepsilon\rho_d > \frac{1}{4} \tag{10}$$

2.2 Equation of motion (EOM)

Fig. 1 illustrates the examined hybrid FSHB rocking frame. The equation of motion is derived using Lagrange's equation:

$$\frac{d}{dt}\left(\frac{\partial L}{\partial \dot{\phi}}\right) - \frac{\partial L}{\partial \phi} = Q \tag{11}$$

where $L = T - V$, with T the kinetic energy, V the potential energy and Q the generalized force. The kinetic energy of the system is:

$$\begin{aligned} T = I_{AB}^{pivot}\dot{\phi}^2 + m_{AB}\left[\dot{u}_g^2 + 2\dot{u}_g R\cos\left(\alpha \mp \phi\right)\dot{\phi}\right] \\ +\tfrac{1}{2}m_{BC}\left[\dot{u}_g^2 + 4R^2\dot{\phi}^2 + 4R\dot{u}_g\cos\left(\alpha \mp \phi\right)\dot{\phi}\right] \end{aligned} \tag{12}$$

where I_{AB}^{pivot} is the mass moment of inertia of the AB column with respect to the pivot point. For a rectangular column is equal with $I_{AB}^{pivot} = (4/3)\, m_{AB}R^2$. The double sign in Eq. (12) and throughout the present study denotes the sign of rotation. In particular, the upper sign corresponds to clockwise (positive) rotations and the bottom to counter-clockwise (negative) rotations.

The potential energy of the hybrid FSHB rocking frame is defined as a contribution from the gravitational and the elastic forces from the tendons. Before rocking starts, the initial prestressing force (P_0) induces an initial elongation (δl_0) to the tendon equal with $\delta l_0 = P_0/k_t$, where $k_t = EA/l$ is the elastic stiffness of the tendon with E being the Young's modulus, A the cross-sectional area and l the length of each tendon. During rocking, each tendon deforms. The elongation of each tendon is equal to the sum of the elongations at the base and the top of each tendon: $\delta l = 4b\sin\left(\phi/2\right)$. Hence, the total elongation of each tendon is $\Delta l = \delta l + \delta l_0$. Therefore, the potential energy of the hybrid FSHB rocking frame takes the form:

$$V = 2m_{AB}gR\cos\left(\alpha - \phi\right) + m_{BC}g\left[2R\cos\left(\alpha - \phi\right) + r_{BC}^{G}\sin\psi_{BC}\right] + k_t\left(4b\sin\frac{\phi}{2} + \frac{P_0}{k_t}\right)^2 \tag{13}$$

where r_{BC}^{G} is the distance from the pivot point B (or C') to the center of mass G_{BC} and the angle ψ_{BC} is shown in Fig. 1.

The calculation of the non-conservative forces Q is based on the virtual work principle $\delta W_D = Q\delta\phi$ and yields:

$$Q = -4b\cos\frac{\phi}{2}\left[\varepsilon k_d u\left(t\right) + \left(1-\varepsilon\right)k_d u_y z\left(t\right)\right] \tag{14}$$

Therefore, Eq. (11) gives:

$$\ddot{\phi} = -\frac{1+2\gamma_m}{1+3\gamma_m}p^2\left[\begin{array}{l} \sin\left(\alpha\mathrm{sgn}\left(\phi\right) - \phi\right) + \frac{\ddot{u}_g}{g}\cos\left(\alpha\mathrm{sgn}\left(\phi\right) - \phi\right) + 4\left(\rho_t + \varepsilon\rho_d\right)\sin\phi \\ +2\sin\alpha p_{str}\cos\frac{\phi}{2} + 8\left(1-\varepsilon\right)\rho_d\sin\frac{\phi_y}{2}\cos\frac{\phi}{2}z\left(t\right) \end{array}\right] \tag{15}$$

where p is the frequency parameter of the column of the frame, which for rectangular columns becomes $p = \sqrt{3g/4R}$. $\mathrm{sgn}(\phi)$ is the sign function and $\gamma_m = m_{BC}/2m_{AB}$ is the mass ratio. Ignoring the presence of the dissipater and of the prestressing force, Eq. (15) verifies the equation of motion of the symmetric rocking frame enhanced with slack (unbonded) central tendons [14], and for $\gamma_m = 0$ the pertinent equation of motion of the anchored rocking block [10].

3 SEISMIC PERFORMANCE OF THE HYBRID FSHB ROCKING BRIDGE BENT

This section examines the seismic response of the planar (freestanding and hybrid FSHB) rocking bent of Fig. 1. Consider a cap-beam 13 m wide with height $2h$ = 2 m. Assume a two-(square)-column frame with $2b$ = 1.4 m base width, same density and height $2H$ = 9.8 m each. Both columns have the same slenderness $\alpha = 8.1^\circ$ and frequency parameter $p = 1.22\ rad/s$, while the distance L is 8 m. The cap-beam/column mass ratio (γ_m) is taken as 5. The yield displacement (u_y) of the braces is assumed 3.5 mm [3], which corresponds to a yield rotation $\phi_y/\alpha = 0.018$. The present section focuses on the influence of the prestressing force on the seismic performance of the hybrid FSHB frame, while it ignores the deformation of its structural members.

3.1 Pulse-type ground motions

This study considers first pulse-type ground motions to examine the seismic performance of the hybrid FSHB rocking frame. Various mathematical expressions have been proposed in the literature that can capture the long distinct pulses of near-fault ground excitations ([41] among others). The present study adopts the Mavroeidis and Papageorgiou (M&P) [24] wavelet according to which the frequency of the pulse (ω_g), the acceleration amplitude (α_g), the number (γ_g) and the phase angle (ν_g) of half cycles are the four parameters which can idealize a wide range of near-fault ground excitations. Eq. (16) provides the expression for the ground velocity of the M&P pulse [24] with parameter A to control the velocity amplitude of the envelope of the signal.

$$\dot{u}_g(t) = \begin{cases} \frac{A}{2}\left[1+\cos\left(\frac{\omega_g}{\gamma_g}(t-t_0)\right)\right]\cos\left[\omega_p(t-t_0)+\nu_g\right], & t_0 - \frac{\pi\gamma_g}{\omega_g} \le t \le t_0 + \frac{\pi\gamma_g}{\omega_g} \\ 0 \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad , & otherwise \end{cases} \tag{16}$$

This analysis compares the seismic performance of the freestanding and the hybrid FSHB rocking bridge bent focusing on the influence of the prestressing force. In other words, the study examines structural systems with fundamentally different behavior (i.e. negative, zero and positive post-uplift lateral stiffness) under two levels of the rocking rotation, (i) for small "safe" rotations $\phi/\alpha = 0.1$ and (ii) large "critical" rotations $\phi/\alpha = 1.0$. Recall that, $\phi/\alpha = 1.0$ represents the "critical" rotation under which the freestanding frame is considered to become unstable. In the hybrid FSHB frame the "critical" rotation increases due to the presence of the tendons and the braces. The exact "critical" rotation (ϕ_{cr}) is given by the solution of the nonlinear equation:

$$\left.\frac{\partial V_{tot}}{\partial \phi}\right|_{\phi=\phi_{cr}} = 0 \tag{17}$$

Contrary to Eq. (13), in Eq. (17) the potential energy accounts also for the presence of the braces by simplifying their behavior from nonlinear hysteretic to bilinear elastic. Thus, the total

potential energy of the system becomes [15]:

$$V_{tot} = 2m_{AB}gR\cos(\alpha-\phi) + m_{BC}g\left[2R\cos(\alpha-\phi) + r_{BC}^{G}\sin\psi_{BC}\right] \\ +k_t\left(4b\sin\tfrac{\phi}{2} + \tfrac{P_0}{k_t}\right)^2 + 16(1-\varepsilon)k_d b^2\sin\tfrac{\phi_y}{2}\sin\tfrac{\phi}{2} + 8\varepsilon k_d b^2\sin^2\tfrac{\phi}{2} \tag{18}$$

Therefore, Eq. (17) gives:

$$\sin(\alpha-\phi_{cr}) + 4\rho_t\sin\phi_{cr} + 2\varepsilon\rho_d\sin\phi_{cr} + 4(1-\varepsilon)\rho_d\sin\frac{\phi_y}{2}\cos\frac{\phi_{cr}}{2} + \frac{2b}{R}p_{str}\cos\frac{\phi_{cr}}{2} = 0 \tag{19}$$

Eq. (19) provides the "critical" rotation of hybrid FSHB rocking bridge bents for various values of the (dimensionless) design parameters ρ_d, ρ_t and p_{str}. The combination of the design parameters ρ_t and ρ_d, yield structural systems with (i) tendons flexible enough, such that the frame maintains its negative stiffness, (ii) zero overall stiffness and (iii) stiffer tendons so that the rocking frame exhibits positive post-uplift lateral stiffness. Recall that, the fracture of the tendons and braces is ignored, hence hybrid rocking frames with zero or positive lateral stiffness theoretically will not overturn.

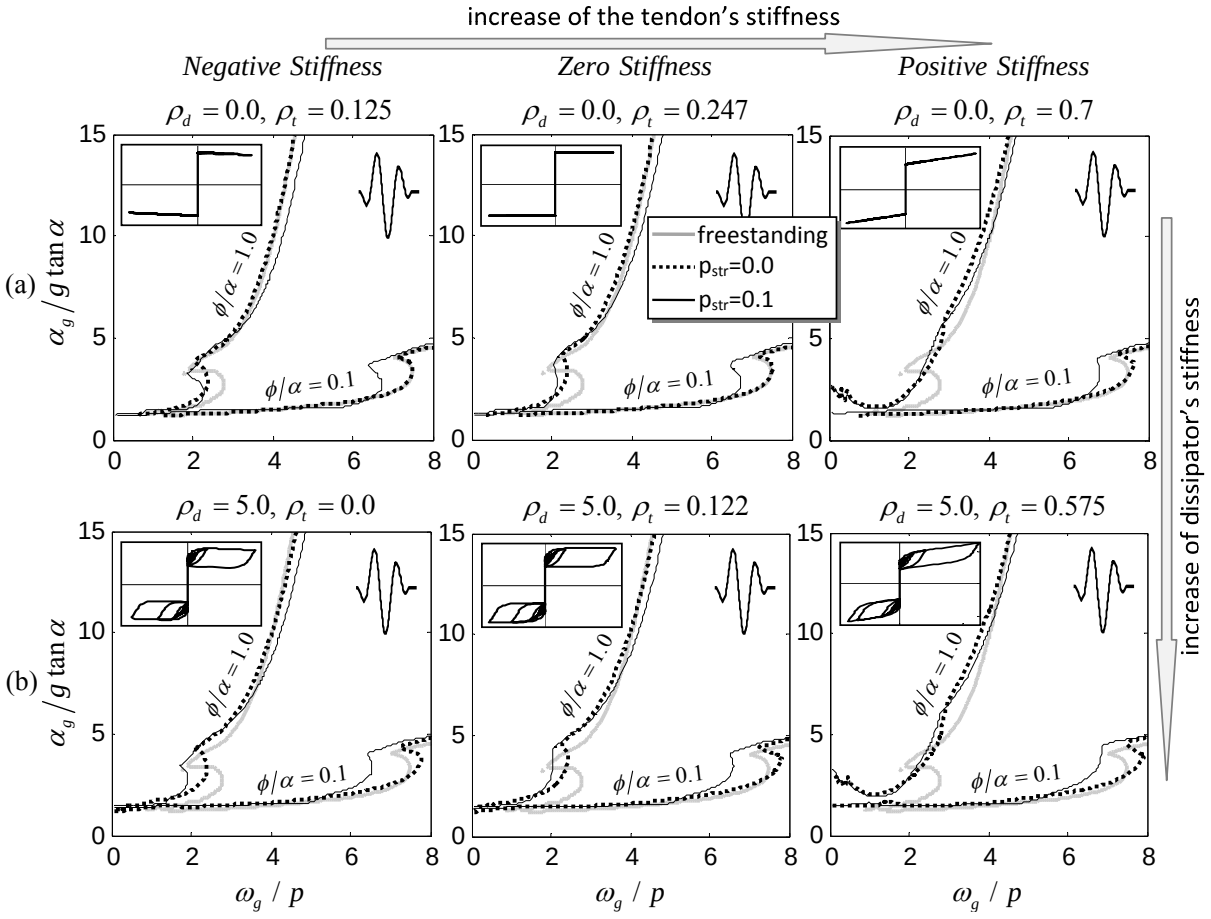

Figure 3: Seismic performance of the rocking bridge bent subjected to M&P pulse with $\nu_g = 45°$, $\gamma_g = 2.0$ for different levels of prestress and for the following dissipation parameters (a) $\rho_d = 0.0$ and (b) $\rho_d = 5.0$.

Fig. 3 compares rocking frames with negative, zero and positive post-uplift lateral stiffness under pulse-type ground motions. Fig. 3 unveils the diverse role of the prestressing force on

the seismic performance of the hybrid FSHB rocking frame. In particular, for large rocking rotations ($\phi/\alpha = 1.0$) and as the size of the columns increases ($\omega_g/p > 3$), the prestressing force has negative effect on the stability of the frame; the lower the prestress the higher the seismic stability. This is true regardless of the sign of the lateral stiffness, but more pronounced to negative stiffness systems. Overall for large rocking rotations, both the freestanding and the hybrid with zero prestressing force exhibit the highest seismic rotation. On the contrary, for either small-sized rocking columns ($\omega_g/p < 3$) and large rotations ($\phi/\alpha = 1.0$) or large rocking columns ($\omega_g/p > 6$) and small rotations ($\phi/\alpha = 0.1$), the prestressing force has beneficial influence on the performance.

Further, note that each column of Fig. 3 considers frames with the same (negative, zero, or positive) lateral stiffness. The ρ_d increase effect is slightly favorable regardless of the sign of the overall stiffness. In addition, increasing the stiffness of the tendons (i.e. increasing ρ_t), the overall lateral stiffness of the system increases. However, Fig. 3 shows that this increase doesn't lead to superior seismic performance (e.g. Fig. 3(a)).

3.2 Historic excitations

The present section examines the seismic response of the hybrid FSHB rocking frame to historic ground motions, regardless of whether they contain distinguishable pulses or not. It employs a well-known set of historic ground motions scaled to yield a probability of exceedance of 2% in 50 years [31].

Number	Record	Magnitude	Scale factor	dt(s)	Duration(s)	PGA(cm/s^2)

Table 1: Earthquake records with probability of exceedance of 2% in 50 years (adapted from [31].

Figs 4, 5 compare the response of the examined rocking frames in terms of peak rotation and time history analysis respectively. Both Figs 4, 5 verify the high seismic performance of the examined rocking frames, since all of them survive the excitations even though the earthquake records are scaled to the maximum credible earthquake level. Note that, according to the assumptions of the present analysis, when the structure survives the excitation, it eventually re-centers with no permanent displacement and/or expected damage. In particular, Fig. 4 confirms the influence of the prestressing force on the seismic behavior. Prestressing the tendons

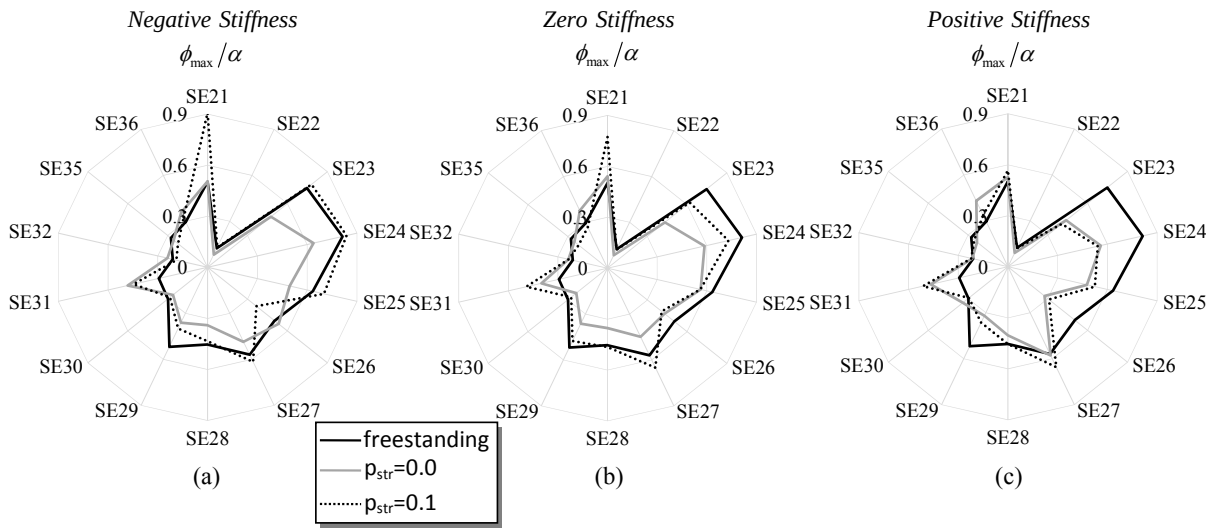

Figure 4: Maximum rotations for the freestanding and hybrid FSHB rocking bridge bent with (a) negative ($\rho_t = 0.075$), (b) zero ($\rho_t = 0.197$), (c) positive ($\rho_t = 0.65$) stiffness, $\rho_d = 2.0$ and different levels of prestress.

deteriorates the seismic performance of the hybrid FSHB rocking frame regardless of the sign of the overall stiffness. This degrading effect becomes even more pronounced on negative stiffness systems when the frame sustains large rocking rotations (see for instance $SE21$, $SE23$, $SE24$ $SE25$, $SE27$ in Figs 4(a), 5). In that cases, both the freestanding and the hybrid frame with slack tendons ($p_{str} = 0$) outperform the hybrid FSHB with $p_{str} = 0.1$. On the contrary, when the frame undergoes small rotations, the prestressing force has indeed beneficial effect (e.g. $SE30$, $SE32$, $SE35$, $SE36$ in Figs 4(a), 5).

Further, Fig. 4 shows that increase of the stiffness of the structure (i.e. from negative to positive) has beneficial effect on the seismic performance of the hybrid FSHB without however changing the effect of the prestress, which remains detrimental regardless of the sign of the lateral stiffness. This (slight) enhancement though, comes at the cost of higher energy demands by the buckling restrained braces (as Fig. 6 shows). Specifically, Fig. 6 compares hybrid FSHB rocking frames with negative, zero and positive overall lateral stiffness, in terms of the net dissipated hysteretic energy. Fig. 6 shows that negative stiffness systems yield the lowest energy demands. This is attributed to the fact that a negative stiffness system cannot resonate (in a classical sense). Overall, positive stiffness systems exhibit the highest energy needs. In other words, the rocking rotation mitigation due to the increased stiffness, comes at the cost of higher energy demands by the dissipaters. Fig. 6 shows that increase of the prestress does not lead to higher energy demands, since for most records the energy dissipated by the braces is slightly lower for prestressed hybrid FSHB frames ($p_{str} \neq 0$) than for slack hybrid FSHB frames ($p_{str} = 0$).

In summary Figs. 3, 4, 5 and 6 show that depending on the characteristics of the examined earthquake record, a different rocking design solution (i.e. freestanding or hybrid with negative, zero, or positive post-uplift lateral stiffness) might yield the optimal rocking design solution in terms of seismic performance. Therefore, the assessment of the seismic performance of hybrid FSHB rocking bridge bents beckons for a probabilistic evaluation [12], which is not however the scope of the present study.

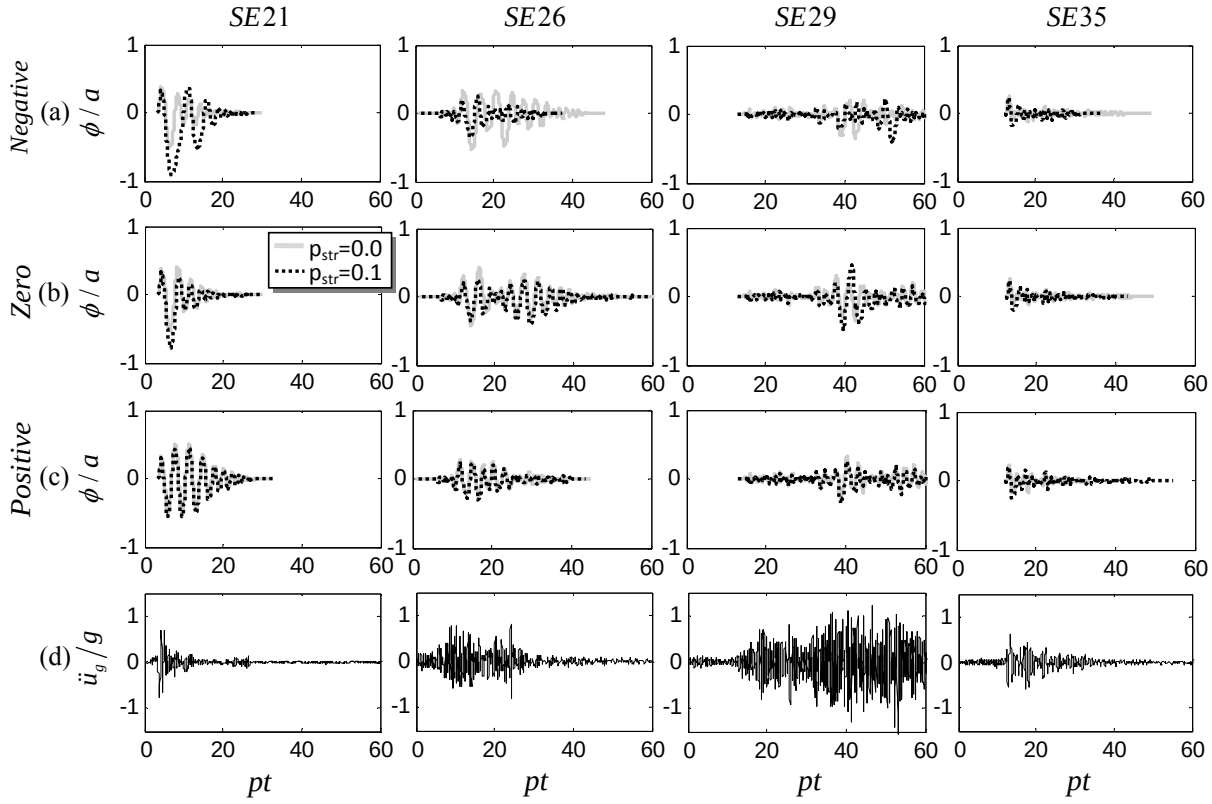

Figure 5: Time history analysis for the hybrid FSHB rocking bridge bent with (a) negative ($\rho_t = 0.075$), (b) zero ($\rho_t = 0.197$), (c) positive ($\rho_t = 0.65$) stiffness, $\rho_d = 2.0$ and different levels of prestress.

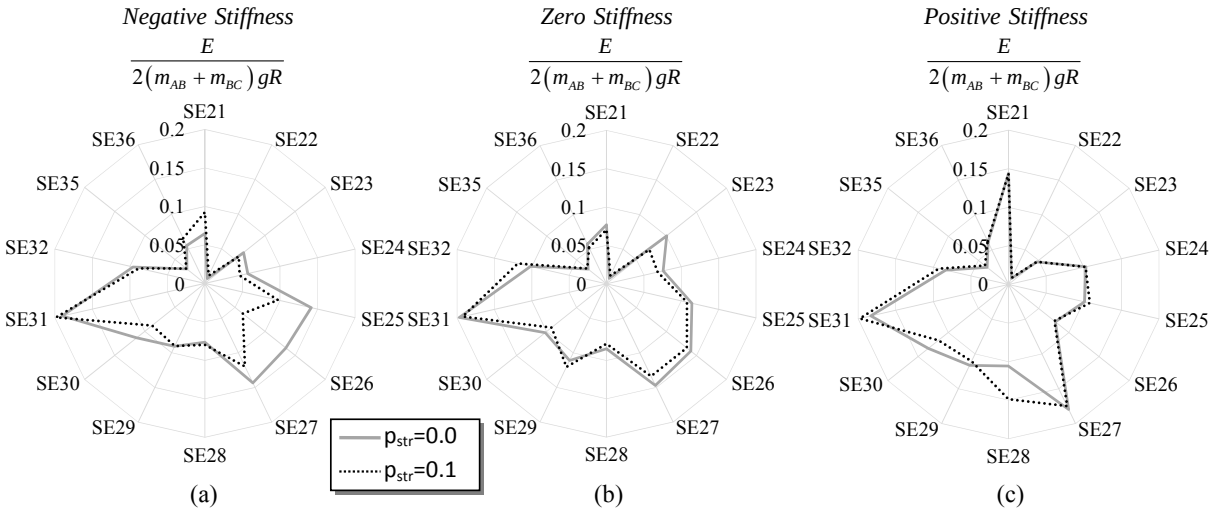

Figure 6: Net dissipated energy for the hybrid FSHB rocking bridge bent with (a) negative ($\rho_t = 0.075$), (b) zero ($\rho_t = 0.197$), (c) positive ($\rho_t = 0.65$) stiffness $\rho_d = 2.0$ and different levels of prestress.

4 CONCLUSIONS

This study investigates the seismic performance of planar freestanding and hybrid rocking frames with flag-shaped hysteretic behavior. This work demonstrates the diverse role of the prestressing force on the performance of the hybrid FSHB rocking bents. Prestressing the tendons deteriorates the frame's seismic performance when it sustains large rocking rotations and as the size of the columns increases; a counter-intuitive conclusion. On the contrary, either for small-sized rocking columns and large rocking rotations or for large-sized rocking columns and small rocking rotations, the influence of the prestress becomes beneficial in restoring the frame. The analysis also confirms the beneficial influence of the dissipater, which is more pronounced for negative stiffness rocking frames. Increasing the overall stiffness, the seismic performance of the frame is slightly enhanced at the expense, however, of higher energy demands by the dissipaters. This is not the case for the prestressing force, since increasing the prestress does not lead to higher energy demands. Finally, this work confirms the sensitivity of the examined rocking frames (freestanding and hybrid FSHB) to the characteristics of the adopted earthquake records, and that none of the rocking design solutions examined is optimal in all cases.

Keywords: rocking, nonsmooth dynamics, linear complementarity problem, impact, flexible rocking structures.

Abstract. *Rocking action isolates the structure from excessive lateral loads and relieves it from deformation and damage. A complete description of the dynamics of a rocking structure entails, apart from the equation of motion, an appropriate treatment of the contact phenomenon. To date, most analytical and numerical investigations of rocking behavior treat contact with the classical impact model or with ad-hoc assumptions. This paper revisits the contact process adopting a nonsmooth dynamics approach. More specifically, it treats impact through a system of inequalities, which is known as the linear complementarity problem (LCP). Throughout the study, impact is considered to be instantaneous. Set-valued contact laws model the behavior in the normal direction of the (unilateral) contact. The analysis assumes that sliding in the tangential direction is prevented. The present study demonstrates the ability of the proposed methodology to capture the impact behavior of different structures rocking on a rigid base. The results show that the proposed LCPs verify the corresponding results of other methodologies. In addition, the proposed nonsmooth dynamics approach offers a more concise description of the impact problem in rocking structures and it contributes to a more realistic treatment and better understanding of the contact phenomenon during rocking.*

1 INTRODUCTION

Rocking action relieves the structure from deformation and damage during strong earthquakes, offering a favorable seismic isolation effect (e.g.[15]). As a consequence, it attracts the attention of researchers which examine the dynamic behavior of rocking structures either experimentally [17] or analytically [25, 10, 24, 28]. While most studies ignore the (e.g. flexural) deformation of the rocking structures, [6, 23] studied the dynamics of flexible (deforming) rocking structures. Those studies compared flexible base-fixed structures with flexible structures allowed to uplift, and showed that in most cases base-fixed structures sustain larger deformations than rocking structures, verifying the earlier results of [19]. They also highlighted the sensitivity of the characteristics of the rocking systems and of the excitation considered on the response. Recent studies [20, 1, 2, 29, 27] revisited the stability of flexible rocking structures sustaining large rotations. They unveiled that for large flexible rocking structures, the effect of flexibility is not detrimental to the stability.

However, a complete description of the dynamics of a rocking structure requires, apart from the equation of motion, an appropriate treatment of the impact. During rocking, the motion of the structure is interrupted by nonsmooth impacts at the contact points. To date, most analytical studies on the rocking behavior treat impacts with ad-hoc assumptions which usually hinge on the conservation of angular momentum (e.g. [15, 18, 12, 13]). The classical approach results in a coefficient of restitution, usually defined as the angular velocity ratio after and before impact [15], which provides the unknown post-impact state. While such approach can provide dependable results for very simple rigid rocking structures, the investigation of progressively more realistic and more complicated rocking structures, creates incentive for more sophisticated analysis/simulation methods of the involved contact/impact phenomenon. More systematic approaches have been proposed in the context of nonsmooth dynamics [4, 14, 16, 21] or finite elements [26]. These methodologies rely on either a rigid multibody approach [5], or assume deformable contact formulations [3], or utilize compliant contact elements between the contacting bodies [30].

The present study describes the impact event adopting a nonsmooth dynamics approach. The aim of this paper is (i) to present briefly the nonsmooth approach, (ii) to treat impact (without sliding) between unilateral contacts and (iii) to evaluate its implementation to various rocking structures.

2 PROPOSED NONSMOOTH ANALYSIS APPROACH

2.1 Nonsmooth dynamics

The proposed herein nonsmooth dynamics approach assumes that the response can be decomposed into *smooth motion* and *nonsmooth events* [4, 14, 16, 8, 9, 11]. The present study examines the impact phenomenon in two archetypal rocking structures (Fig. 2): (i) the rigid block, and (ii) the flexible oscillator. The proposed approach originates from multibody dynamics with unilateral contacts [22, 16]. Specifically, impact, between rigid bodies which cannot overlap (impenetrability constraint), is considered instantaneous. Subsequently, all non-impulsive forces are considered negligible. Under these assumptions, instantaneous contacts (i.e. impacts) induce sudden, velocity changes ("jumps") making the response discontinuous (nonsmooth). The focus of the present study is on structures designed to exhibit planar rocking. Hence, this study assumes that sliding between contacting bodies is prevented, either by proper detailing of the contact connections to act as shear keys or by sufficient friction coefficient.

2.2 Linear complementarity problem (LCP) for impact

In general, the LCP is based on determining from a system of linear equations $\mathbf{y} = \mathbf{A}\mathbf{x} + \mathbf{b}$, with the matrices $\mathbf{A}$ and $\mathbf{b}$ known, the two unknown non-negative vectors $\mathbf{x} \geq 0$ and $\mathbf{y} \geq 0$ satisfying the complementarity condition: $\mathbf{y}^T\mathbf{x} = 0$. The LCP encapsulates a great variety of contact states, such as impact, "flight" (detachment/separation), bouncing and full contact [4].

The (Newton-Euler) equation of motion for a multibody system with unilateral contacts can be written as:

$$\mathbf{M}\ddot{\mathbf{q}} - \mathbf{h}(\mathbf{C}, \mathbf{K}, \ddot{u}_g(t)) - \mathbf{W}_N\lambda_N - \mathbf{W}_T\lambda_T = \mathbf{0} \tag{1}$$

where $\mathbf{q}$ is the generalized coordinates vector. $\mathbf{M}$, $\mathbf{C}$ and $\mathbf{K}$ are the mass, the damping and the stiffness matrices respectively, and $\mathbf{h}$ is the vector containing all the non-impulsive forces e.g. external excitation ($\ddot{u}_g(t)$), dissipating and elastic forces. $\mathbf{W}$ are the direction matrices of the contact forces in the normal (subscript '*N*') and the tangential (subscript '*T*') direction of contact respectively, and λ are the pertinent contact force vectors. To capture the impact-induced velocity jumps, we integrate the equation of motion (Eq. (1)) over the time interval of impact. Let t^- (and superscript $^-$) and t^+ (and superscript $^+$) denote the time at the beginning and at the end of impact respectively.

$$\lim_{t^-\to t^+}\int_{t^-}^{t^+}\mathbf{h}(\mathbf{C}, \mathbf{K}, \ddot{u}_g)dt = \mathbf{0}, \quad \lim_{t^-\to t^+}\int_{t^-}^{t^+}\lambda_N dt = \mathbf{\Lambda}_N, \quad \lim_{t^-\to t^+}\int_{t^-}^{t^+}\lambda_T dt = \mathbf{\Lambda}_T \tag{2}$$

Eq. (1) becomes:

$$\dot{\mathbf{q}}^+ + \dot{\mathbf{q}}^- = \mathbf{M}^{-1}\mathbf{W}_N\mathbf{\Lambda}_N + \mathbf{M}^{-1}\mathbf{W}_T\mathbf{\Lambda}_T \tag{3}$$

where vector $\dot{\mathbf{q}}$ denotes the generalized velocities. Pre-multiplying Eq. (3) by $\mathbf{W}_N^T$ (and $\mathbf{W}_T^T$) returns the vectors of the relative contact velocities in the normal $\dot{\mathbf{g}}_N = \mathbf{W}_N^T\dot{\mathbf{q}}$ (and in the tangential $\dot{\mathbf{g}}_T = \mathbf{W}_T^T\dot{\mathbf{q}}$) direction accordingly:

$$\begin{aligned}\dot{\mathbf{g}}_N^+ - \dot{\mathbf{g}}_N^- &= \mathbf{G}_{NN}\mathbf{\Lambda}_N + \mathbf{G}_{NT}\mathbf{\Lambda}_T \\ \dot{\mathbf{g}}_T^+ - \dot{\mathbf{g}}_T^- &= \mathbf{G}_{TN}\mathbf{\Lambda}_N + \mathbf{G}_{TT}\mathbf{\Lambda}_T\end{aligned} \tag{4}$$

where the $\mathbf{G}$ matrices are:

$$\begin{aligned}\mathbf{G}_{NN} &= \mathbf{W}_N^T\mathbf{M}^{-1}\mathbf{W}_N, \quad \mathbf{G}_{NT} = \mathbf{W}_N^T\mathbf{M}^{-1}\mathbf{W}_T \\ \mathbf{G}_{TN} &= \mathbf{W}_T^T\mathbf{M}^{-1}\mathbf{W}_N, \quad \mathbf{G}_{TT} = \mathbf{W}_T^T\mathbf{M}^{-1}\mathbf{W}_T\end{aligned} \tag{5}$$

This study assumes that sliding is prevented, therefore the tangential relative (contact) velocity is zero $\dot{\mathbf{g}}_T = \mathbf{0}$, and Eq. (4) gives:

$$\mathbf{\Lambda}_T = -\mathbf{G}_{TT}^{-1}\mathbf{G}_{TN}\mathbf{\Lambda}_N \tag{6}$$

Newton's impact law : Newton's law defines the ratio of the relative normal contact velocities, before ($\dot{g}_N^-$) and after impact ($\dot{g}_N^+$), as the coefficient of restitution ε_N:

$$\dot{\mathbf{g}}_N^+ = -\bar{\bar{\varepsilon}}_N\dot{\mathbf{g}}_N^- \tag{7}$$

$\bar{\bar{\varepsilon}}_N$ is the diagonal matrix of the dissipative coefficient of restitution ε_N, and varies from zero for perfectly inelastic (plastic) impact to one for perfectly elastic impact. The velocity jump along the normal direction of impact is:

$$\mathbf{v}_N = \dot{\mathbf{g}}_N^+ + \bar{\bar{\varepsilon}}_N\dot{\mathbf{g}}_N^- \tag{8}$$

then, Eq. (4) yields a system of linear equations:

$$\mathbf{v}_N = \left(\mathbf{G}_{NN} - \mathbf{G}_{NT}\mathbf{G}_{TT}^{-1}\mathbf{G}_{TN}\right)\boldsymbol{\Lambda}_N + \left(\mathbf{E} + \overline{\overline{\varepsilon}}_N\right)\dot{\mathbf{g}}_N^- \tag{9}$$

for which the additional complementarity conditions hold:

$$\mathbf{v}_N \geq \mathbf{0},\ \boldsymbol{\Lambda}_N \geq \mathbf{0},\ \mathbf{v}_N^T\boldsymbol{\Lambda}_N = 0 \tag{10}$$

In Eq. (9), $\mathbf{E}$ is the identity matrix. Eqs (9), (10) define a LCP which treats (non-sliding) impacts according to Newton's law. The complementarity conditions (Eq. 10) reflect the inequality character of (dry) contacts. Fig. 1 illustrates this complementary relationship; the positive part of the horizontal axis allows positive normal impulses with zero velocities, while the vertical axis allows positive relative velocities with zero normal impulses.

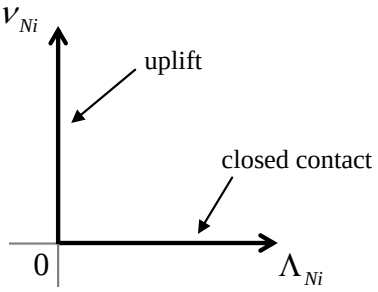

Figure 1: The inequality character of contact [22].

3 REVIEW OF THE ROCKING BLOCK USING THE PROPOSED APPROACH

The present section revisits the impact behavior of the rigid rocking block of Fig. 2(a) adopting the proposed nonsmooth dynamics approach. Consider a rigid block with base width $2b$ and height $2H$ as in Fig. 2(a). The generalized coordinates vector for the planar rocking motion of the block is: $\mathbf{q}^T = \begin{bmatrix} x & y & \phi \end{bmatrix}$, where x and y are the translations along the pertinent axes, and ϕ is the planar rocking rotation. Assume that the two closed contact points (pivot points "1" and "2") produce two forces/impulses in the normal direction of contact (one force per point), but only one force in the tangential direction of contact, the resultant of the two tangential forces at the two pivot points (e.g. as in Fig. 3). The consideration of the resultant tangential force (instead of its constituents) is eligible by the rigid body assumption (the two constituents are linearly dependent) and most importantly, does not overconstraint the problem [8, 9, 11]. Thus, the mass matrix and the direction matrices in the normal and tangential direction of contact become respectively:

$$\mathbf{M} = \begin{bmatrix} m & 0 & 0 \\ 0 & m & 0 \\ 0 & 0 & I_0 \end{bmatrix},\ \mathbf{W}_N = \begin{bmatrix} 0 & 0 \\ 1 & 1 \\ -b & b \end{bmatrix},\ \mathbf{W}_T = \begin{bmatrix} 1 \\ 0 \\ H \end{bmatrix} \tag{11}$$

where I_0 is the mass moment of inertia with respect to the center of mass of the block. For a rectangular block $I_0 = (1/3)\,mR^2$, where m is the mass of the block and R is the half diagonal distance (Fig. 2(a)).

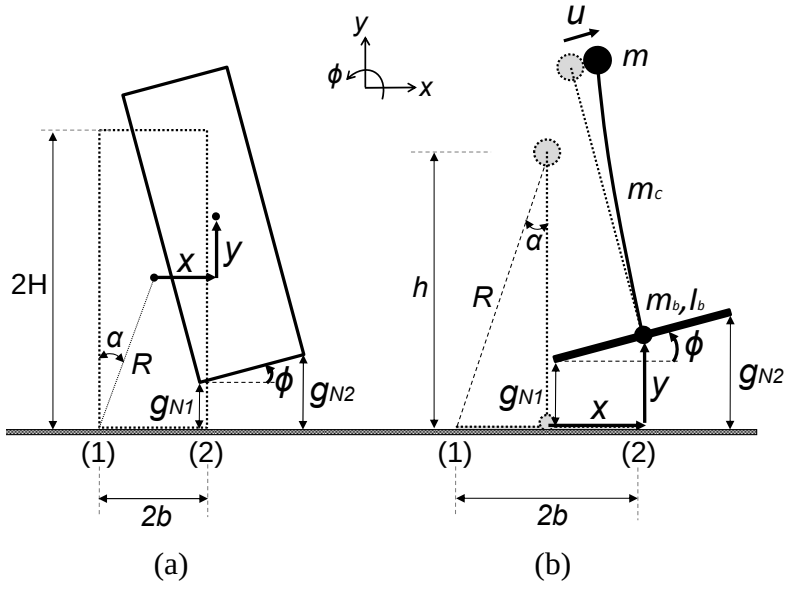

Figure 2: The examined rocking structures: (a) rigid block, (b) flexible oscillator.

3.1 Analysis of all physically feasible post-impact states

With reference to Fig. 3, consider a rigid block performing pure rotation (without sliding) about pivot point "1" ($g_{N1}^- = \dot{g}_{N1}^- = 0$). Impact takes place at pivot point "2" at the moment $g_{N2}^- = 0$ and with pre-impact contact velocity $\dot{g}_{N2}^- = 2b\dot{\phi}^- < 0$. There are four possible (post-impact) states (Fig. 3(E)): (i) full contact ($E_{1/1}$), (ii) bouncing ($E_{1/2}$), (iii) rocking ($E_{2/1}$), and (iv) "flight" ($E_{2/2}$). This section examines all physically feasible post-impact states, and determines the conditions under which each (post-impact) state occurs.

Full contact ($A \to E_{1/1}$) or bouncing ($A \to E_{1/2}$) (Fig. 3): When after impact, point "1" remains in contact with the ground ($\dot{g}_{N1}^+ = 0$), point "2" might stay in contact or not ($\dot{g}_{N2}^+ \geq 0$). The corresponding velocity jumps at the two contact points are (Eqs (7), (8)):

$$\begin{aligned} \nu_{N1} &= \dot{g}_{N1}^+ + \varepsilon_N \dot{g}_{N1}^- = \dot{g}_{N1}^+ = 0 \\ \nu_{N2} &= \dot{g}_{N2}^+ + \varepsilon_N \dot{g}_{N2}^- = -\varepsilon_N \dot{g}_{N2}^- + \varepsilon_N \dot{g}_{N2}^- = 0 \end{aligned} \tag{12}$$

Eq. (12) implies that the block bounces at point "2" with a contact velocity $\dot{g}_{N2}^+ = -\varepsilon_N \dot{g}_{N2}^- > 0$ for a nonzero (Newton) coefficient of restitution $\varepsilon_N > 0$, and it stays in full contact at point "2" ($\dot{g}_{N2}^+ = 0$) for $\varepsilon_N = 0$. In either case, both velocity jumps are zero (Eq. (12)) and thus known. It follows (Eq. 10) that the remaining two unknowns, the normal impulses Λ_{N1} and Λ_{N2}, are both positive. The solution of the LCP of Eq. (9) yields their values:

$$\begin{aligned} \frac{\Lambda_{N1}}{m\dot{g}_{N2}^-} &= (1+\varepsilon_N)\left(\frac{1}{3\sin^2\alpha} - \frac{1}{2}\right) \\ \frac{\Lambda_{N2}}{m\dot{g}_{N2}^-} &= -(1+\varepsilon_N)\frac{1}{3\sin^2\alpha} \end{aligned} \tag{13}$$

with the help of which, Eq. (6) gives the (dimensionless) tangential impulse:

$$\frac{\Lambda_T}{m\dot{g}_{N2}^-} = (1+\varepsilon_N)\frac{\cot\alpha}{2} \tag{14}$$

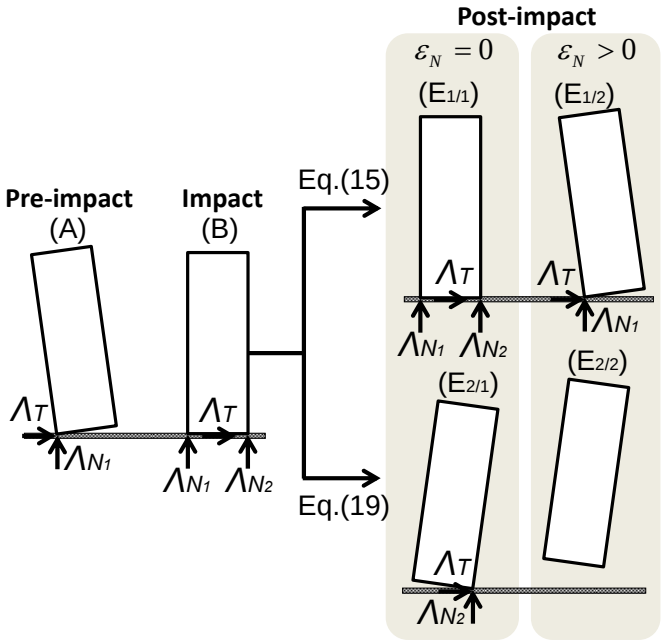

Figure 3: Post-impact states for the rocking block according to Newton's law.

Note that, all unknowns (contact velocities and/or impulses) are given in dimensionless terms.

The inequality character of contact determines the (existential) conditions under which each post-impact state occurs. Specifically, the $\Lambda_{N1} > 0$ condition and Eq. (13) show that the block can bounce or remain in full contact with the ground after impact when:

$$\frac{H}{b} < \frac{1}{\sqrt{2}} \tag{15}$$

in agreement with [5].

Rocking ($A \rightarrow E_{2/1}$) or "flight" ($A \rightarrow E_{2/2}$) (Fig. 3): Assume that after impact the block changes pivot point. Hence, contact at point "1" is lost $\dot{g}_{N1}^{+} > 0$, while the new contact at point "2" is either maintained $\dot{g}_{N2}^{+} = 0$, or also lost $\dot{g}_{N2}^{+} > 0$. The velocity jumps for the two contact points are (Eqs (7), (8)):

$$\begin{aligned} \nu_{N1} &= \dot{g}_{N1}^{+} + \varepsilon_N \dot{g}_{N1}^{-} = \dot{g}_{N1}^{+} > 0 \\ \nu_{N2} &= \dot{g}_{N2}^{+} + \varepsilon_N \dot{g}_{N2}^{-} = 0 \end{aligned} \tag{16}$$

The velocity jumps of Eq. (16) give $0 = \nu_{N2} = \varepsilon_N \dot{g}_{N2}^{-}$. When ε_N is nonzero, contact at point "2" is lost ($\dot{g}_{N2}^{+} = -\varepsilon_N \dot{g}_{N2}^{-} > 0$) and uplifting (detachment) of both contact points takes place. The former case ($\varepsilon_N = 0$) leads to pure rocking behavior while the latter ($\varepsilon_N > 0$) to "flight" behavior. For velocity jumps $\nu_{N1} > 0$ and $\nu_{N2} = 0$, the complementarity conditions (Eq. (10)) return $\Lambda_{N1} = 0$ and $\Lambda_{N2} > 0$. The solution of the LCP of Eq. (9) yields the remaining two unknowns, the normal impulse Λ_{N2} at point "2", and the post-impact normal contact velocity $\dot{g}_{N1}^{+}$ of point "1":

$$\begin{aligned} \frac{\Lambda_{N2}}{m\dot{g}_{N2}^{-}} &= (1+\varepsilon_N)\left(\frac{3\sin^2\alpha}{4} - 1\right) \\ \frac{\dot{g}_{N1}^{+}}{\dot{g}_{N2}^{-}} &= (1+\varepsilon_N)\left(\frac{3\sin^2\alpha}{2} - 1\right) \end{aligned} \tag{17}$$

and from Eq. (6), the tangential impulse becomes:

$$\frac{\Lambda_T}{m\dot{g}_{N2}^-} = \frac{3}{4}(1+\varepsilon_N)\sin\alpha\cos\alpha \tag{18}$$

Again, the inequality character of contact dictates the (existential) conditions under which each post-impact state occurs. Specifically, when contact at point "1" is lost ($\Lambda_{N1} = 0$), the complementary behavior (Fig. 1) requires $\dot{g}_{N1}^+ > 0$. Hence, Eq. (17) shows that the block exhibits rocking or "flight" post-impact behavior when [5]:

$$\frac{H}{b} > \frac{1}{\sqrt{2}} \tag{19}$$

In summary, Eqs (12) to (19) describe completely all possible post-impact states for the rigid rocking block. Thus, the proposed methodology verifies the corresponding results from other methodologies, while at the same time encapsulates all physically feasible post-impact states. Specifically, the geometric slenderness criterion, derived by [5], is in agreement with Eqs (15), (19). For non-sliding (sticking) impacts, a rocking block is considered "stocky" when Eq. (15) is satisfied, whereas when Eq. (19) holds, the block is regarded as "slender". In many studies, including past work of the authors ([10, 7, 12, 13] among others), the ratio $\eta = \dot{\phi}^+ \big/ \dot{\phi}^-$ defines a coefficient of restitution with respect to the angular velocities. When a (slender) block rocks or separates ("flight" mode) from the ground after impact (Fig. 3($E_{2/1}$/$E_{2/2}$)), Eq. (3) with the aid of Eqs (17), (18) shows that the relationship between pre- and post-impact angular velocity ratio is:

$$\eta = \frac{\dot{\phi}^+}{\dot{\phi}^-} = 1 - \frac{3}{2}\sin^2\alpha - \frac{3}{2}\varepsilon_N\sin^2\alpha \tag{20}$$

Eq. (20) verifies the pertinent equation derived by [25, 17]. For perfectly inelastic (plastic) impact ($\varepsilon_N = 0$), the block exhibits pure rocking behavior, and Eq. (20) agrees with the Housner's angular coefficient of restitution [15].

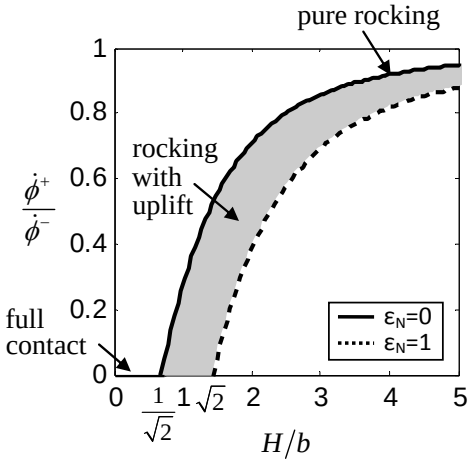

Figure 4: Admissible regions for all the post-impact states for the rocking block.

Eqs (13), (14) treat the bouncing and full contact behavior of the block (Fig. 3($E_{1/1}$/$E_{1/2}$)), with the help of which Eq. (3) gives:

$$\eta = \frac{\dot{\phi}^+}{\dot{\phi}^-} = -\varepsilon_N \tag{21}$$

Eq. (21) shows that for $\varepsilon_N = 0$ the block remains in full contact after impact ($\dot{\phi}^+ \big/ \dot{\phi}^- = 0$), while for perfectly elastic impact ($\varepsilon_N = 1$), the rocking block bounces without any loss of kinetic energy.

Fig. 4 illustrates the admissible regions of all the examined post-impact states of the rigid rocking block. For non-sliding impacts, Fig. 4 shows the admissible domain when rocking occurs. A slender block exhibits pure rocking motion (Eq. (20)) when $\varepsilon_N = 0$. The grey area in Fig. 4 describes the rocking behavior of the block which is accompanied by uplifts/jumps of the pivot points immediately after impact occurs [25, 17]. Note that, the higher the slenderness ratio H/b, the less energy is dissipated during impact, and, in the limit, as this ratio becomes (theoretically) infinite, the block rocks without any energy loss.

4 NUMERICAL EVALUATION OF THE PROPOSED APPROACH

This section illustrates the versatility of the proposed approach by examining (numerically) the behavior of a rigid rocking block and a flexible oscillator in terms of time history analysis (Fig. 2). Consider (i) a stocky block with $2b$ = 1.4 m base width and $H/b = 1\big/\sqrt{2}$ (Eq. (15), Fig. 5(a)) and (ii) a slender block with the same base width but $H/b = 7.0$ (Eq. (19), Fig. 5(b)). The frequency parameter of a rocking block is $p = \sqrt{3g/4R}$, where g is the gravitational acceleration and R is the half-diagonal distance (Fig. 2(a)). Fig. 5 plots the free rocking response of both a stocky and a slender block (Fig. 5(a) and Fig. 5(b) respectively). Specifically, Fig. 5(a)(top) plots the response of the block for three different (Newton) coefficients of restitution. Both blocks have an initial rotation equal with $\alpha/3$, where α denotes the slenderness of the block (Fig. 2(a)). The stocky block does not change pivot point after impact and hence, exhibits bouncing behavior. When $\varepsilon_N = 0$ the impact is considered totally inelastic (plastic) and the block remains in full contact after impact with the ground. On the contrary, for totally elastic impacts ($\varepsilon_N = 1$) the stocky block bounces without any energy loss at impact. The slender block though, changes pivot point after each impact and exhibits pure rocking motion for $\varepsilon_N = 0$ (Fig. 5(b)(top)). Fig. 5(bottom) shows the normal relative distance g_N of the two contact points (as Fig. 2 shows) for both the bouncing and the rocking motion of the two blocks. It is important to note, that both bouncing and rocking behavior are captured numerically with the aid of the same LCP.

Fig. 6 plots the response of the slender rocking block by comparing the proposed nonsmooth dynamics approach for $\varepsilon_N = 0$ with the classical impact model [15] assuming an angular coefficient of restitution equal with 0.97 (according to Eq. (20)). The two (identical) blocks exhibit pure rocking motion and are subjected to the same sine pulse excitation with $\alpha_g/g = 0.45$ and $\omega_g/p = 5.75$. Fig. 6 shows that the results derived by the proposed methodology are in complete agreement with the classical impact model. In addition, the proposed methodology encapsulates all physically feasible post impact states; something that is not feasible with the classical impact model.

Further, the proposed approach is also applicable to more complicated rocking structures. Consider the flexible rocking oscillator of Fig. 2(b) with slenderness $\alpha = 0.1\ rad$ and $H/b = 10$ [29]. The oscillator has a deformable column with mass m_c uniformly distributed along its length. Assume the concentrated (lumped) mass m on the top has zero moment of inertia, whereas the base mass m_b gives moment of inertia $I_b = (1/3)\, m_b b^2$ with respect to its center of mass. The generalized coordinates vector for the planar rocking motion of the flexible rocking oscillator is: $\mathbf{q}^T = \begin{bmatrix} u & x & y & \phi \end{bmatrix}$, where x and y are the translations of the base mass along the pertinent axes, u is the elastic relative translation of the lumped mass and ϕ is the planar

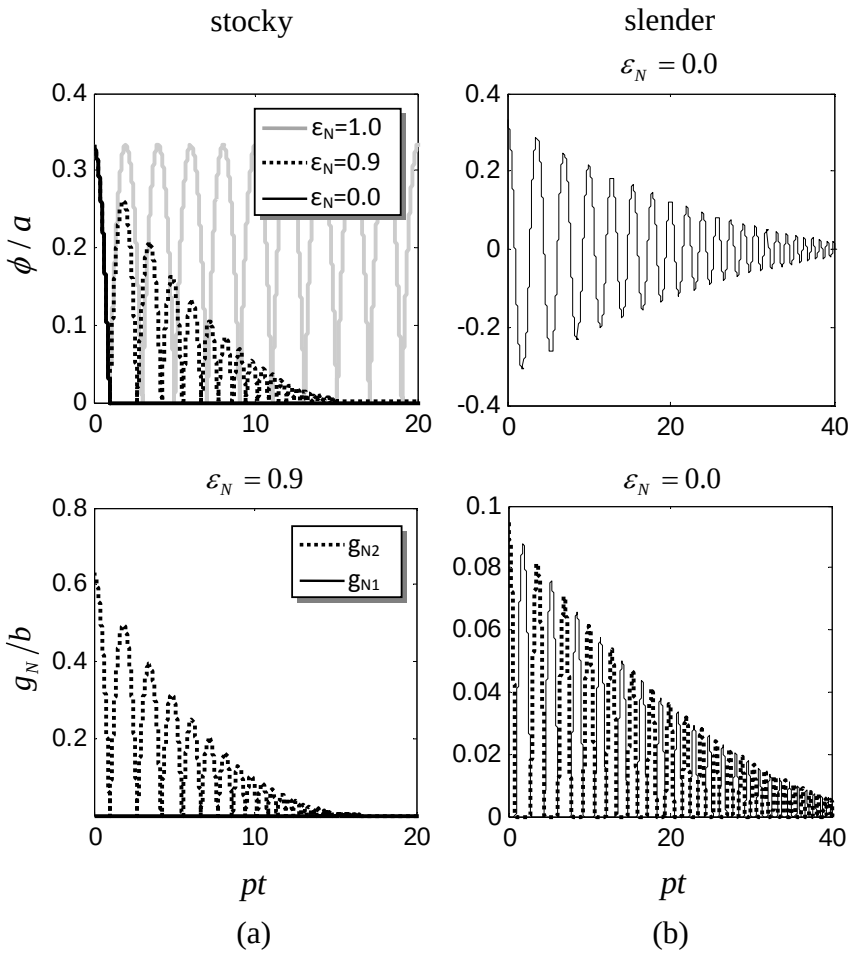

Figure 5: Free rocking response for (a) a stocky and (b) a slender block.

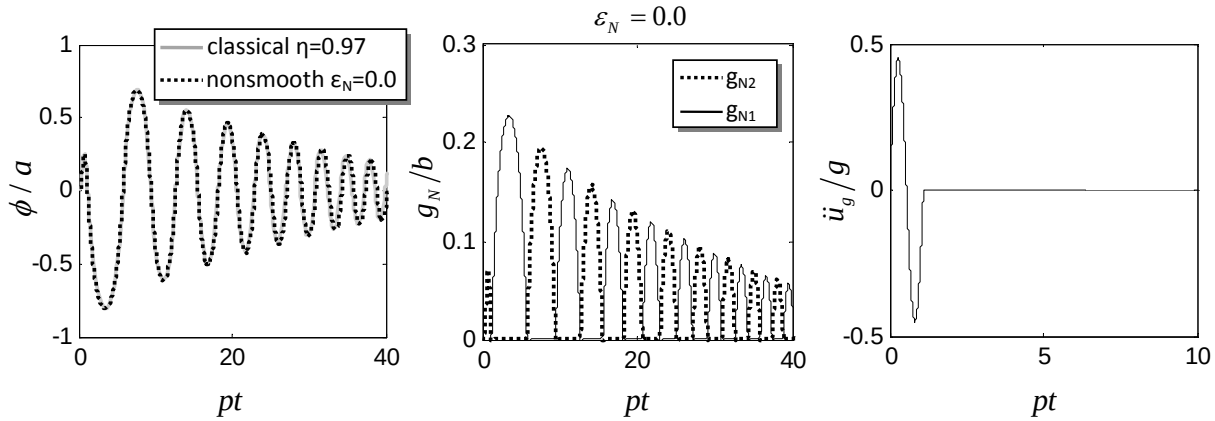

Figure 6: Comparison between the nonsmooth dynamics approach and the classical impact model for a (slender) rocking block subjected to sine pulse with $\alpha_g = 0.45g$ and $\omega_g = 5.75p$.

rocking rotation (Fig. 2(b)). Following [29], the present study assumes $\gamma_{m_b} = m_b/m = 2$ and $\gamma_{m_c} = m_c/m = 1$. Further, the damping ratio is taken as 1%, while the natural frequency ω_n/p is considered as 5, with p being the frequency parameter of the oscillator equal with $p = \sqrt{g/R}$.

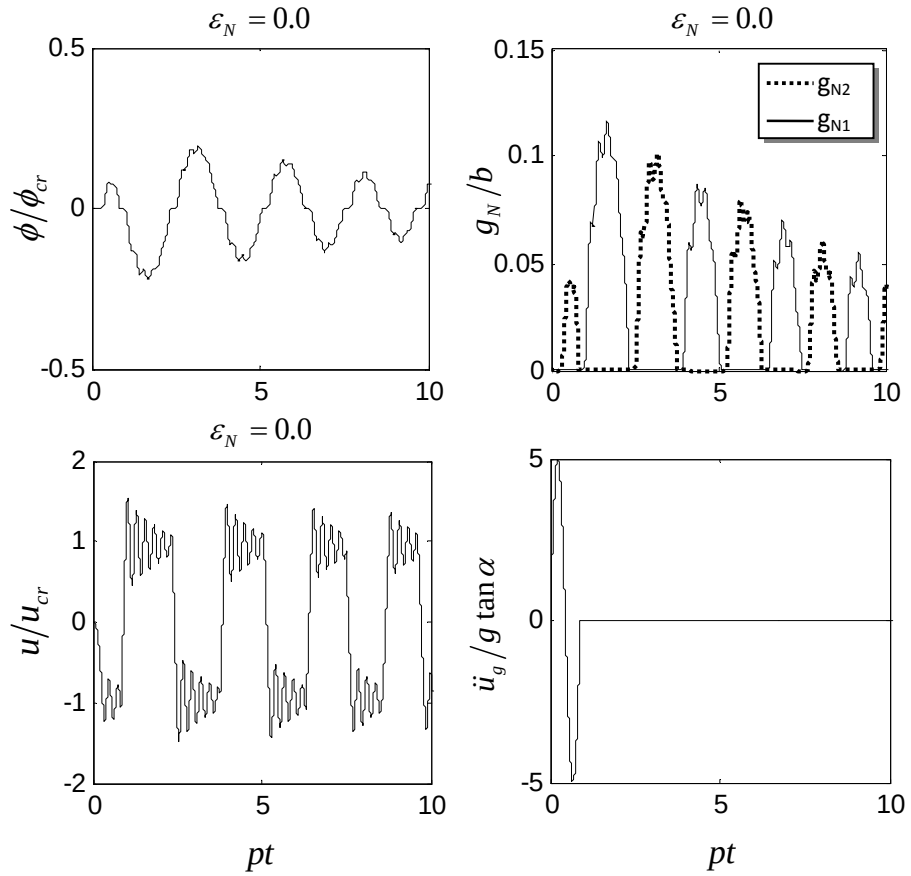

Figure 7: Time history response of the (slender) flexible rocking oscillator subjected to sine pulse with $\alpha_g = 5g\tan\alpha$ and $\omega_g = 7p$.

Fig. 7 shows that subjected to a sine pulse excitation with $\alpha_g/g\tan\alpha = 5$ and $\omega_g/p = 7$, the flexible rocking oscillator of Fig. 2(b) exhibits pure rocking motion, which is in good agreement with the pertinent results from [29]. Note that, ϕ_{cr} denote the "critical" rocking angle of unstable equilibrium for the rigid rocking oscillator, and u_{cr} the "critical" relative displacement of the mass m at the time-instant rocking initiates [29].

5 CONCLUSIONS

The present study revisits the contact/impact phenomenon encountered in rocking structures adopting a nonsmooth dynamics approach. In particular, it formulates the impact problem as a system of inequalities, known as linear complementarity problem (LCP), and examines the impact of two archetypal rocking structures: the rigid rocking block and the flexible rocking oscillator. In the normal direction of contact, the present analysis adopts the Newton's contact law, while in the tangential direction sliding is prevented (non-sliding contact). The analysis shows that the results from the proposed LCPs are in total agreement with the pertinent results

of other methodologies. Overall, this work demonstrates the ability of the proposed nonsmooth dynamics approach to capture all physically feasible post-impact states in a systematic and condensed manner; at least for the rocking systems examined.

Abstract. *A simple analytical model for simulating a controlled rocking system consisting of a Precast Wall with End Columns (named as PreWEC) has been developed and compared against experimental results. The wall panel and end columns are secured to the foundation using prestressing, allowing PreWECs to experience rocking motions. The proposed model accounts for its predominant rotational degree of freedom formulation based on existing knowledge and adds new features to accurately capture the measured responses. They include a migrating rotation center that recognizes the variation in the contact length and its effect on the elongation in the post-tensioned tendons. Supplemental energy dissipation in PreWEC is provided by steel O-connectors, which horizontally join the wall panel to the end columns. These connectors are modelled using a system of nonlinear springs. Two different experiments were used to demonstrate the accuracy of the model validation, which include: a) a 5/18-scale PreWEC subjected to shake table motions; and b) a 1/5-scale PreWEC subjected to free vibration motions. It is shown that rotation responses and associated peaks experienced by the PreWEC rocking system can be accurately predicted using a simplified model.*

1 BACKGROUND

Rocking is a phenomenon that can influence the response of structures, which are allowed to uplift from their base. The eminent work by Housner [1] provided the fundamental knowledge and first steps towards modelling free rocking response of rigid members.

The topic of rocking response has received significant attention in recent years when vertical post-tensioning is introduced along the member length to control the rocking response and allow structural members to re-center upon removal of the lateral load [7, 10]. A simple form of a controlled rocking system is shown in **Fig. 1**, which shows the post-tensioning tendons anchored at the top of the member and the foundation. This concept has paved the way for developing new seismic resilient structural systems that are able to minimize both structural damage and residual drifts when subjected to earthquake input motions.

As part of the *NEES* Rocking Wall Project, a shake table testing of four controlled rocking concrete walls has been recently conducted by Nazari et al. [8] at 1/3.6 scale. As expected, the walls experienced negligible residual displacements and minimal damage that was mainly concentrated at wall compression toes. In another study, Ma [5] followed the original theory of Housner and extended it to modelling of controlled rocking systems as guided by experimental results from a rocking post-tensioned masonry wall. Ma observed from the experimental data that the assumption made in the Housner model of stationary pivot points at the bottom corners of the block did not hold for this controlled rocking unit. Instead, it was noted that the wall developed a contact over a finite area with the foundation surface, which was varying as a function of its angular displacement. This variation led to a continuously migrating rotation center residing within the contact area. The empirical model by Ma, therefore, accounted for this behavior by tracking the correct location of the pivot point. A method that provides a good estimate for the variation in the contact area of a controlled rocking body was suggested by Aaleti and Sritharan [1].

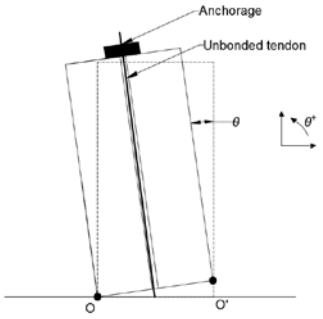

Figure 1: An idealized controlled rocking block.

2 RESEARCH SIGNIFICANCE

The focus of this paper is on modelling of a specific controlled rocking unit, as the PreWEC system. This system, shown schematically in **Fig. 2**, is one of the latest improvements in controlled rocking systems that incorporate supplemental hysteric damping. The PreWEC system consists of a precast wall with end columns with the wall panel and the end columns being individually anchored to the foundation using unbonded post-tensioned tendons [11]. The end columns are horizontally connected to the wall with mild steel O-connectors, which can be tailed to the strain and displacement demands [2]. This study presents analytical results from a model developed for the PreWEC system and compares them with experimental results obtained from shake table testing of PreWEC[1] [9] as well as from free vibration tests of another unit conducted by Twigden et al. [12].

3 SUMMARY OF EXPERIMENTAL STUDIES

3.1 PreWEC system from *NEES* Rocking Wall Project

Test Setup

The unit designated as PreWEC[1] used twelve O-connectors and a wall specimen that was 1.524 mm long, 4,876.8 mm tall and 127 mm thick. The wall was post-tensioned to the foundation with five 270 Grade centrally placed steel strands. The total initial prestressing force applied through these strands was 865.18 kN.

The PreWEC[1] system was placed within a small pocket on top of the foundation with a layer of grout ensuring full contact between the prefabricated members. This unit was tested using a shake table, whose base was attached to the laboratory strong floor using tie-downs. A seismic mass consisting of a frame and two mass blocks (each block being 2,489.2 mm tall with a square cross-section of 1,219.2 x 1,219.2 mm^2) was used outside of the shake table, as shown in **Fig. 3**, connected to the wall panel using a rigid link beam.

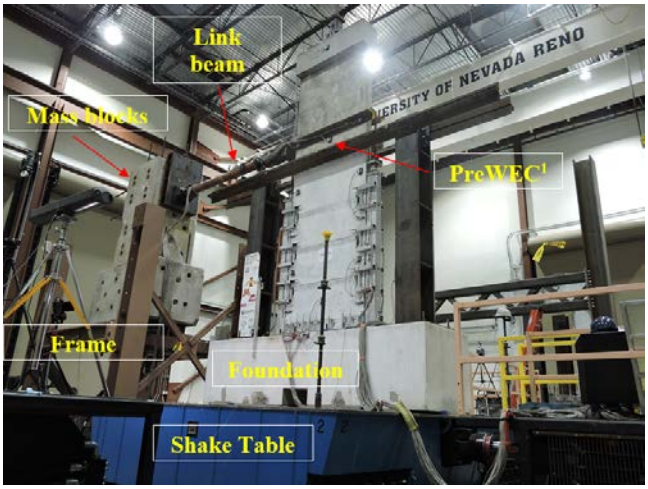

Figure 3: Test Setup for the PreWEC[1] [9].

Input Motions

The PreWEC[1] was subjected to a series of 42 test runs consisted of several input motions, including recorded earthquake excitations with varying intensities. Analysis of the PreWEC[1]

response in this study focused on the 23 first test runs, during which the O-connector experienced no deterioration or fracture. More information regarding the test setup, type of O-connectors, instrumentation and input motions are available on *NEEShub* by Nazari et al. [9].

3.2 PreWEC system tested by Twigden et al. [12]

Test Setup

The unit was 800 mm long, 3,000 mm high and 125 mm thick. The wall was anchored to the foundation with three steel strands of 15.2 mm diameter, each prestressed to $0.5\,f_{py}$. As shown in the test setup of **Fig 4**, this wall base was also placed in a grout pocket on the top of a foundation. Concrete mass blocks were placed on top of the wall to provide additional seismic mass. A lateral support frame was employed to minimize any out-of-plane motion of the system.

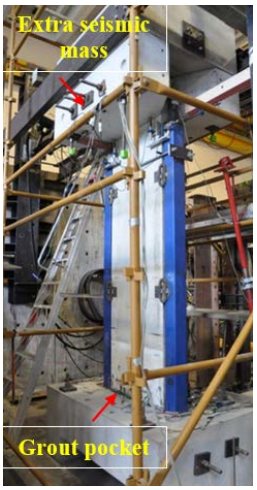

Figure 4: Test Setup for the PreWEC by Twigden et al. [10].

Input Motions

Two free vibration test runs were conducted on this specimen using: a) four (system designated as PreWEC-1); and b) six (system designated as PreWEC-2) O-connectors joining each end column with the wall panel. The specimen was tilted laterally using a hydraulic actuator and quickly released at the desired top lateral displacement level (i.e., 60 mm). More information about these experiments can be found in the paper by Twigden et al. [12], while information about the O-connectors used in this study can be found in Twigden and Henry [13].

4 MODELLING OF THE PREWEC SYSTEM

4.1 Equation of motion for PreWEC[1]

A dynamic system consisting of two generalized coordinates (q_1 and q_2) was built for simulating the response of PreWEC[1], where q_1 corresponds to the wall rotation and q_2 represents the rotation of the mass blocks with respect to the frame as observed from test videos. A schematic representation of this model is shown in **Fig. 5**. It is noted that the end columns were not included in this model and the contribution of O-connectors was included by assuming that the displacement demand imposed on the connectors was equal to the uplift of the wall panel

at one end and compression of the wall toes at the other end. This is consistent with experimental observations [11].

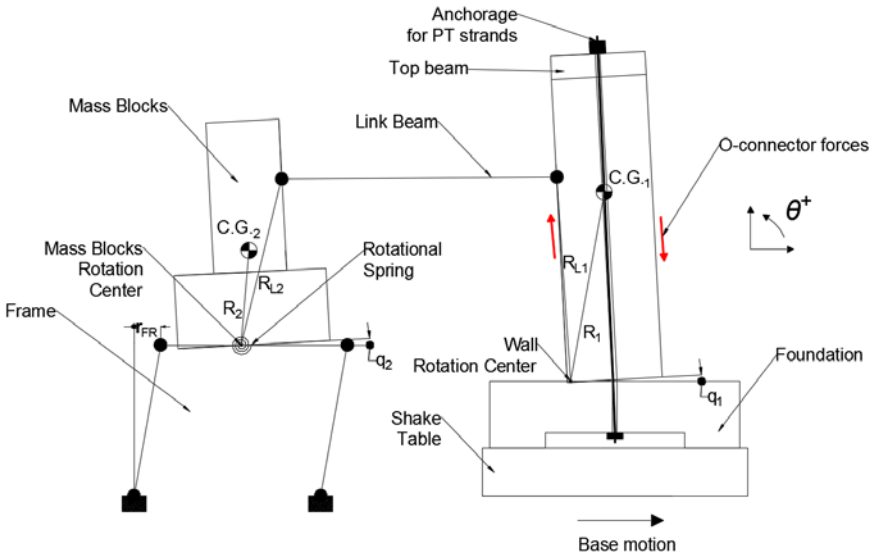

Figure 5: A schematic view of the model developed for PreWEC[1].

Modelling of the PreWEC[1] followed the Housner approach. However, the rotation center was assumed to be located in the middle of the wall contact length at the foundation interface and is, therefore, migrating as a function of the rotation q_1. The simplified method proposed by Aaleti and Sritharan [1] was employed to compute the expected contact length at 2% top lateral drift of the wall, assuming properties of confined concrete and an equivalent stress block at the wall toes. The variation of contact length from $0 \rightarrow 2\,\%$ drift was modified from the original method using the Meregotto-Pinto equation [6] as shown in **Fig. 6**.

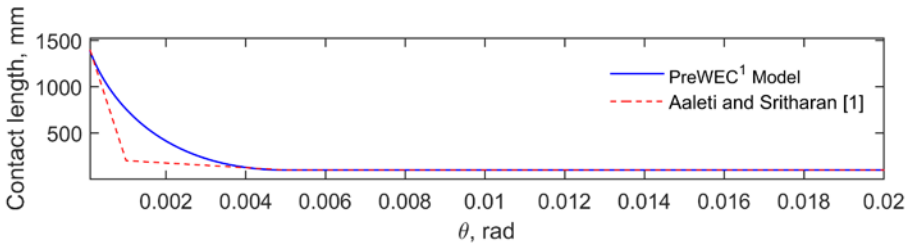

Figure 6: Contact length variation for PreWEC[1] model.

Similarly, the degree of freedom, q_2, corresponding to the mass concrete block rotation was modelled assuming an inverted pendulum, in which a linear rotational spring was used to capture the observed rotation of the mass blocks with respect to the supporting frame (see **Fig. 5**). The rotation center of the block was also modelled to vary as a function of its rotation in a similar fashion with **Fig. 6** with a minimum distance of 495 mm from its bottom corner being reached at $\theta = 0.005\,\text{rad}$.

In addition to the hysteric dissipation provided by the O-connectors, the system's energy dissipation included three damping components. As shown below, these components were provided by: a) the rocking wall panel; b) mass blocks; and c) frame supporting the mass blocks.

$$M_{damp,wall} = c_1 \dot{q}_1 \tag{1}$$

$$M_{damp,blocks} = c_2 \dot{q}_2 \tag{2}$$

$$F_{damp,\,frame} = sign\left(\dot{r}_{FR}\right) c_3 \sqrt{\left|\dot{r}_{FR}\right|} \tag{3}$$

where c_1, c_2 and c_3 were damping coefficients which were trained in an error minimization process using a set of two test runs (i.e., Test#4 and Test#18) [9]. Variables $M_{damp,wall}$ and $M_{damp,blocks}$ also served as numerical damping parameters in the numerical ODE solver.

Estimation of energy dissipation due to impact followed an approach described in Kalliontzis et al. [4]. Their proposed expression assume that the rotation centers of a rocking member just before and just after impact are as shown in **Fig. 7**. Using conservation of angular momentum before and after impact about the rotation center after impact, the equation for the coefficient of restitution (*COR*) in this approach is expressed as:

$$COR = \left[\frac{1 + \frac{MR^2}{I_{cm}} \left(1 - \left(\sin a\right)^2 \left(1 + k^2\right)\right)}{1 + \frac{MR^2}{I_{cm}} \left(1 - \left(\sin a\right)^2 \left(1 - k^2\right)\right)} \right]^2 \tag{4}$$

where k is a factor defining the location of rotation centers just before and just after impact; and I_{cm} denotes the mass moment of inertia of the block with respect to its gravitational center. With respect to Eq. 4, in the absense of a suitable value, $k = 0.72$ is recommended for concrete rocking members, which is used in this study.

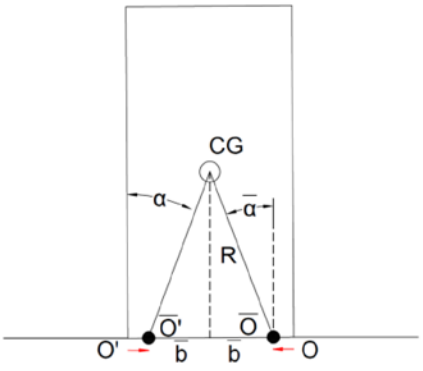

Figure 7: Rocking block with rotation centers $\bar{O}$ and $\bar{O}'$ just before and just after impact, respectively; where $\bar{b} = kb$ with $0 \le k \le 1$ and b is the block half-width [4].

Assuming the two rotational degrees of freedom shown in **Fig. 5** (i.e., one for the wall panel and the other for the mass blocks), two equations of motion were derived and they are presented in **Eqs. 5** and **6**.

$$\left(I_o + M_{EM}L_{L_1}{}^2 - \frac{M_{EM}{}^2}{\bar{I}_{o,b}}\left(L_{L_1}L_{L_2}\right)^2\right)\ddot{q}_1 = -p_1{}^2\left[\frac{\ddot{u}_g}{g}\cos\left(a_1 - |q_1|\right) + sign(q_1)\sin\left(a_1 - |q_1|\right)\right]$$
$$-sign(q_1)F_{PT}\left[\frac{W}{2} - \frac{C}{2}\right] - sign(q_1)\left[F_{down}\left(W - \frac{C}{2}\right) + F_{up}\frac{C}{2}\right] - M_{damp,wall} \quad (5)$$
$$-M_{EM}L_{L_1}\left(\ddot{u}_g + R_{L_1}\dot{q}_1{}^2\sin\left(a_{L,1} + q_1\right) + R_{L_2}\dot{q}_2{}^2\sin\left(a_{L,2} - q_2\right) + L_{L_2}\ddot{q}_{2,1}\right) - F_{damp,\,frame}L_{L_1}$$

$$\left(I_{o,b} + M_{EM}L_{L_2}{}^2\right)\ddot{q}_2 = -p_2{}^2 sign(q_2)\sin\left(a_2 - |q_2|\right) - M_{damp,blocks} - k_r q_2$$
$$-M_{EM}L_{L_2}\left(\ddot{u}_g + R_{L_1}\dot{q}_1{}^2\sin\left(a_{L,1} + q_1\right) + R_{L_2}\dot{q}_2{}^2\sin\left(a_{L,2} - q_2\right)\right) - F_{damp,\,frame}L_{L_2} \quad (6)$$
$$-M_{EM}\left(L_{L_1}L_{L_2}\right)\ddot{q}_1$$

with,

$$\ddot{q}_{2,1} = \frac{\begin{bmatrix} -p_2{}^2 sign(q_2)\sin\left(a_2 - |q_2|\right) - M_{damp,blocks} - k_r q_2 \\ -M_{EM}L_{L_2}\left(\ddot{u}_g + R_{L_1}\dot{q}_1{}^2\sin\left(a_{L,1} + q_1\right) + R_{L_2}\dot{q}_2{}^2\sin\left(a_{L,2} - q_2\right)\right) - F_{damp,\,frame}L_{L_2} \end{bmatrix}}{\left(I_{o,b} + M_{EM}L_{L_2}{}^2\right)} \quad (7)$$

$$L_{L_1} = -R_{L_1}\cos\left(a_{L,1} + q_1\right) \quad (8)$$

$$L_{L_2} = -R_{L_2}\cos\left(a_{L,2} - q_2\right) \quad (9)$$

$$p_1 = \sqrt{M_w g R_1} \quad (10)$$

$$p_2 = \sqrt{\frac{2}{3}M_{EM}gR_2} \quad (11)$$

$$\bar{I}_{o,b} = I_{o,b} + M_{EM}L_{L_2}{}^2 \quad (12)$$

In the above equations, $a_{L,1}$ and $a_{L,2}$ are the "slenderness" ratios with respect to the link beam location on the wall and mass blocks, respectively, which are updated with respect to the rotation center location; R_{L_1}, R_{L_2}, R_1 and R_2 are as identified in **Fig. 5**; F_{PT} represents the total force applied through the post-tensioned strands to the wall panel and it was estimated as per the Aaleti and Sritharan approach [1]; and F_{down} and F_{up} denote the O-connector forces, respectively, on the the uplift and compression sides of the wall panel due to the wall rotation.

In addition, the response of the wall system was also computed by using the experimentally recorded force applied through the link beam to the wall as the input parameter. In this case, the dynamic system consisted of a single degree of freedom, q_1, and its equation of motion is described in **Eq. 13**.

$$I_o\ddot{q}_1 = -p_1{}^2\left[\frac{\ddot{u}_g}{g}\cos\left(a_1 - |q_1|\right) + sign(q_1)\sin\left(a_1 - |q_1|\right)\right] - sign(q_1)F_{PT}\left[\frac{W}{2} - \frac{C}{2}\right]$$
$$-sign(q_1)\left[F_{down}\left(W - \frac{C}{2}\right) + F_{up}\frac{C}{2}\right] - M_{damp,wall} - F_{LinkBeam}L_{L_1} \quad (13)$$

where $F_{LinkBeam}$ represents the experimentally obtained link beam forces recorded using a load cell.

4.2 Modelling of O-connectors

Fig. 8a presents experimental data obtained from a quasi-static cyclic reversal test on the O-connector used in PreWEC[1] (Courtesy of Nazari Maryam, Ph. D. candidate at Iowa State University). Using a similar test setup to the one described by Henry et al. [2], the two pairs of O-connectors were subjected to the vertical displacement history shown in **Fig. 8b**.

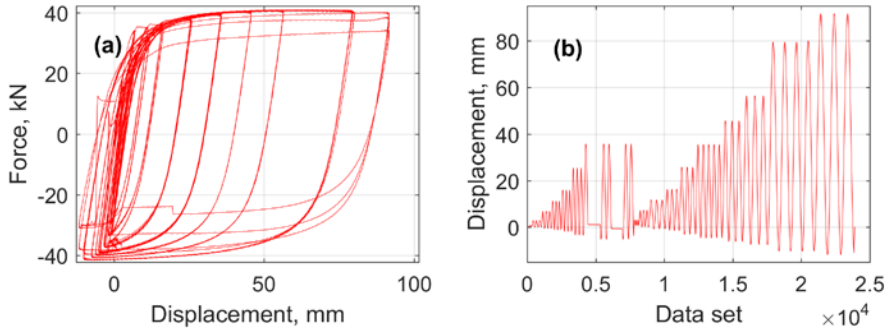

Figure 8: O-connector used in PreWEC[1] (a) measured force vs displacement response of one connector; and (b) applied displacement history protocol.

The recorded O-connector data was used to develop a numerical model for simulating the resistance of the connectors in the simulation of the PreWEC system. This model used the Meregotto-Pinto equation [6] to develop rules for the envelope, load reversals and reloading branches of the connector responses. **Fig. 9** compares model response with the experimental data, showing satisfactory agreement including the strength degradation experienced by the connector toward the end of testing.

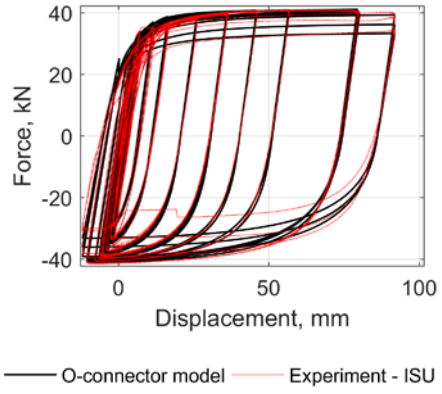

Figure 9: Comparison of force-displacement responses produced by the O-connector model and experimental data.

4.3 Initiation of rocking motion

Previous research studies that employed the Housner model for investigating free rocking motion routinely assumed that a free-standing rigid block is expected to uplift once the overturning moment produced by the ground acceleration exceeds the moment resistance of

the block, which depends on its mass and geometric properties. Considering the case of PreWEC[1], this limit is expressed as follows:

$$\frac{\ddot{u}_g}{g}+\frac{F_{LinkBeam}L_{L_1}}{Mgh}\geq\left[1+\frac{F_{PT,i}}{Mg}\right]\frac{b}{h} \tag{14}$$

with h representing the height of the gravity center of the system; and $F_{PT,i}$ is the initial post-tensioning force in the strands of the wall panel. While the above limit may accurately predict the initiation of controlled rocking of systems that can be reliably idealized as rigid blocks, its application to systems influenced by a migrating rotation center may not be satisfactory. Considering such a system at an initial rest condition being subjected to a horizontal ground motion, its imminent rotation point is unlikely to be located at its bottom corner. Hence, the moment equilibrium about this point is inapprorpiate without taking into account of the reaction forces at the wall base. To overcome this concern, the moment equilibrium may be taken about the correct rotation center, assuming that the rotation center coincides with the resultant compression force at the base.

Fig. 10 shows an example based on the PreWEC[1] model that the limiting expression in **Eq. 14** will not accurately capture when the rocking motion will initiate. The figure compares two analytical solutions established for the PreWEC[1] response assuming the aforementioned limit. The first case assumed a migrating rotation center during rocking motion as described in section 4.1, while the second case assumes that the rotation center is always located at one of the bottom wall corners (i.e., the wall is fully rigid). The corresponding experimental rotation time history is also plotted in the figure. It is seen that the two models fail to detect the beginning of rocking motion by approximately 2 seconds, while the first case predicts a significantly higher peak angular displacement response compared to the experimental observation. On the contrary, due to the higher moment resistance resulting from a fully rigid wall assumption, the second case significantly underestimates the peak displacement.

In order to tackle this issue associated with the initiation of rocking motion, the proposed model does not include a lower-bound limit for the overturning moment by assuming that the rotation center is located at the center of the wall base when the wall is at an initial rest mode. It is shown in the next section that this choice significantly contributes to accurately capturing the wall response for very small and large rotations.

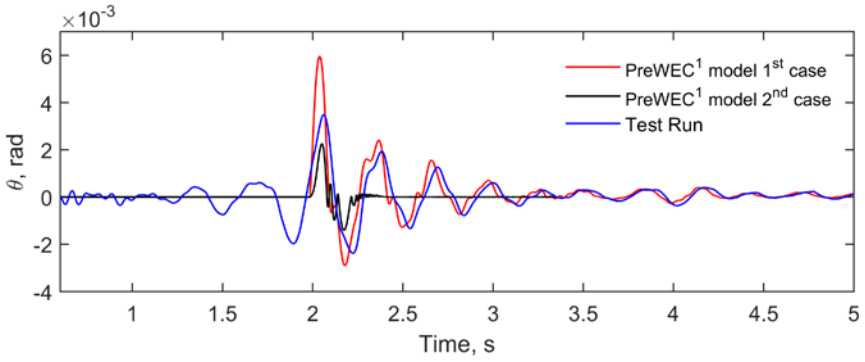

Figure 10: Measured rotation vs time of PreWEC[1] in the second input motion of Test#4 compared with analytical responses based on the limit of **Eq. 14**.

4.4 Modelling of PreWEC-1 and PreWEC-2 systems

Modelling of these systems followed the same approach as that described for PreWEC[1]. Variation of contact length in these systems was similarly estimated using the simplified

method proposed by Aaleti and Sritharan [1]. Moreover, these PreWECs used O-connectors with different dimensions and thus, the modelling rules were modified accordingly.

5 COMPARISON WITH EXPERIMENTAL RESPONSES

5.1 PreWEC[1] system

Fig. 11 presents several comparisons of PreWEC[1] model as per **Eq. 13**, with measured rotation time histories using $c_1 = 5I_o$. It is seen that the model is able to accurately reproduce the experimental responses for earthquake excitations of various intensities. Similar results were obtained with the use of the 2DOF system of **Eqs. 5-6** with suitable selections of the stiffness and damping parameters characterizing the seismic mass (i.e., $k_r = 39.63^5$ kN-mm; $c_2 = 6I_{o,b}$; $c_3 = 0.88$ kN$\sqrt{\text{s/mm}}$). These results are shown in Fig. 12.

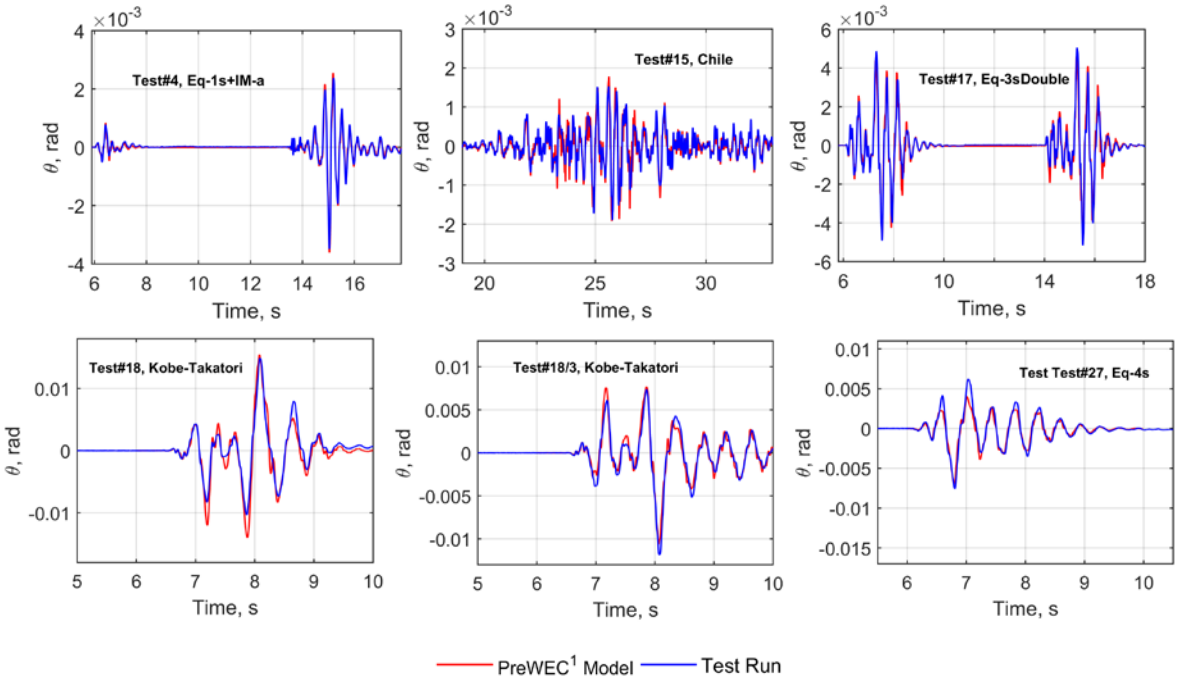

Figure 11: PreWEC[1] rotation time history responses from experimental and analytical results

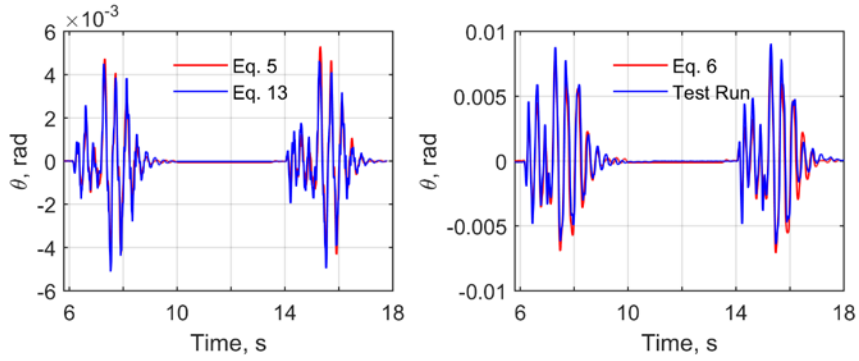

(a) (b)

Figure 12: Rotation time history responses of a) the PreWEC[1] using analytical results of **Eq. 5** and **Eq. 13**; and b) the mass blocks using analytical results of **Eq. 6** and experimental data (Test#17).

In **Fig. 13**, typical force-displacement responses are also presented for both the analytical and experimental data, showing that the numerical model can accurately follow the experimentally observed behavior.

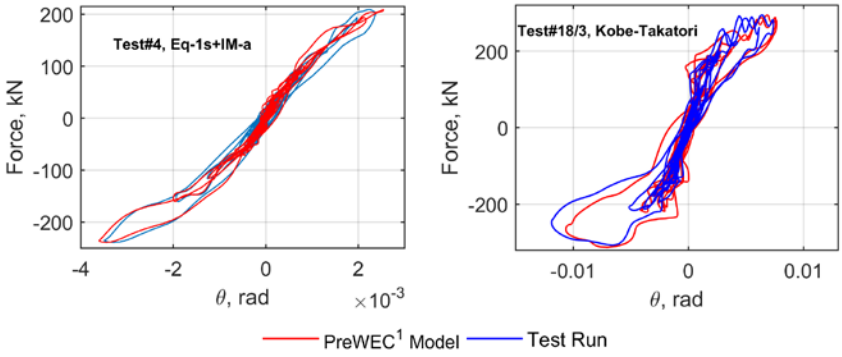

Figure 13: Comparison of force-displacement responses of the PreWEC[1] system

Finally, **Fig. 14** presents the error obtained between peak rotation responses as computed by the model of **Eq. 13** and experimental data, where positive values correspond to underestimation of the peaks while the negative peaks reflect overestimation of the peak responses. It is seen that the model is able to accurately capture the maximum responses established from the shake table tests, while the measured error remains below 10% for most of the cases. A mean value computed from all the absolute error measures was found to be approximately 5%.

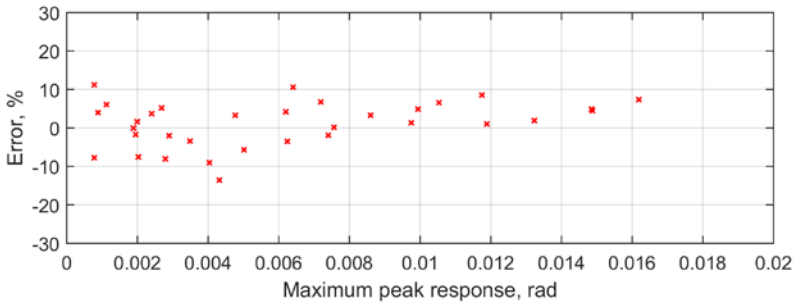

Figure 14: Estimated error for the maximum peak responses predicted by the analytical model

5.2 PreWEC-1/2 systems

Fig. 15 presents the analytical solutions for the free vibration motion of these PreWECs conducted by the model of **Eq. 13** (where $F_{LinkBeam} = 0$ and $\ddot{u}_g = 0$) using a) four, and b) six O-connectors. Note that a value of $c_1 = 2.5I_o$ was selected in this case. Also included in this figure are experimentally recorded responses. For both cases, the free vibration responses closely match measured responses.

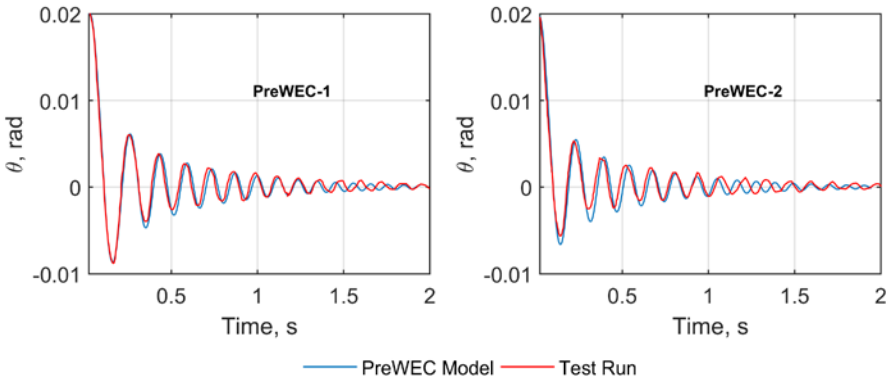

Figure 15: PreWEC-1 and PreWEC-2 Models vs experimental results of free vibration tests.

6 CONCLUSIONS

An analytical approach for estimating the dynamic response of PreWEC systems is introduced in this paper. The proposed method uses the Housner's model as the basis for developing the equation of motion, while allowing a migrating rotation center that was defined based on the contact length-rotation relationship by the Aaleti and Sritharan method [1]. Energy dissipation in the proposed model consisted of a) an impact mechanism that was expressed per the Kalliontzis et al. approach [4], b) hysteric dissipation provided by the O-connectors, and c) empirically selected continuous damping mechanisms, which additionally served as numerical damping parameters for solving the equation of motion.

Validation of the analytical model used two independent experimental investigations conducted using: a) shake table, and b) free vibration testing. Comparison with these experimental results show that the model developed for the PreWEC with hysteric energy dissipation is appropriate for both cases.

7 ACKNOWLEDGEMENTS

The work presented in the paper was undertaken as part of the "*NEES* Rocking Wall" Project with funding from the National Science Foundation (NSF) under Grant No. 1041650. The authors would like to thank Maryam Nazari, Ph.D. candidate and Lin Shibin, Postdoctoral Research Associate, both at Iowa State University, for their help with the experimental data analyses. Any opinions, findings and conclusions or recommendations expressed in this material are those of the authors and do not necessarily reflect the views of NSF.

Keywords: Rocking, Uplift, Seismic Isolation, Earthquake Engineering.

Abstract. *It has been shown that assemblies of large rocking bodies have remarkable seismic stability and minimal residual displacement. Such dynamic response characteristics make freely rocking systems desirable for their superior seismic performance, but challenging to design. In Russia and the former Soviet Union structures have been constructed with an intentionally "soft story" that comprises rocking columns able to take the seismic displacement. The uplift of the columns works as a mechanical fuse and limits the forces transmitted to rest of the structure. This paper describes an experimental investigation of the dynamic response of specimens comprising an elastic single-degree-of-freedom system fixed to a rigid beam that is rocking on rigid columns. The goal of the tests is to verify and validate the dynamic rocking model of a two-degree-of-freedom system of such rocking podium structures. The time history responses computed using the numerical model are in good agreement with the results obtained in the experimental tests. Furthermore, the model predicts both the rocking column rotations and the superstructure deformation relatively well. The prediction is better for smaller tilt angles.*

1 INTRODUCTION

Base isolation has been used for decades. It decreases the design forces of the superstructure and takes most of the displacement demand through a soft and specially designed layer between the structure and the ground. Usually this soft layer comprises either rubber or (concave) sliding bearings. Simplified models, experimental validation of them, and code provisions have resulted in the increasing use of seismic isolation.

In Russia and the former Soviet Union states another method of seismic isolation has been used. The soft layer does not comprise bearings placed under the base slab, but the entire bottom story intentionally designed as "soft". Its concrete columns are designed to uplift and sustain rocking motion during an earthquake. Thus, the design forces of the superstructure are controlled by the uplift force of the bottom story. The critical design parameters for such podium building structure are the geometric properties of the columns. Column ends are protected by steel plates to avoid concrete crushing when they uplift (Figure 1). Unlike for concave or lead-rubber bearings (which have a hysteretic form of damping that results in residual displacements) energy dissipation due to uplift and rocking is instantaneous and happens at every impact. Therefore the rocking podium system has minimal (if any) residual deformation and has a resilient behavior. Added dampers can be used to diminish the magnitude of the rocking motion. Interestingly, full-scale dynamic tests of rocking podium structures have been performed on real structures. The structures were excited using a hydraulic jack to push the structure to an initial displacement and then release it [1, 2]. It should be mentioned that this system does not rely on the size of the rocking elements for its stability, as the rocking isolation techniques proposed for solitary columns or rocking assemblies do [3–60].

The force-displacement response of concave friction-pendulum and lead-rubber bearings can be approximated by a bilinear envelope curve with positive stiffnesses. This allows for a rough approximation of the base isolated structure response using a secant stiffness linear model with viscous damping [61, 62]. On the contrary, a rocking podium structure has negative post-uplift stiffness (the restoring force decreases as the lateral displacement increases). It has been proven that these kind of systems cannot be approximated by a SDOF elastic systems and, hence, the widely used elastic response spectra are not applicable [12].

This paper presents a simplified model to describe the behavior of an elastic structure sitting on a rocking podium. The model was validated using the results from small-scale experiments performed in the Swiss Federal Institute of Technology (ETH) in Zurich, in the context of the Masters Semester project of the 2nd and 3rd author.

Figure 1: Left: Basement with rocking columns. Right: Close up of a column out of reinforced concrete. [1]

2 DYNAMIC MODEL

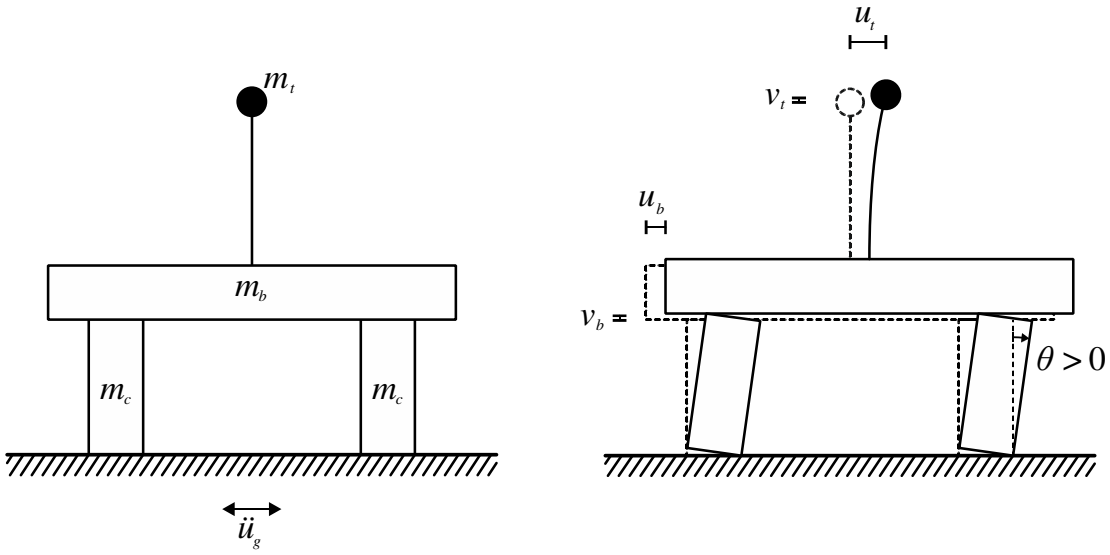

Figure 2: Dynamic model of a rocking podium structure. Left: Initial position. Right: Rocking position.

In order to gain insight into the behavior of rocking podium structure, an elementary planar analysis can be performed using a simple 2-DOF model. The parameters of the model are shown in Figure 2. It comprises two rocking columns (N = 2), one cap beam, and a SDOF system fixed to the beam. The elastic behavior of a more complex superstructure is described using an equivalent SDOF elastic system, thus neglecting any higher modes effects. The columns and the slab are assumed to behave rigidly. Two dimensionless parameters γ and η are introduced.

$$\gamma = \frac{m_b}{N m_c} = \frac{m_b}{2m_c}$$
$$\eta = \frac{m_t}{N m_c} = \frac{m_t}{2m_c} \tag{1}$$

The SDOF system on top with the mass m_t has a fixed-base natural frequency ω_s and a viscous damping ratio ζ. Using a Lagrangian formulation, the following equations of motion are obtained:

$$\ddot{u}_t + \omega_s^2 \left(u_t - u_b\right) + \ddot{u}_g + 2\zeta\omega_s \left(\dot{u}_t - \dot{u}_b\right) = 0 \tag{2}$$

$$\begin{aligned} &\ddot{\theta}\left[\gamma + \frac{I_C}{4R^2 m_c} + \frac{1}{4} + \eta \sin\left(\pm\alpha - \theta\right)\right]\frac{2R}{g} - \dot{\theta}^2\eta\left[\cos\left(\pm a - q\right)\sin\left(\pm a - q\right)\right]\frac{2R}{g} + \\ &+\left(\gamma + \frac{1}{2} + \eta\right)\sin\left(\pm\alpha - \theta\right) + \frac{\ddot{u}_g}{g}\left(\gamma + \frac{1}{2}\right)\cos\left(\pm\alpha - \theta\right) + \\ &-\frac{\omega_s^2\eta}{g}\left(u_t - u_b\right)\cos\left(\pm\alpha - \theta\right) - \frac{2\zeta\omega_s\eta}{g}\cos\left(\pm\alpha - \theta\right)\left(\dot{u}_t - \dot{u}_b\right) = 0 \end{aligned} \tag{3}$$

where I_C is the rotational moment of inertia of one column around its center of mass. The slenderness α of the column (Figure 3a) controls the magnitude of the forces transferred to the

superstructure. The ground acceleration that leads to the uplift of a single rigid column, and therefore initiates rocking motion, is:

$$\ddot{u}_{g,uplift} = g\tan(\alpha)$$
$$\tan(\alpha) = \frac{2B}{2H} = \frac{B}{H} \tag{4}$$

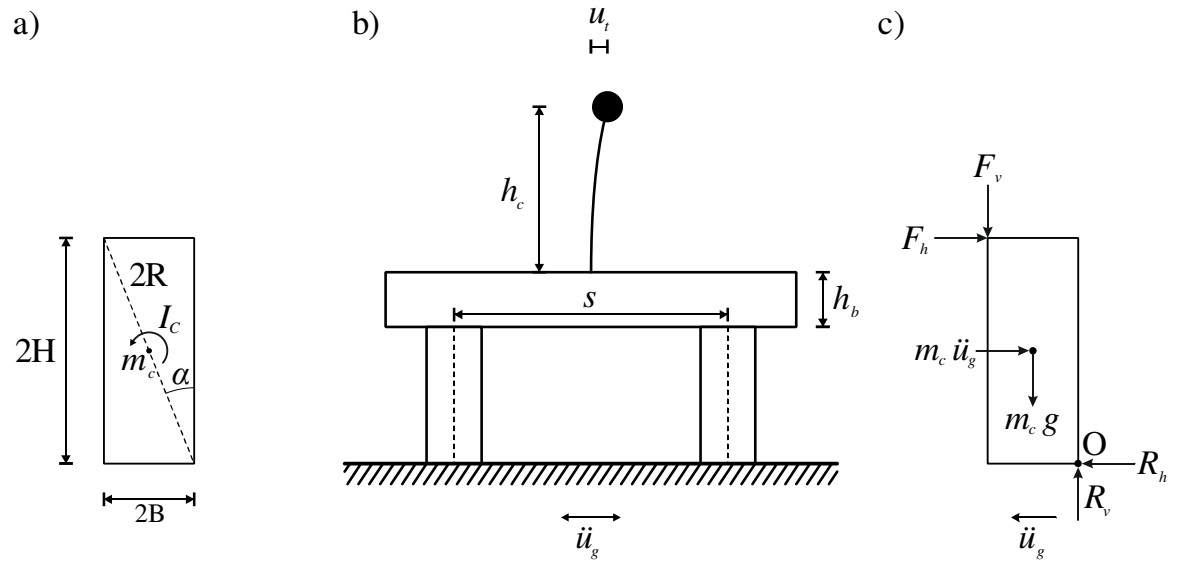

Figure 3: a) Column. b) State of the structure at incipient uplift. c) Forces at incipient uplift.

The contact forces acting on a single column right at the verge of uplift, rotating around point O, are shown in Figure 3c and given in equation (5).

$$F_h = \frac{m_t\left(\omega_s^2 u_t + 2\zeta\omega_s\dot{u}_t\right)}{2} - \frac{m_b\ddot{u}_g}{2}, \quad F_v = \frac{\left(m_t + m_b\right)g}{2} \pm \frac{m_t\left(\omega_s^2 u_t + 2\zeta\omega_s\dot{u}_t\right)\left(h_c + h_b\right)}{s} \tag{5}$$

For the model under consideration, the principle of virtual work at incipient uplift gives:

$$\delta\theta\left(Hm_c + 2Hm_b\right)\ddot{u}_g - \delta\theta\left(\omega_s^2 m_t u_t + 2\zeta\omega_s m_t\dot{u}_t\right)2H - \delta\theta\left[Bm_c + 2Bm_b + 2Bm_t\right]g = 0 \tag{6}$$

The SDOF superstructure will always start to oscillate before the columns start to rock because rocking starts only when the ground acceleration reaches the uplift limit of the podium structure. This limit not only depends on the ground acceleration $\ddot{u}_g$ but also on the actual displacement u_t of the top mass (Figure 3b). Equation (6) leads to the two following thresholds for the podium structure uplift acceleration $\ddot{u}_g$:

$$\ddot{u}_g \geq g\tan(\alpha)\left[\frac{1+2\gamma+2\eta}{1+2\gamma}\right] + \omega_s^2 u_t\left[\frac{2\eta}{1+2\gamma}\right] + 2\zeta\omega_s\left[\frac{2\eta}{1+2\gamma}\right]$$
$$\ddot{u}_g \leq -g\tan(\alpha)\left[\frac{1+2\gamma+2\eta}{1+2\gamma}\right] + \omega_s^2 u_t\left[\frac{2\eta}{1+2\gamma}\right] + 2\zeta\omega_s\left[\frac{2\eta}{1+2\gamma}\right] \tag{7}$$

Hence, the uplift acceleration for the podium structure can be higher or lower than $g\tan(\alpha)$, the uplift acceleration for a single rocking column (equation (4)).

As soon one of the thresholds in equation (7) is reached, the rocking motion of the podium structure starts. When the structure rocks back and hits the ground it is assumed to have

stopped rocking until equation (7) is fulfilled again – this could happen instantly, or not at all. There are limitations for this assumption: if the top mass is light a structure might not start rocking again in the numerical model although it could do so in reality. This, however, was not the case in the conducted experiments since only relatively top-heavy superstructures were used. A different approach is needed to model the response of rocking podium structures with light superstructures.

The model dissipates input energy through structural damping of the SDOF model of the superstructure and through rocking impacts. Since the podium structure model has two degrees of freedom, two equations are necessary to formulate the energy loss. The model proposed by Housner [63] assumes that impact happens instantaneously and that the contact forces are concentrated at the new pivot point. For a solitary column this means that the angular momentum about the new pivot point is conserved. Applying Housner's assumptions to the 2-DOF model led to the first equation. The second equation was derived by assuming that the horizontal velocity of the top mass m_t stays the same before and after impact [13, 43]. Thus, the coefficient of restitution for the 2-DOF system was derived:

$$c = \frac{\dot{\theta}_{after}^2}{\dot{\theta}_{before}^2} = \left[1 - \frac{\sin^2(\alpha)\left(2\gamma + 2\eta + \frac{1}{2}\right)}{\frac{1}{4} + \frac{I_C}{4m_c R^2} + \gamma + \eta} \right]^2 \tag{8}$$

Equation (8) can be compared to the expressions for coefficient of restitution of other, simpler, systems. With $\eta = \gamma = 0$ it yields exactly what Housner proposed for his rigid block, and with $\eta = 0$ it yields the solution of Makris and Vassiliou [39] for an array of free-standing columns capped with a free-standing rigid beam.

Uplift of the podium structure affects the vibration properties of the SDOF superstructure [7, 27, 58]. An eigenfrequency analysis reveals that there are two distinct mode shapes of the podium structure: one is overturning of the rocking frame structure with a natural frequency of 0 Hz, and the other is the vibration of the SDOF system when the rocking frame structure is uplifted. In this state the natural frequency of the SDOF $f_{s,u}$ is amplified compared to its fixed-base counterpart, f_s, and is given by equation (9):

$$f_{s,u} = \sqrt{\frac{3\gamma + 3\eta + 1}{3\gamma + 3\eta \sin^2(\alpha) + 1}}\, f_s \tag{9}$$

For top-heavy structures ($\eta \to \infty$) the amplification factor simplifies to $\sin^{-1}(\alpha)$.

3 SPECIMEN AND TEST SETUP

The 2-DOF model presented in the previous section was instantiated in the lab using two frames on top of each other, the first representing the rocking podium, and the second one representing the elastic SDOF system (Figure 4). In order to allow for replacements or improvements during the testing campaign, the specimen was screwed together. The base plate was fixed to the shake table. The material used for the specimens and the setup, apart from the steel masses on top, was aluminum (EN AW-6060).

The rocking podium structure (i.e. the first story) has a total height of 500 mm and a column slenderness α of 0.1385 rad, determined by the column width of 69.7 mm. The two 480 mm tall columns are identical, and stiff enough to be modelled as rigid. To achieve a high stiffness, each column is built out of two hollow 60 mm x 60 mm x 4 mm sections. Rectangular plates (5 mm x 50 mm x 400 mm), two at the bottom and two at the top of the columns are

used to connect the columns into a rigid frame. When rocking, the frame is assumed to rotate around the outer edges of these plates.

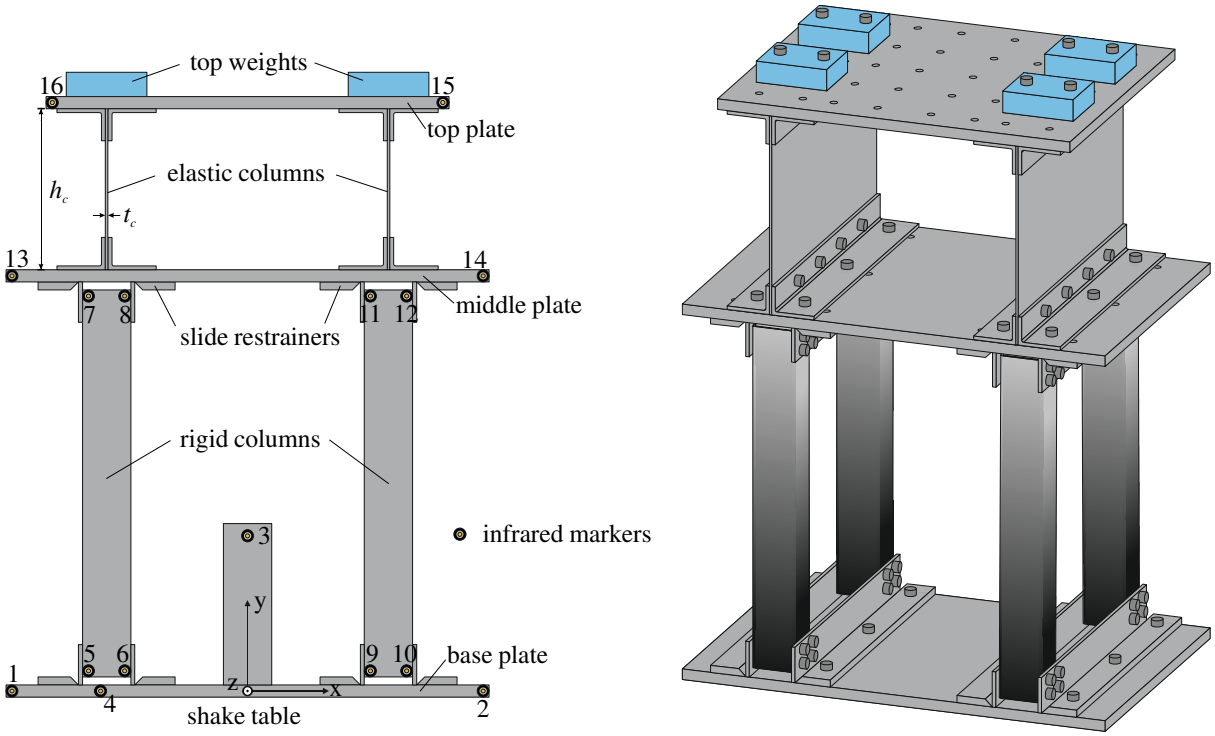

Figure 4: Left: front view of the specimen with locations of the infrared markers. Right: 3D view of the specimen.

The elastic SDOF superstructure was fixed to the aluminum plate positioned on top of the rocking columns. It comprises two elastic columns, the top plate, the top weights, and the connecting L-sections. The height of an aluminum sheet representing the elastic column is 441 mm, the thickness is 3 mm and the depth is 400 mm. The connecting extruded L sections have a length of 400 mm and a cross section of 60 mm x 40 mm x 5 mm.

Part	**Mass** [kg]	**Quantity** [-]	**Ground** [kg]	**Columns** [kg]	**Beam** [kg]	**Top** [kg]
base plate	10.96	1	10.96			
slide restrainers	0.54	8	2.16		2.16	
1 rigid column setup	3.94	2		7.88		
middle plate	11.09	1			11.09	
L section	0.56	8			2.24	2.24
1 elastic column	1.56	2			1.56	1.56
top plate	7.88	1				7.88
top weights	7.92	2				15.84
Total	65.57		13.12	7.88	17.05	27.52

Table 1: Masses of the different parts.

Table 1 shows the weights of the different parts of the experimental setup, including screws and other small parts. The mass of the elastic columns of the superstructure is evenly distributed to the top and bottom mass.

Then the mass ratios are:

$$\gamma = \frac{m_b}{N m_c} = \frac{17.05kg}{7.88kg} = 2.16$$
$$\eta = \frac{m_t}{N m_c} = \frac{27.52kg}{7.88kg} = 3.49 \quad (10)$$

3.1 Similitude Analysis

The above mentioned model dimensions were chosen so that it reproduces, as closely as possible, a typical full size prototype podium structure. The main laboratory constraint was the size of the model, which resulted in a scaling down of the rocking column length dimension by a factor of 6 (given that a typical floor would have a height of 3.0 m). The other properties of the model were chosen so that similitude is maintained. The similitude analysis between the Prototype full-scale podium structure and the Model is shown in Table 2.

Parameter	**Prototype**	**Model**
Story height	3.0 m	500 mm
Excitation frequency	f_p	$\sqrt{6}\,f_p$
Superstructure period	0.544 s	0.222 s
Mass ratio γ	2.16	2.16
Mass ratio η	3.49	3.49

Table 2: Properties of the Prototype and Model podium structures.

The fundamental vibration of the prototype superstructure was targeted to be in the range between 0.5 s and 0.6 s, chosen as typical for a 5-story masonry building. The fundamental vibration period of the fixed-base superstructure model was 0.222 s, corresponding to a fundamental period of 0.544 s for the prototype. The mass ratio $\gamma = 2.16$ (Table 1) is larger than what may be expected (as the slab weight would be much larger than the total column weight) but lower values were not possible in the lab, given that the model column had to be practically undeformable under its loads. The uplifted period was measured at 0.145 s which is 1.53 times smaller than the fixed-base natural period of 0.222 s, confirming the value that equation (9) predicts, namely 1.53.

3.2 Experimental Setup

The experimental setup is shown in Figure 5. To avoid sliding, restrainers were added to the baseplate. The green steel columns and plywood plates were used for safety reasons and to prevent the specimen from collapsing.

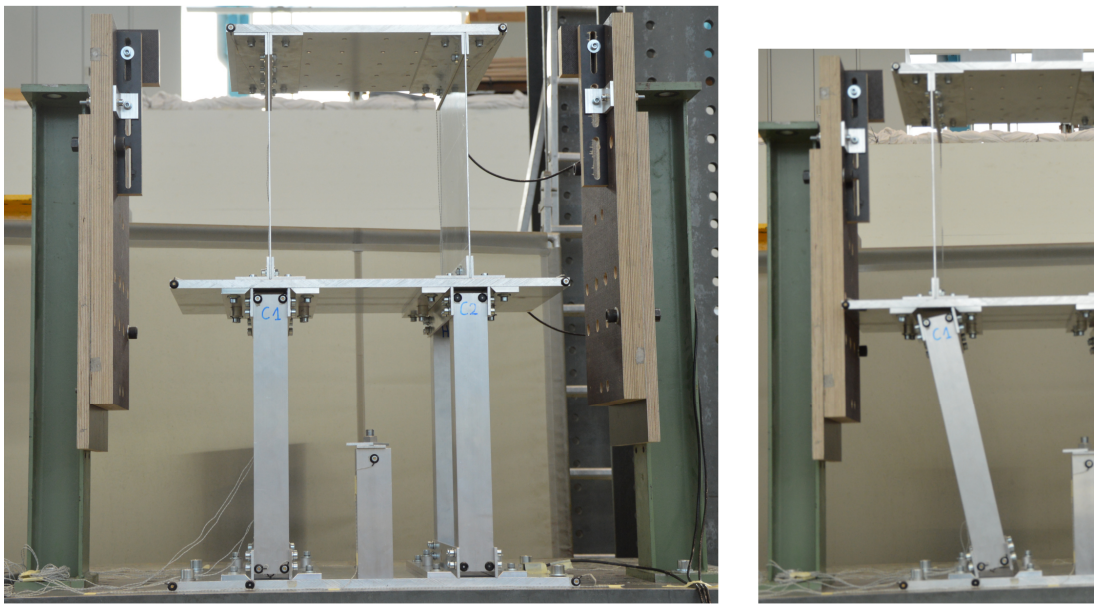

Figure 5: Left: Front view of the specimen. Right: Overturned specimen at the end of the test.

3.3 Excitation

The ETH 1-D shaking table was used to apply a base motion to the specimen. It is supported by roller bearings and actuated using servo-hydraulic actuators to move only in one horizontal direction. The stroke of the table is 250 mm, and the maximum velocity is 225 mm/s. Each specimen was tested using 12 different symmetric Ricker wavelets and 12 different antisymmetric Ricker wavelets.

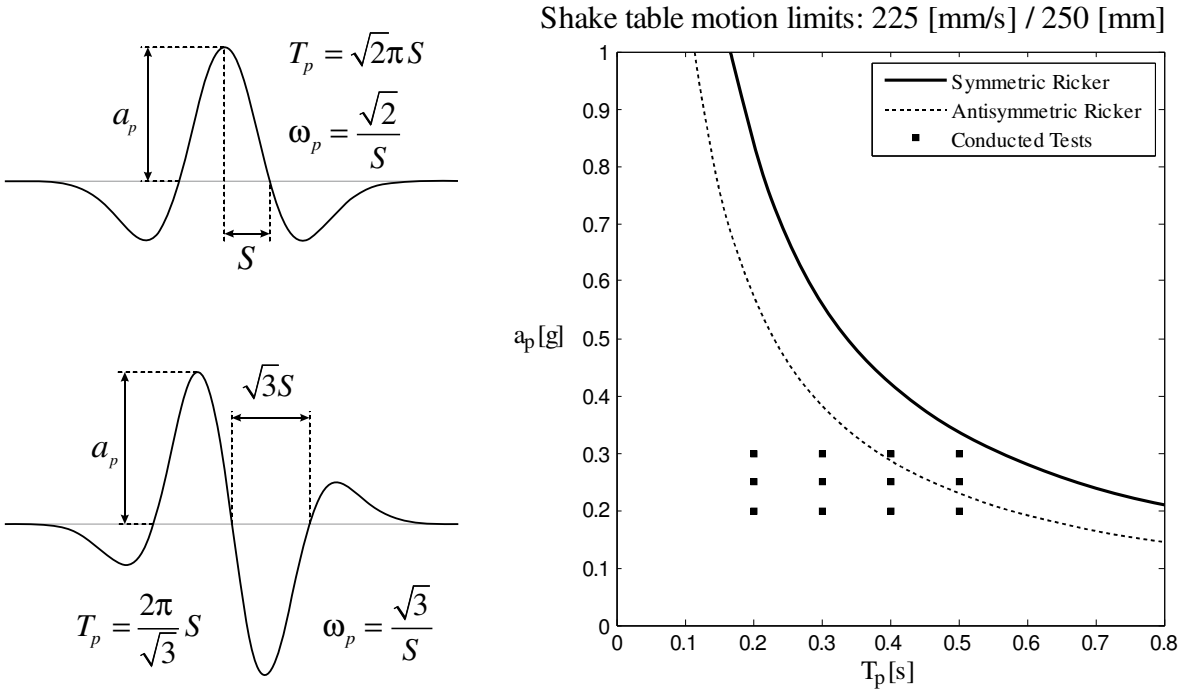

Figure 6: Left: Symmetric and antisymmetric Ricker wavelets. Right: Shake table motion limits

A Ricker wavelet approximates the main pulse of pulse-type ground motions [64]. Typical symmetric and antisymmetric Ricker wavelets are shown in Figure 6. The acceleration amplitude, a_p, and period, T_p, of a Ricker wavelet are discussed further in [33, 65]. The Ricker wavelets used in this study had acceleration amplitudes of a_p = {0.20, 0.25, 0.30}g and the pulse periods of T_p = {0.20, 0.30, 0.40, 0.50}s. At the Prototype scale these values correspond to periods of {0.49, 0.74, 0.98, 1.23}s.

For 3 out of the 24 different Ricker wavelets the shake table would reach its motion limits (Figure 6), namely the velocity limit of 225 mm/s. For our study this did not pose any problems. The acceleration and displacement output of the shake table was measured in all tests and subsequently used as input for the numerical model for comparison. Unfortunately, the shaking table reproduced the command motions with different degrees of accuracy during the test campaign, depending on the characteristics of the motion and numerous factors associated with the state of the shaking table.

3.4 Data Acquisition System

An Optotrak Certus System, manufactured by Northern Digital Inc., was used to track the position of the specimens during the tests. This system uses active infrared-emitting diodes as markers and a trinocular camera system to determine the position of the markers (Figure 4). Three markers (1, 2, 3) were placed on the shake table and parts of the specimen rigidly connected to the shake table. These markers were used to define a rigid plane; the displacements measured during the tests were relative to marker 1. Eight other markers (5-8 & 13-16) were placed on the moving parts of the specimen to measure their position. The built-in tools of the Optotrak Certus System software were able to measure angles, either in 2D or 3D, between lines defined by two markers. Lines defined by markers 1-2 and 5-7 were used to identify the rocking angle in real time during the experiments. Other output parameters were defined to show the out-of-plane behavior of the specimen, to measure the differential rotation of the middle and top plate compared to the base plate. The position sampling frequency was 250 Hz.

The accuracy of the system has been determined in previous experiments [56]. In the x- and y-directions in the plane where rocking motion takes place, the accuracy is about 0.02 mm. In the z-direction, perpendicular to the plane of motion, the accuracy is about 0.10 mm.

3.5 Experiment Outcomes and Observations

Table 3 lists the 24 tests with Ricker wavelets, numbered for reference.

No.	Excitation type	a_p [g]	T_p [s]	Exp.	Num.
1	Antisymmetric Ricker	0.20	0.20		
2	Antisymmetric Ricker	0.20	0.30		
3	Antisymmetric Ricker	0.20	0.40		
4	Antisymmetric Ricker	0.20	0.50	overturn	overturn
5	Antisymmetric Ricker	0.25	0.20		
6	Antisymmetric Ricker	0.25	0.30		
7	Antisymmetric Ricker	0.25	0.40		
8	Antisymmetric Ricker	0.25	0.50	overturn	overturn
9	Antisymmetric Ricker	0.30	0.20		
10	Antisymmetric Ricker	0.30	0.30

23	Symmetric Ricker	0.30	0.40		
24	Symmetric Ricker	0.30	0.50	overturn	

Table 3: List of tests with Ricker wavelet excitation

Typical test response is one where the frame uplifts and rocks without overturning, without out-of-plane motion, or stepping or sliding on the rocking surface, and where the superstructure SDOF vibrates in its uplifted frequency. The following deviations in specimen response were observed:

- Sliding:
  Two different types of sliding were observed. One type was sliding occurring at every impact during rocking and the other type was sliding occurring when there was no rocking. The amount of sliding during the rocking motion was small, and very difficult to detect in measured data (the transition from one edge of the rocking column to the other was usually fast and clear). Sliding while the columns were not rocking was significantly larger and could be detected in measurements. Such sliding occurs because the still-vibrating SDOF superstructure excites the podium frame, causing the relatively light columns to overcome friction at their bases and slide. Restrainers were placed near the column bases to keep such sliding to a minimum (< 0.3 mm) for small and light specimens tested in this study.
- Out-of-plane movement:
  The large number of rocking interfaces (2 rocking columns with 4 rocking edges each) accompanied by unnoticeable but still present imperfections and asymmetry caused small out-of-plane movements during a few tests, accumulating to 2 mm in the worst case.

4 COMPARISON BETWEEN EXPERIMENTAL AND ANALYTICAL RESULTS

The objective of the experimental campaign was to validate the analytical model of a rocking podium structure presented in the Section 2. The specimen was tested against 12 different symmetric and antisymmetric Ricker pulses. Figures 9-32 compare the numerical and experimental time histories of the normalized tilt angle (θ/α), the absolute and relative top mass displacement (u_T and u_T-u_B), and the accelerations of the ground, beam, and the top mass (a_{ground}, a_{beam}, and a_{top}). For the numerical solution, the measured shaking table (i.e. ground) acceleration was used as input.

Even though some tilt angle time histories were captured very well by the numerical solution, it is generally difficult to predict the entire time history correctly. Unlike elastic systems, the "period" of rocking oscillators strongly depends on their amplitude of vibration. In turn, the amplitude depends on the energy dissipated at each impact. Therefore, any error introduced grows larger, since the solution goes out of phase with the experiment. This confirms the observations of many researchers and suggests that a stochastic (rather than a deterministic) treatment of the rocking problem should be employed.

Nevertheless, for analytical pulses, where the maximum tilt angle occurs in the beginning of the time history, the matching in terms of tilt angle maxima is generally good, even though the shake table controller was not able to enforce a clear pulse motion. Figures 7 and 8 demonstrate this match by comparing the maximum tilt angles. For small absolute tilt angles ($\theta/\alpha < 0.5$) the results compare better. As the tilt angles increase, the negative post-uplift stiffness of the rocking structure affects the highly nonlinear behavior more and more, leading to larger discrepancies between the computed and measured maximum tilt angles.

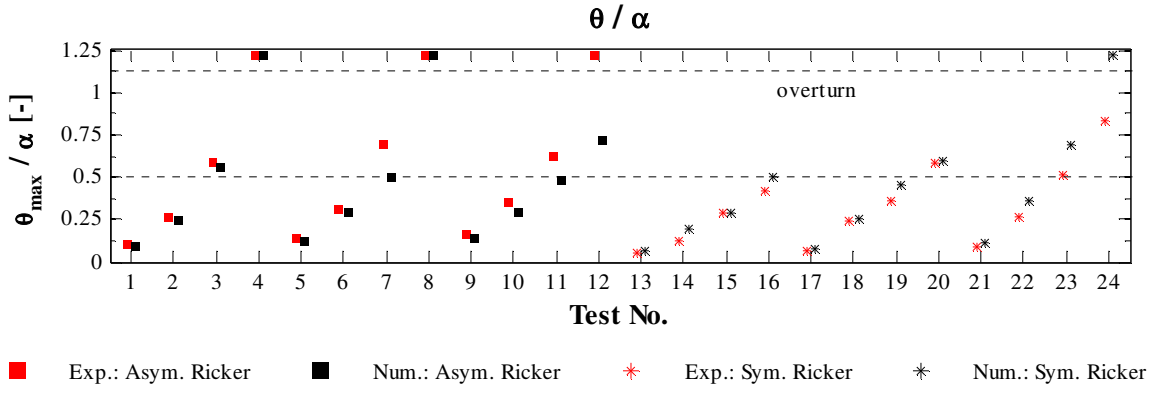

Figure 7: Comparison of computed and measured maximum normalized tilt angle θ/α

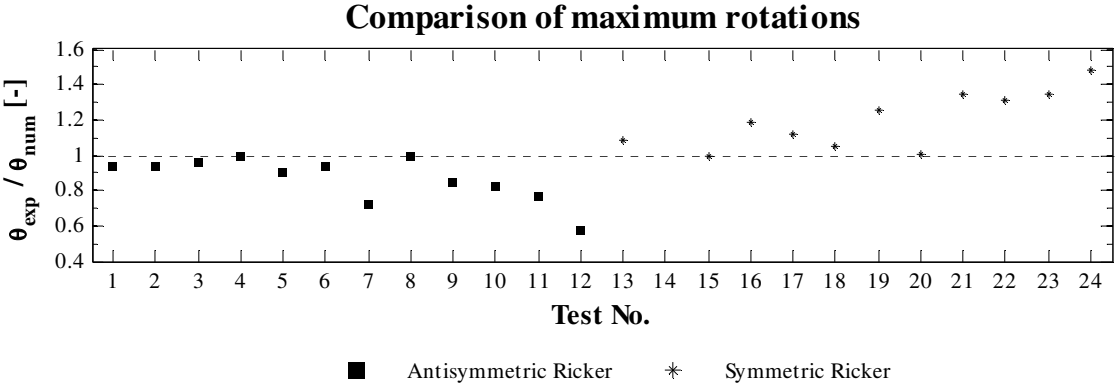

Figure 8: Comparison of computed and measured maximum tilt angle θ

The maximum superstructure deformation (u_T-u_B) is also captured quite well, with an average error of 8% (Table 4). The tests highlighted in gray were not taken into account because in these tests either the numerical and/or the experimental model overturned.

Antisymmetric Ricker			**Symmetric Ricker**		
No.	**Exp.**	**Num.**	**No.**	**Exp.**	**Num.**
[-]	[mm]	[mm]	[-]	[mm]	[mm]
1	5.03	6.09	13	4.61	4.39
2	6.48	6.20	14	5.92	6.53
3	8.27	7.49	15	8.14	7.26
4	*5.83*	*4.47*	16	8.51	7.60
5	5.93	5.82	17	5.54	4.53
6	8.79	7.77	18	6.57	6.14
7	8.63	7.51	19	8.34	7.10
8	*4.54*	*4.50*	20	7.74	7.15
9	6.46	6.16	21	6.69	5.30
10	7.83	6.49	22	8.35	6.82
11	8.55	8.40	23	8.02	7.40
12	*8.44*	*3.74*	*24*	*6.63*	*7.43*

Table 4: Comparison of computed and measured superstructure deformation u_T-u_B [mm]. Overturning occurred in tests highlighted in gray.

The recorded motions of the top mass and have a pronounced high frequency component. This component is attributed to the rocking impacts. It cannot be captured by the analytical model, since the impacts excite higher modes of vibration which are not taken into account in the analytical model.

5 CONCLUSIONS

A small-scale model of a rocking podium structure was constructed and tested. A 2-DOF analytical model of a rocking podium structure was derived and verified and validated against the test results. The computed responses compare well to the test results in terms of the maximum tilt angle and peak superstructure deformation, as well as in terms of the eigenfrequency of the superstructure in the uplifted state. The computed and measured response time histories generally do not match equally well because rocking motion is very sensitive to imperfections at the rocking surfaces, imperfections in the specimens and errors in applying the excitation. The above observation urges for a probabilistic treatment of the rocking problem.

Abstract. *Following the work by Psycharis [1], in this paper we study the dynamic behavior of a rocking block resting on an elastic Winkler-type foundation for the out-of-plane seismic assessment of masonry walls. The equations of motion are derived and implemented for the simple smooth-rocking block and the calibration of the Winkler-type foundation stiffness is carried out according to the experimental results available in the literature. The dynamic response under natural seismic records is evaluated and the effect of the stiffness on the overall response is analyzed for different natural accelerograms. Both demand and capacity are calculated with reference to the kinetic and potential energies of the system and different intensity measures are considered with the aim of identifying the most representative one for the rocking motion. Finally, a comparison between non-linear time history analyses and a possible energy-based approach is discussed.*

1 INTRODUCTION

The out-of-plane rocking of masonry walls is the most recurrent mechanism triggered by earthquake shocks in historical constructions. This is why, increasing interest is shown in the study of this type of mechanism for the purpose of predicting existing buildings responses during a seismic event. Even though this behavior is complicated to capture, it is seen that could be well represented by means of a single degree of freedom oscillator. This simple approach has been often preferred to more complex models, which, while having greater chance to better grasp the response, may present inherent difficulty in the choice of inputs parameters.
The first major study on the behavior of slender structures subjected to rocking motion was carried out by Housner [2] in the well known “The behavior of inverted pendulum structures

during earthquakes". He described the rocking motion with a model that included a linear force-displacement relation for the block and damping concentrated at impacts. Thanks to this simple but powerful approach, which proved able to reproduce the main feature of rocking behavior, Housner was the first to point up that a gravity structure can exhibit significant capacity towards overturning by tilting/rocking. Recently it has been demonstrated that the same model may be extended also to study the response of a wider set of mechanisms developed by masonry constructions (Mauro et al. [3]). After Housner fundamental study, many other authors have defined different force-displacement relationships for describing the motion of the block from the triggering of the mechanism until the out-of-plane collapse. In 2002 Doherty et al. [4] presented a trilinear curve used to reproduce the nonlinear force–displacement relationship obtained experimentally for unreinforced brick masonry walls. In Shawa et al. [5], starting from existing rocking models, a new three-branch model is formulated which takes into account the asymmetry resulting from the restraint provided by transverse walls and the out-of-plumb of the block. Ferreira et al. [6] proposed a simplified analytical approach based on a linearized four-branch model used to characterize the response of stone masonry s*acco* walls in terms of overturning moment-rotation relationship. The models adopted so far in literature proved able to reproduce the rocking of masonry blocks tested in laboratory. Nevertheless, their main drawback depends on the fact that, in order to increase the accuracy, the number of parameters is increased and that these parameters may lack a physical meaning.

In this paper, a smooth single degree of freedom model is presented for reproducing the rocking behavior of masonry walls. With respect to the Housner model, only one parameter is added which consists in the stiffness of the foundation represented with a set of unilateral springs.

2 GENERAL FORMULATION OF THE PROBLEM

As mentioned before, the most known rocking block in literature is the one developed by Housner [2] that can only oscillate alternatively around the two pivot points O and O' (Figure 1, a). Therefore it is assumed that the static friction coefficient between the block and its base is high enough for sliding to be negligible, verified hypothesis for adequately slender objects.

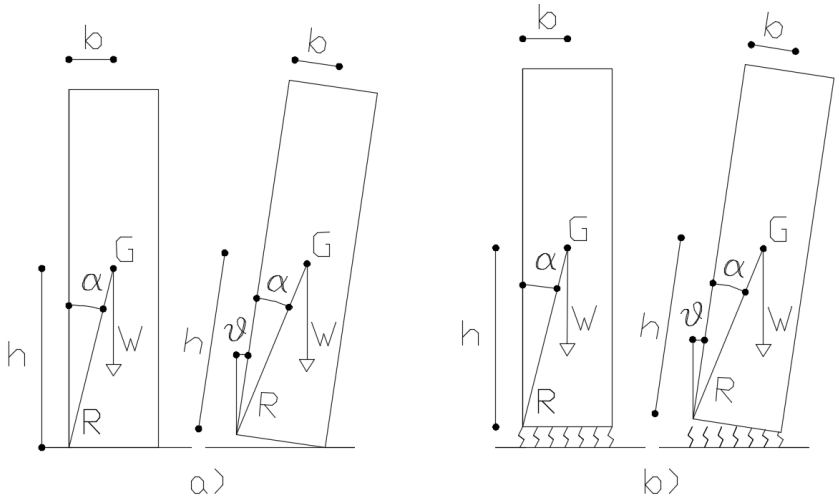

Figure 1. Comparison between the rigid model (a) and the smooth-rocking model (b).

This inverted pendulum has only one degree of freedom, the tilting angle θ from the vertical position and its motion under a horizontal ground acceleration $\ddot{u}_g$ can be described by equation 1. The significant parameters are the moment of inertia of the block I_0 about the point 0, the restoring moment M_R, that depends on wall geometry and self-weight W=g m, and the ground acceleration $\ddot{u}_g$. Symbols are depicted in Figure 1.

$$I_0\,\ddot{\theta} + \; M_R(\theta, sign(\theta)) = -m\,\ddot{u}_g R\,cos(\alpha\,sign(\theta) - \theta) \tag{1}$$

The block will initiate rocking only if the ground acceleration is greater than a threshold value depending on its slenderness α. During rocking, motion is interrupted by subsequent impacts at the pivot points with consequently dissipation of energy [7]. In this paper, such phenomenon is treated as in Housner [2], by reducing the angular velocity when the block passes the resting position, as shown in eq. (2).

$$\dot{\theta}^{+} = \eta\,\dot{\theta}^{-} \tag{2}$$

where $\dot{\theta}^{+}$ and $\dot{\theta}^{-}$ are the angular velocities before and after impact, respectively. The equation of motion (1), together with the impact treatment, equation (2), have been implemented in Matlab R2015b and integrated numerically using a Runge-Kutta algorithm with integration step and tolerances sufficiently appropriate to guarantee an adequate accuracy of the solution.

2.1 The smooth-rocking moment-rotation relationship

Various experimental evidences ([4]) have shown that the actual response of masonry walls loaded out-of-plane may be far different from the rigid (bilinear) moment-rotation relationship assumed by Housner [2]. More precisely, when dealing with brick or stone masonries, a smoother response has been observed ([6]). In this paper, in order to better simulate the actual behavior of masonry walls, a smooth restoring moment-rotation is obtained by considering a rigid block resting on a Winkler-type foundation (Figure 1b). This approach makes it possible to introduce only one additional parameter with respect to those defined by Housner, precisely the stiffness k of the springs on which the wall is resting.
The equations relative to the Winkler-type foundation, derived in Shawa et al [6] for the case of one-sided rocking, are here reported for the two-sided case (eq. 3) where M_R is the restoring moment, θ_{cr} is the relative rotation corresponding to lift-off of the block, the other symbols have the same meaning as in Housner [2] (Figure 1b).

$$M_R = WR\,sin(\alpha\,sign(\theta) - \theta) - Wb\,sign(\theta) + \frac{2}{3}\,k\,b^3\theta \qquad for\ \theta \le \theta_{cr}$$

$$M_R = WR\,sin(\alpha\,sign(\theta) - \theta) - \frac{1}{6}\,k\,\theta\sqrt{\left[\frac{2\,W}{k\,\theta\,sign(\theta)}\right]^3} \qquad for\ \theta > \theta_{cr} \tag{3}$$

$$\theta_{cr} = \frac{W}{2b^2k}$$

The vertical component of the displacement is neglected during the motion of the block and the rotations instead are considered sufficiently small. In order to model the inability of the ancient mortar to sustain tensile stresses, it is assumed that the block is just resting on the springs, without any bond between them. In particular, the moment-rotation curve presents two fictitious branches corresponding to the case where the coupling of the springs is perfectly reagent ($\theta \leq \theta_{cr}$), and the case where contact is lost in one of the base edges and a limited portion only of the base section is reacting ($\theta > \theta_{cr}$).

In Figure 2 the moment-rotation relationship for a block having 2b = 0.25 m and 2h = 3 m and a specific weight of 12.06 kN/m^3 is presented, comparing the results for different values of the stiffness k. For finite values of k, a linear behavior is exhibited until $\theta \leq \theta_{cr}$, then the response suddenly curves to the maximum allowable restoring moments and then goes to an almost linear branch with negative stiffness until the ultimate rotation is reached. Noteworthy, the maximum rotation the block can bear without overturning is not reached for $\theta = \alpha$ as in the Housner [2] oscillator but it also depends on the stiffness of the springs and is derived here numerically starting from equation 3b). When the foundation springs are very stiff, the block is expected to behave as if it was rocking on a rigid foundation, therefore, for $k \rightarrow \infty$, the second branch of the restoring moment-rotation curve ($\theta > \theta cr$) tends to WR sin($\alpha - \theta$) and the first branch tends to infinity in the vertical direction.

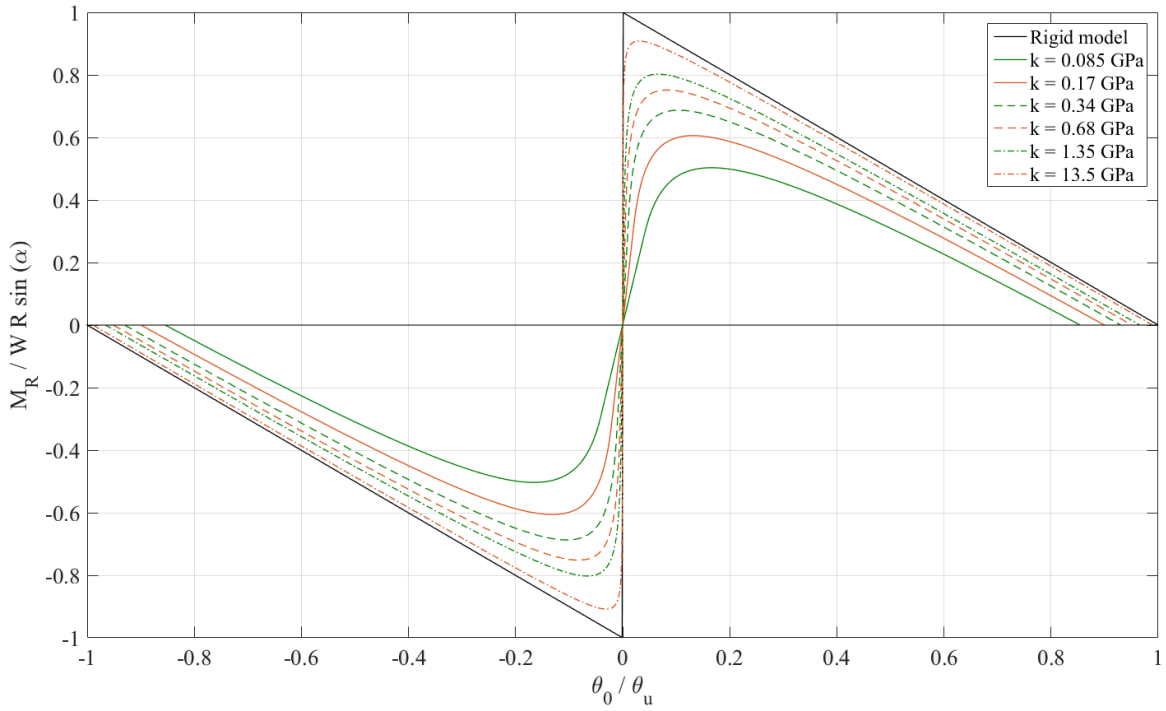

Figure 2. Moment rotation variation for different stiffness values.

It is worth underlining that the curves represented in Figure 2 by varying the values of k resemble those obtained by de Felice [8] for multi-leaf walls exhibiting failure for disaggregation because of the absence of connection throughout the thickness of the wall. Accordingly, the introduction of the parameter k would make it possible to fictitiously account for any losses of monoliticity of the wall by reducing its restoring moment and ultimate displacement capacity.

The free oscillatory motion of a block occurs with a period which, as known, is a function of the maximum angle of rotation that is reached during the motion. In Figure 3, there are shown the values of the period of a block, obtained numerically according to the maximum rotation θ_u referring to different value of stiffness k. For initial rotation $\theta_0 < \theta_{cr}$ the period T is constant and corresponds to oscillations without partialization of the base joints. When approaching the overturning rotation periods tends to infinity.

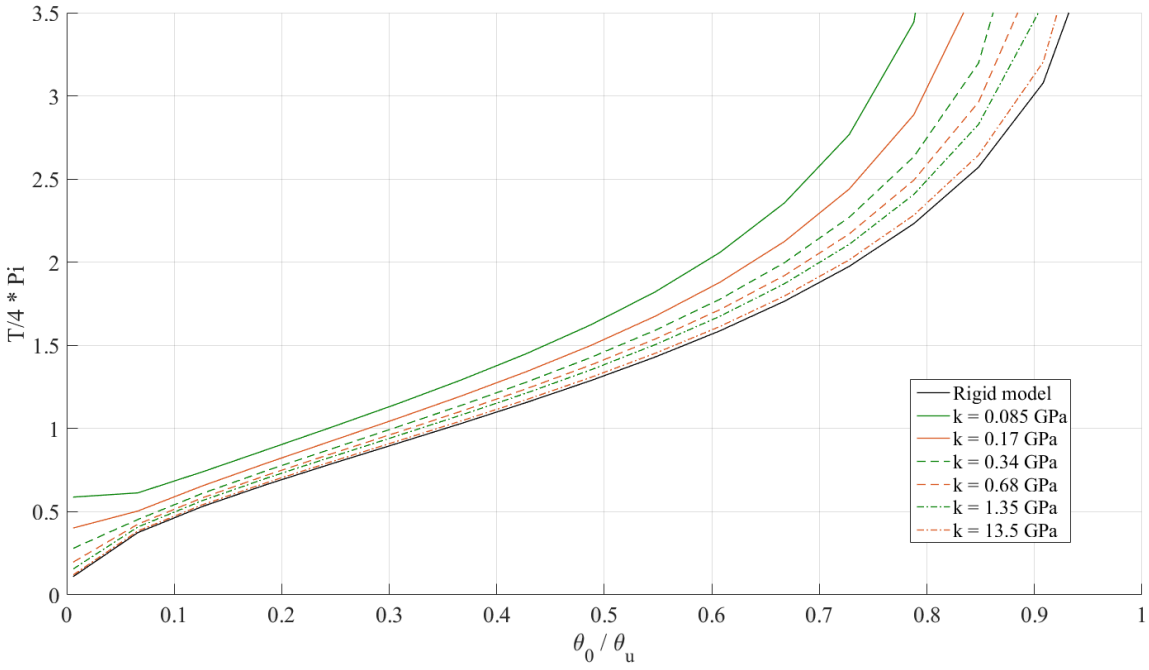

Figure 3. Period T of block laying in different stiffness layer rocking with amplitude θ_0.

3 CALIBRATION OF THE STIFFNESS K BASED ON EXPERIMENTAL DATA

The equations of motions (eq. 3 and eq. 2) have been implemented in Matlab R2015b and integrated using the ode solver. Different integration options have been considered in order to better evaluate the response of the block. Aiming at investigating the feasibility of the proposed approach some comparisons with experimental data are briefly reported.

3.1 Static tests

The first comparison is made with respect to the experimental results presented by Ferreira et al. [6] which have performed static tests on six full-scale (1.3m x 0.65m x 2.50 m) unreinforced regular *sacco* stone masonry specimens subjected to horizontal out-of-plane loading and three different vertical loadings N. Here are compared the results of the wall without force on the top (N = 0 kN) undergoing a uniform pressure applied by means of an airbag. Among the others setups tested, the wall selected exhibited a cracking pattern which is more in line with the assumption made in the present work, *i.e* characterized by a single crack at the base, while the other tests yielded to a bending-rocking pattern. The results reported in Figure 4, confirms that the proposed approach is able to fit reasonably well the response of a masonry wall undergoing static overturning forces. The image representing the cracking pattern is taken from [12].

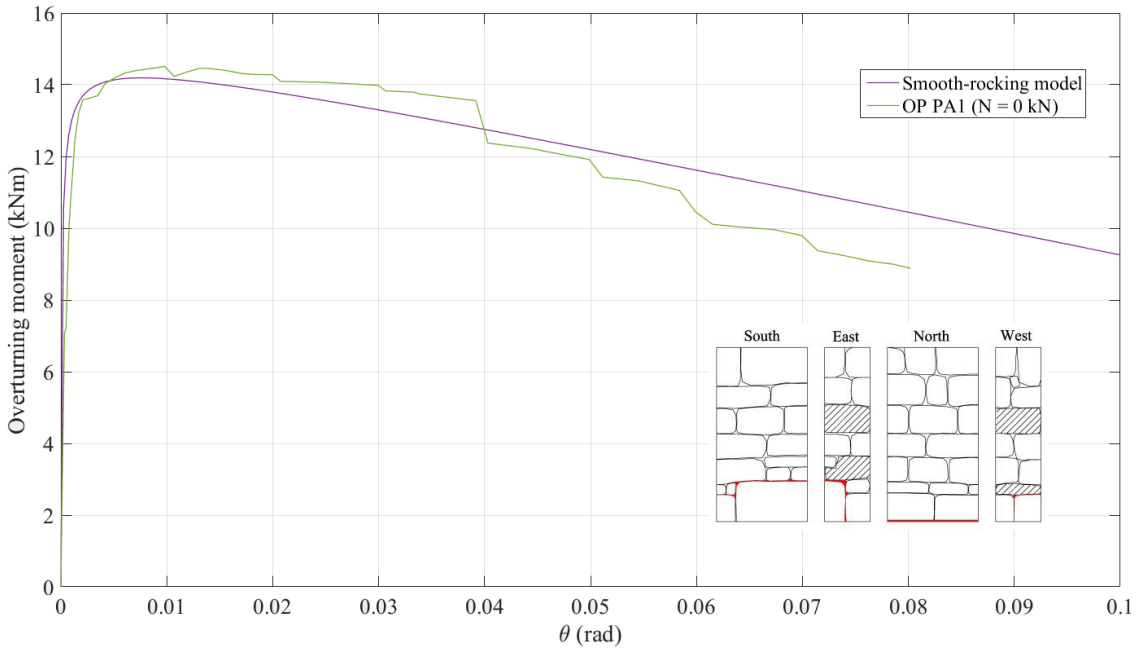

Figure 4. Overturning moment-rotation curves for airbag tests compared to the smooth model.

3.2 Dynamic tests

El Gawady et al. [9] performed some free rocking experimental tests of walls rocking on foundations made of different materials. Each block was initially tilted to an angle θ_0, held still, and then released with zero angular velocity at time t = 0, thereafter rocking back and forth freely. In order to validate the equations of motion derived for free vibrations, we are comparing here the results for three different interface material: concrete, 4-layer rubber and timber for a block with aspect ratio 5. The parameters to calibrate for fitting the curves are two: the stiffness k and the coefficient of restitution η because they both depend on the foundation material. The parameter k has been calibrated referring to the half-period – rotation graphics starting from typical stiffness values for each interface material. Then the coefficient of restitution η is calibrated in order to better fit the rest of the experimental data. The results in figure 5 demonstrate that the proposed model can fit rationally well the free vibration of blocks resting on foundation made by different materials.

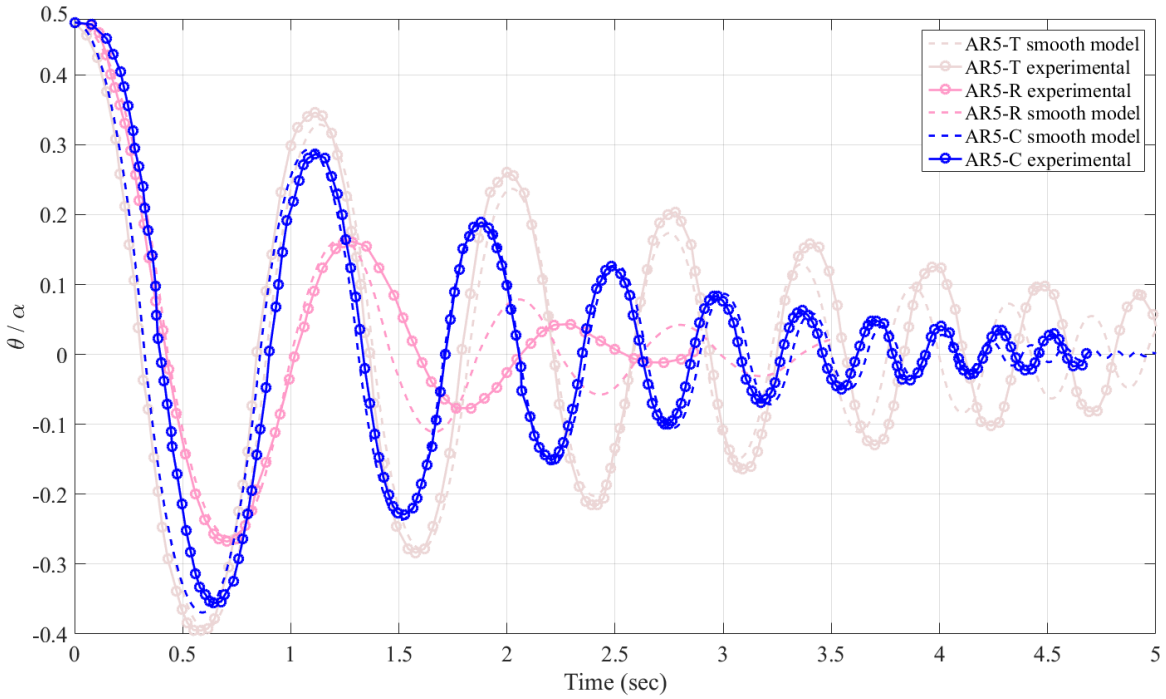

Figure 5. Comparison between experimental results and smooth model free oscillations on different interface material.

4 ASSESSMENT STRATEGIES FOR THE SMOOTH-ROCKING BLOCK

For the purpose of understanding how actual walls behave during the rocking motion, in this section we compare the non-linear time-history analyses of the smooth-rocking block with Italian code-procedures [10] and a possible energy-based approach [11]. Given the strong numerical integration sensitivity, a parametric analysis varying from time to time the accelerograms is performed. The latter varies in a purely random way by multiplying both the time-axis and the acceleration-axis with random coefficients belonging to a normal distribution having 3% coefficient of variation and unity mean [5]. Four walls, having (2b, 2h) = (0.125, 1.5), (0.20, 3.0), (0.25, 3.0), (0.375, 3.0) m, are considered. The four accelerograms of table 1 are used, whose amplitudes are scaled with ten coefficients varying from 0.2 to 2.0.

Earthquake	Year	Mw	Station	Soil type	Record	PGA (g)	PGV (m/s)
Irpinia	1980	6.9	Bagnoli Irpino	A	BagnirWE	0.167	0.377
Umbria-Marche	1997	6.0	Nocera Umbra	B	R1168EW	0.438	0.280
Irpinia	1980	6.9	Calitri	B	CalitWe	0.181	0.317
Irpinia	1980	6.9	Sturno	B	SturWE	0.313	0.700

Table 1: Accelerograms selected to perform numerical analyses.

From each dynamic analysis an energy demand/capacity ratio, ED/EC, is obtained as originally proposed by Shawa et al. [5] for the rigid model while closed form solution equations are derived for the smooth model. In particular, the capacity EC is evaluated as the area underneath the restoring-moment – rotation curve and differs from block to block (Fig.

6b). The demand ED is evaluated as the maximum potential energy recorded during the motion if $\theta < \theta_u$, or otherwise, as the sum of potential and kinetic energies evaluated at $\theta = \theta_u$. Moreover, a reduced coefficient of restitution, $\eta = 0.85$, which multiplies angular velocity before impact to give angular velocity after impact, is used, based on experimental results. Each *dot* in the following figures represents the median demand/capacity ratio out of one hundred time histories, in order to account for the scatter of the response. A total of 16 000 time history analyses have been performed.
The demand/capacity ratio of the smooth-rocking block is then compared with force-based and displacement based procedures. In particular, for the force-based assessment procedure it is checked ED/EC in comparison to PGA/($2a_0^*$) where PGA is the Peak Ground Acceleration, 2 is a behavior factor and a_0^* is defined in equation 4, where λ_0 is the static collapse load multiplier of the mechanism at rest and its value is calculated as tan(α), while $e^* = 1$ defines the participating mass and CF = 1 is a confidence factor.

$$a_0^* = \frac{\lambda_0 g}{e^* \, CF} \tag{4}$$

As far as regards the displacement-based procedure, the comparison is made between the demand/capacity ratio and the fraction between the spectral demand evaluated for the secant period $S_{De}(T_s)$ and the displacement capacity d_u^*.

Then, a possible energy based verification is considered as initially introduced by Sorrentino et al. in [11]. In this case, the verification is satisfied if the kinetic energy KE, multiplied by 2, is not larger that the area below the skeleton moment-rotation curve (E0) of the rigid block. The kinetic energy of the system is defined considering instead of the translational velocity v, the Peak Ground Velocity (PGV) of each accelerogram reported in table 1. Bearing in mind that the block motion is rotational, its kinetic energy depends on the angular velocity $\dot{\theta}$ instead of the translational one.
The first comparison is made between the smooth block and the rigid one in terms of demand/capacity ratios (Figure 6). As it can be seen from the graph, the smooth model is probably more realistic since it reacts even in the field of small oscillations differently from the rigid block that starts rocking only if it is exceeded a certain threshold. Moreover the smooth model is less conservative as it has a smaller capacity as also shown in Figure 6b) which compares the various capacity curves between the four block studied, normalized with respect to block 4.

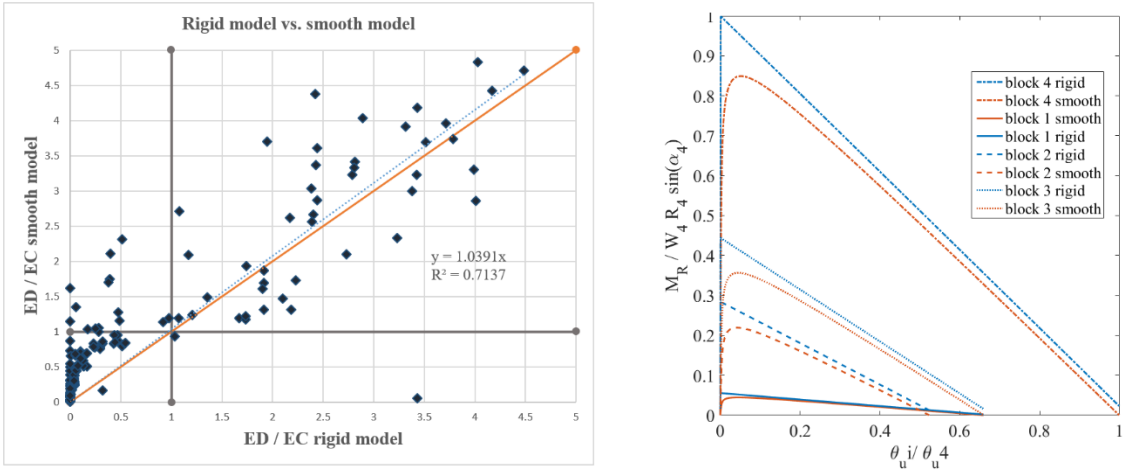

Figure 6. Comparison between the smooth and rigid model in terms of demand/capacity ratios (a) capacity curves for the four blocks considered (b).

In the following, the behavior of masonry walls subjected to out-of-plane loads predicted by the proposed model is compared to the one predicted by the force-based (fig. 7a) and displacement-based procedures (fig. 7b) reported in the Italian code [10]. The discussion of the results is made in terms of conservativeness of the procedure and scatter of the response, measured through the coefficient of correlation R^2 for a linear regression passing through the origin. When neglecting the results in which the block overturns for both numerical analysis and code-based procedures, force and displacement-based approaches seem very conservative while the energy-based approach (see fig. 8) seems less conservative also showing a slightly less scatter response. Currently there is a considerable scatter between non linear numerical analyses and simplified approaches models offset by adequate safety margins. This confirms the fact that the non-linear analysis prove valuable for a more physical representation of the phenomenon and also that the accuracy of the predictions using linear elastic spectra for rocking structures will always be very limited [13].
Anyway, further numerical analysis, considering a wider range of signals and blocks, should be done to better assess the level of reliability of the approaches proposed in the Italian code [10].

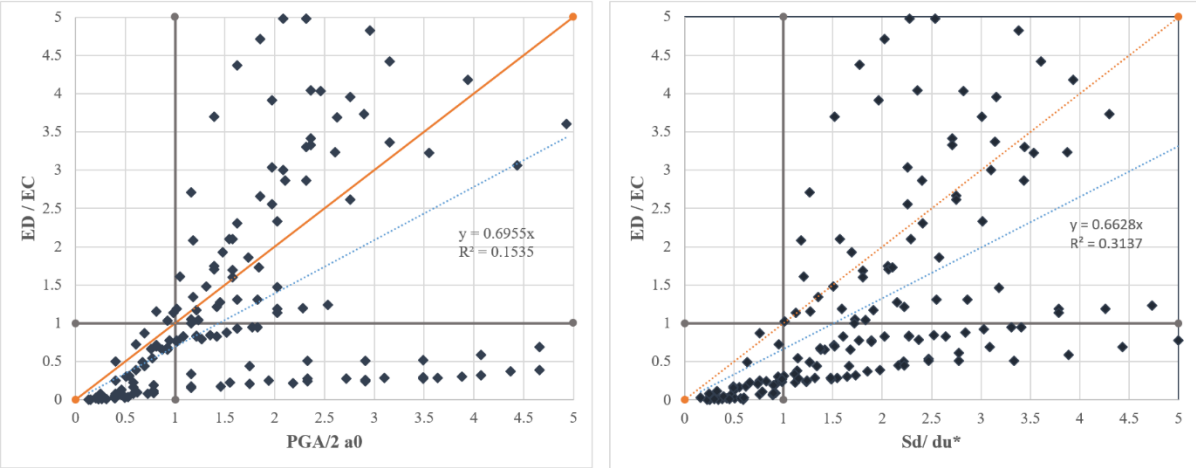

Figure 7. Comparison between the smooth model and code demand/capacity ratios (a) force-based and (b) displacement-based.

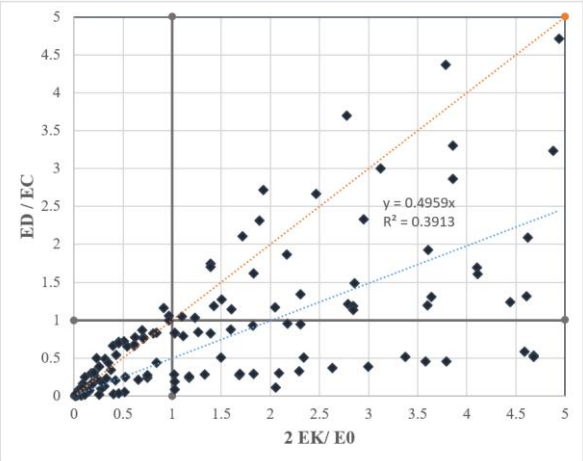

Figure 8. Comparison between the smooth model and the energy-based approach.

5 CONCLUSIONS

- In this paper, a smooth moment-rotation relationship for describing the response of a block subjected to rocking motion is presented and the most significant aspects of its behavior have been highlighted.
- The replicated experimental tests have evidenced that the model is able to capture quite well the skeleton curve of the block in static conditions and the response under free oscillations, taking into account the stiffness of the foundation.
- Preliminary results suggest that the model may be able to be adopted for simulating the behavior of walls with loss of monoliticity, but this issue should be still addressed in detail.
- Comparing the results of the parametric analysis in terms of energy based ratios between the rigid and smooth block, it seems that the latter could be a good model to describe the behavior of rocking structures given that it reacts also in the field of small oscillations. Further numerical analysis should be done to better assess the reliability of code approaches.

Keywords: Rocking structures, Earthquake Engineering, Experimental Testing, Uplifting Structures

Abstract. *Rocking modifies the seismic response of structures, because uplifting works as a mechanical fuse and limits the forces transmitted to the structure. However, the engineering community is in general reluctant to let a structure uplift because it can overturn, and, more important, an unanchored structure has no redundancy against this failure mode. Using a safety factor for the design of a flat rocking foundation (i.e. designing it larger than minimum required to prevent overturning) goes against the essence of the rocking seismic isolation method, as the structure would end up behaving as fixed to the ground. To protect against overturning but preserve the ability to uplift we propose to extend the flat rocking foundation using curved wedges at its ends. This paper presents the results of dynamic tests of small bodies rocking on curved foundations. The results compare relatively well with the analytical solutions, but they are shown to be very sensitive to the coefficient of restitution.*

1 INTRODUCTION

Since Housner published his seminal paper [1] on rocking of rigid blocks, a plethora of studies on uplifting structures has been published [2-60]. The remarkable property of rocking blocks is that, for a given height to base slenderness ratio, they become more stable as their size increases. There are even cases when out of two columns with the same base, the taller one survived an earthquake while the shorter one did not [60]. It has also been proven that the presence of a cap beam atop of rocking columns, like in the case of the ancient Greek and Roman temples, increases the stability of the system [12, 38, 46]. These results have led researchers to propose rocking as a seismic isolation technique, as the uplift works as a mechanical fuse and limits the forces transmitted to the structures. However, even though some rocking structures have been built in New Zealand [2, 5], the former Soviet Union and Russia [63] and Greece [64], practicing engineers are generally reluctant to apply this method. One reason for that is the lack of codes and simplified methods of analysis. However, this reluctance also stems on the inherent fear of engineers to design unanchored structures that may overturn. Engineers are used to the safety factors, where all the material, geometric, modelling and loading uncertainties are "hidden".

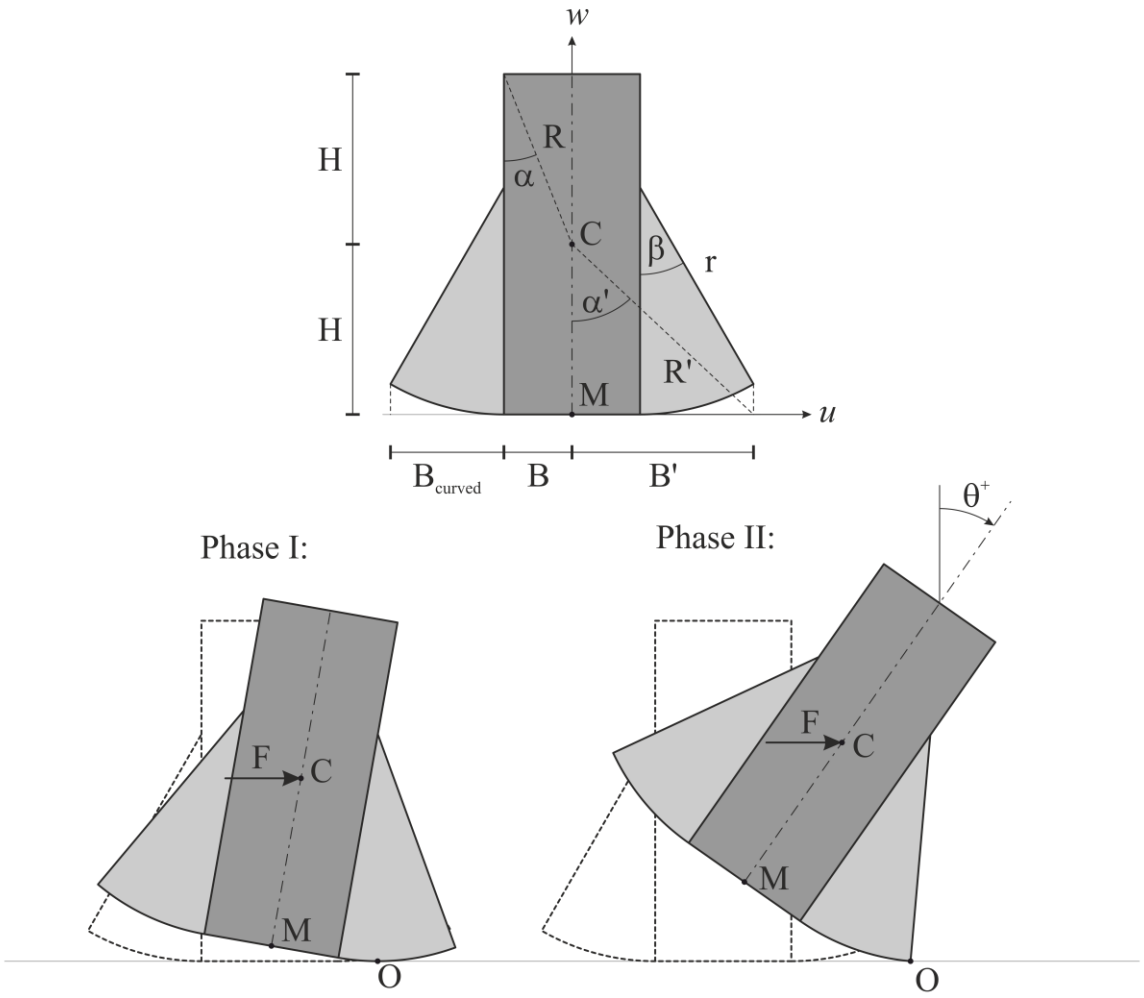

Figure 1. Top: Rigid block with curved wedges - resting position [65]
Bottom: Rigid block with curved wedges - Phase I (rolling) and Phase II (rocking)

In the case of rocking foundations, when it comes to overturning "resistance", the application of a safety factor would simply mean that the foundation should become larger. This goes against the essence of the rocking seismic isolation method, as the structure would end up behaving as fixed to the ground. To protect against overturning but preserve the ability to uplift we propose to extend the flat rocking foundation using curved wedges at its ends [65] (Figure 1). This paper presents the results of dynamic tests of small bodies rocking on curved foundations. The tests were performed in the ETH Zurich within the semester project of the second and third author. The results compare relatively well with the analytical solutions, but they are shown to be very sensitive to the coefficient of restitution.

2 REVIEW OF THE ROCKING RESPONSE OF A RIGID BLOCK.

With reference to Figure 2 and assuming that the coefficient of friction is large enough so that there is no sliding, the equation of motion of a rocking block with size $R=\sqrt{h^2+b^2}$ and slenderness α = arctan(b/h) for rotation around O and O' respectively is (Yim et al. [3], Makris and Roussos [9], Zhang and Makris [10] among others)

$$I_O\ddot{\theta}(t)+mgR\sin\left[-\alpha-\theta(t)\right]=-m\ddot{u}_g(t)R\cos\left[-\alpha-\theta(t)\right],\quad \theta(t)<0 \tag{1}$$

$$I_O\ddot{\theta}(t)+mgR\sin\left[\alpha-\theta(t)\right]=-m\ddot{u}_g(t)R\cos\left[\alpha-\theta(t)\right],\quad \theta(t)>0 \tag{2}$$

Where I_o is the moment of inertia of the block around the pivot point.

For rectangular blocks, $I_O=(4/3)mR^2$, and the above equations can be expressed in the compact form

$$\ddot{\theta}(t)=-p^2\left\{\sin\left[\alpha\,\mathrm{sgn}\left(\theta(t)\right)-\theta(t)\right]+\frac{\ddot{u}_g}{g}\cos\left[\alpha\,\mathrm{sgn}\left(\theta(t)\right)-\theta(t)\right]\right. \tag{3}$$

The oscillation frequency of a rigid block under free vibration is not constant, because it strongly depends on the vibration amplitude (Housner [1]). Nevertheless, the quantity

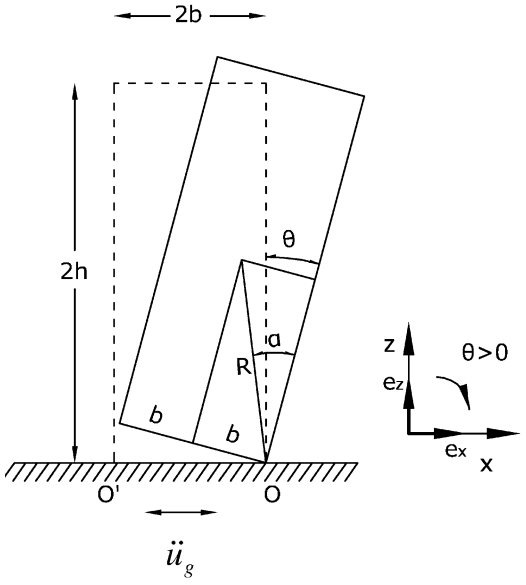

Figure 2. Geometric characteristics of the rocking body model

$p = \sqrt{\frac{3g}{4R}}$ is a measure of the dynamic characteristics of the block. For the 2.0m×0.5m block shown in Figure 2 (e.g. a modern refrigerator), p = 2.67 *rad/s*, while $p \approx 8$ *rad/s* for a typical clay masonry brick. When the angle of rotation reverses, it is assumed that the rotation continues smoothly from points *O* to *O'* and that the impact force is concentrated at the new pivot point, *O'*. The ratio of angular velocity after and before the impact is $\varepsilon = \dot{\theta}_2 / \dot{\theta}_1$. Assuming (a) that the impact is instantaneous and (b) that all the impact forces are concentrated at the new pivot point, one can apply conservation of angular momentum about the new pivot point (Housner, [1]). This gives the following coefficient of restitution

$$\varepsilon = 1 - \frac{3}{2}\sin^2 \alpha \tag{4}$$

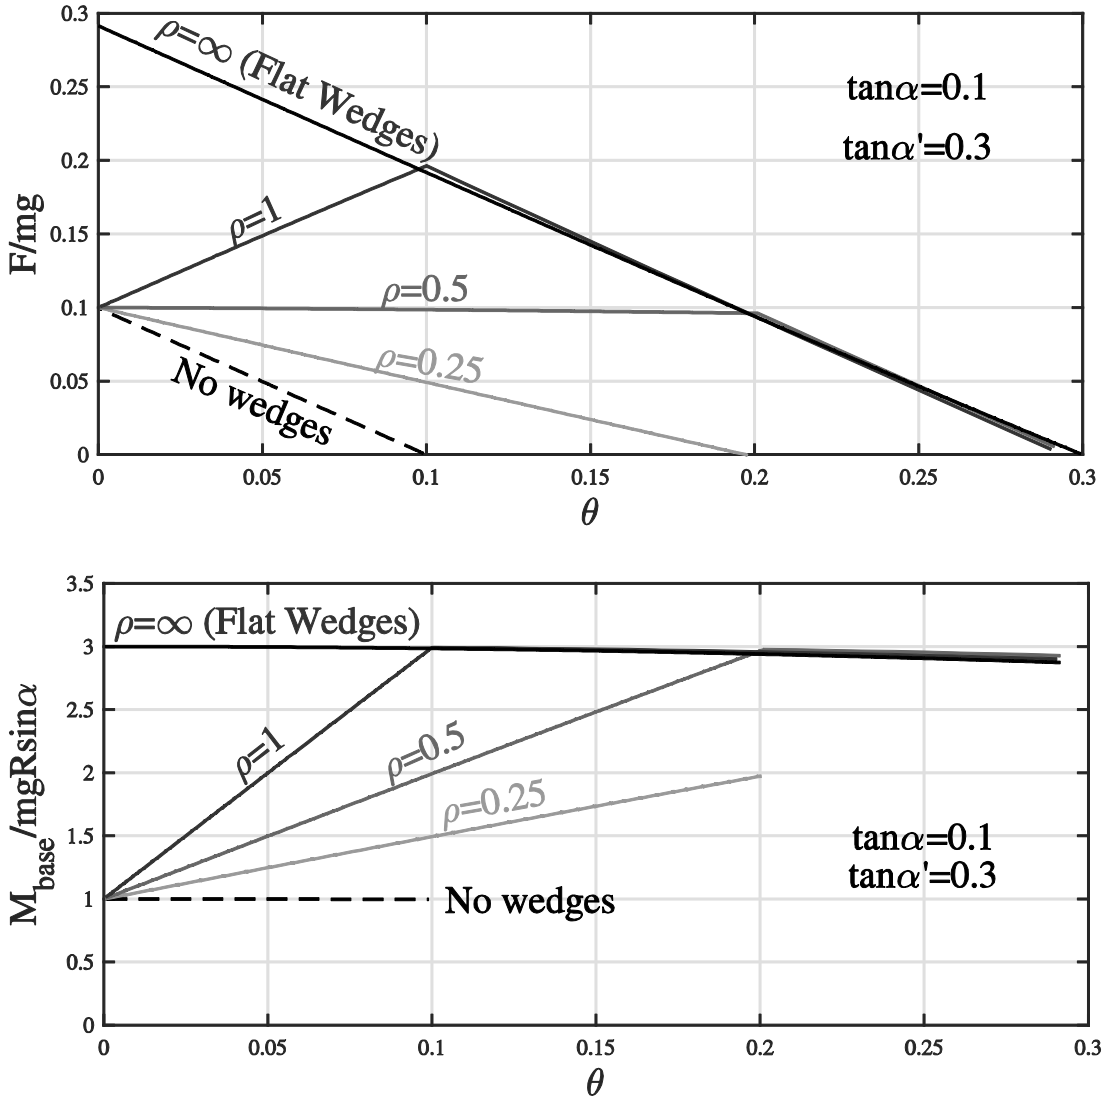

Figure 3 Response of blocks with different wedge curvature. Top: Lateral force – base rotation pushover response curves; Bottom: Base moment – base rotation pushover response curves.

Under the action of a horizontal force F is applied at the center of mass of the block a rigid block does not displace until the force reaches the uplift equilibrium value. The force – rotation pushover response curve of a rigid block is

$$F = mg\tan\left(\alpha - \theta\right) \tag{5}$$

It is plotted in Figure 3 (top – dashed line).

The base moment – rotation relationship is given by equation (6)

$$M_{base} = mgR\sin a\cos\theta \tag{6}$$

and is plotted in Figure 3 (bottom – dashed line).

It is evident that the block has negative post-uplift stiffness while the base moment stays almost constant. An extensive discussion on the significance of the negative post-uplift stiffness is offered in Makris and Vassiliou [47] and Vassiliou and Makris [58]

3 ROLLING AND ROCKING RESPONSE OF A BLOCK ON A BASE WITH CURVED ENDS

This section presents the model of a rigid block rocking and rolling on an extended curved base [65] (Figure 3) and briefly discusses its properties. An extended presentation of the above model and the numerical study of tis properties under seismic excitation is a subject of ongoing research and lies beyond the scope of this paper.

The geometric properties of the block are shown on Figure 1. The added wedges are characterized by their radius of curvature r and by their angle β. The curved wedges are assumed to be massless. When a horizontal force is applied to the center of mass of the block, the block stays initially at rest until the load reaches the critical value of $mg\tan(\alpha)$. Next, the block rolls on the curved surface (Phase I) until the tilt angle reaches the value β. Phase II follows where the block rocks, i.e. rotates around the edge of the curved base. The force deformation relationships for the different cases are given in equations (7) and (8) (for positive θ):

Phase I – Rolling:

$$F = mg\frac{\sin\left(\alpha-\theta\right)+2\rho\cos\alpha\sin\theta}{\cos\left(\alpha-\theta\right)+2\rho\cos\alpha\left(1-\cos\theta\right)}, \quad \theta<\beta \tag{7}$$

Phase II – Rocking:

$$F = mg\frac{\sin\left(\alpha-\theta\right)+2\rho\cos\alpha\left(\sin\left(\beta-\theta\right)+\sin\theta\right)}{\cos\left(\alpha-\theta\right)+2\rho\cos\alpha\left(\cos\left(\beta-\theta\right)-\cos\theta\right)}, \quad \theta>\beta \tag{8}$$

where ρ is the normalized wedge radius of curvature:

$$\rho = \frac{r}{2H} \tag{9}$$

Linearization of the above equations gives:

Phase I – Rolling:

$$F = mg\left(\alpha+\left(2\rho-1\right)\theta\right), \quad \theta<\beta \tag{10}$$

Phase II – Rocking:

$$F = mg\left(\alpha+2\rho\beta-\theta\right), \quad \theta>\beta \tag{11}$$

Therefore, the post-uplift stiffness of the rolling phase is positive, if $\rho > 0.5$, and negative, if $\rho<0.5$.

The base moment is equal to

Phase I – Rolling:

$$\frac{M_{base}}{mgR\sin\alpha} = \cos\theta + 2\rho\cot\alpha\sin\theta, \quad \theta < \beta \tag{12}$$

Phase II – Rocking:

$$\frac{M_{base}}{mgR\sin\alpha} = \cos\theta + 2\rho\cot\alpha\left(\sin\left(\beta-\theta\right)+\sin\theta\right), \quad \theta > \beta \tag{13}$$

Linearization of the above equations gives:

Phase I – Rolling:

$$M_{base} = mg\left(B + r\theta\right), \quad \theta < \beta \tag{14}$$

Phase II – Rocking:

$$M_{base} = mg\left(B + B_{curved}\right), \quad \theta > \beta \tag{15}$$

The F-θ and the M_{base}-θ pushover response curves are shown in Figure 3. The post-uplift stiffness in Phase I depends on the curvature of the curved part of the base and can lie anywhere from negative to positive, resembling the behavior of the restrained rocking column presented in [58]. Overturning can occur either in the rocking phase, or in the rolling phase (when the wedge curvature is relatively large, e.g. case ρ=0.25 in Figure 3).

The equation of motion for the Phase I is:

$$\ddot{\theta} = \frac{\left(\begin{array}{l} -\frac{3}{2}\rho\cos\alpha\dot{\theta}^2\left(\sin\left(\pm a-\theta\right)+2\rho\cos\alpha\sin\theta\right)- \\ \qquad -p^2\left(\sin\left(\pm\alpha-\theta\right)+2\rho\cos\alpha\sin\theta+\frac{\ddot{u}_g}{g}\left(\cos\left(\pm\alpha-\theta\right)+2\rho\cos\alpha\left(1-\cos\theta\right)\right)\right) \end{array}\right)}{\left(\frac{3}{4}+\frac{I_c}{\frac{4}{3}m_cR^2}+6\rho^2\cos^2\alpha\left(1-\cos\theta\right)+3\rho\cos\alpha\left(\cos\left(\pm\alpha-\theta\right)-\cos\alpha\right)\right)} \tag{16}$$

and for the phase II it is:

$$\ddot{\theta} = -p^2\left(\frac{\left(\begin{array}{l} \sin\left(\pm\alpha-\theta\right)+2\rho\cos\alpha\left(\sin\left(\pm\beta-\theta\right)+\sin\theta\right)+ \\ \qquad +\frac{\ddot{u}_g}{g}\left(\cos\left(\pm\alpha-\theta\right)+2\rho\cos\alpha\left(\cos\left(\pm\beta-\theta\right)-\cos\theta\right)\right) \end{array}\right)}{\left(\frac{3}{4}+\frac{I_c}{\frac{4}{3}m_cR^2}+6\rho^2\cos^2\alpha\left(1-\cos\beta\right)+3\rho\cos\alpha\left(\cos\left(\alpha-\beta\right)-\cos\alpha\right)\right)}\right) \tag{17}$$

where p is defined as in the case of a rectangular rocking block:

$$p = \sqrt{\frac{3g}{4R}} \tag{18}$$

ρ is the normalized radius of curvature:

$$\rho = \frac{r}{2H} \tag{19}$$

I_c is the moment of inertia of the system around its center of mass. In order to take into account the mass of the wedges, they need to be accounted for in the computation of I_c.

Following Housner, it is assumed that at each impact is instantaeous and that all the impact forces are concentrated at the new pivot point (i.e. at a distance B from the axis of symmetry), the coefficient of restitution is:

$$\varepsilon = \frac{\dot{\theta}_{post-impact}}{\dot{\theta}_{pre-impact}} = 1 - \frac{2mR^2}{mR^2 + I_c}\sin^2 a \tag{20}$$

If the wedges are assumed massless the coefficient of restutition is given by the well known Housner coefficient:

$$\varepsilon = \frac{\dot{\theta}_{post-impact}}{\dot{\theta}_{pre-impact}} = 1 - \frac{3}{2}\sin^2 a \tag{21}$$

It is evident that according to the above assumptions the coefficient of restitution, and hence the damping, are controlled only by the slederness ratio, α, and are not influenced by the wedges.

4 FREE VIBRATION TESTS OF A RIGID COLUMN WITH CURVED WEDGES

4.1 Specimens and test setup

A specimen consists of two columns (C), two link plates (L) and four changeable feet (F), all made of aluminium (Figures 4, 5 and 6). Two linked columns (instead of one) were used to avoid out-of-plane motion. The top feet were used because the specimens will be used in the future to test the response of a rocking frame on columns with curved end. For the tests presented herein, the top feet are obsolete and only result to the center of gravity being at column mid-height.

The total height of all the specimens is 2H = 500mm. The horizontal projection of the curved feet ($2 \times (B_{\text{curved}} + B)$) is identical in all specimens and equal to 150mm, giving $\tan(\alpha') = 150/500 = 0.3$. Two groups of specimens are examined: One with a flat base equal to 2B = 50mm ($\tan(\alpha) = 0.1$) and one with a flat base equal to 2B = 75mm ($\tan(\alpha) = 0.15$). In each group, 4 different curvatures of the curved part are tested: *flat*, r = {500mm, 250mm, 125mm}. For the curved specimens $\rho = r/2H = \{1, 0.5, 0.25\}$. These curvatures correspond to a positive, zero and negative post-uplift stiffness. These geometrical properties of the specimens are sketched in Figure 7 and are summarized (together with the specimen masses) in Table 1.

Table 1: Geometric characteristics of the specimens

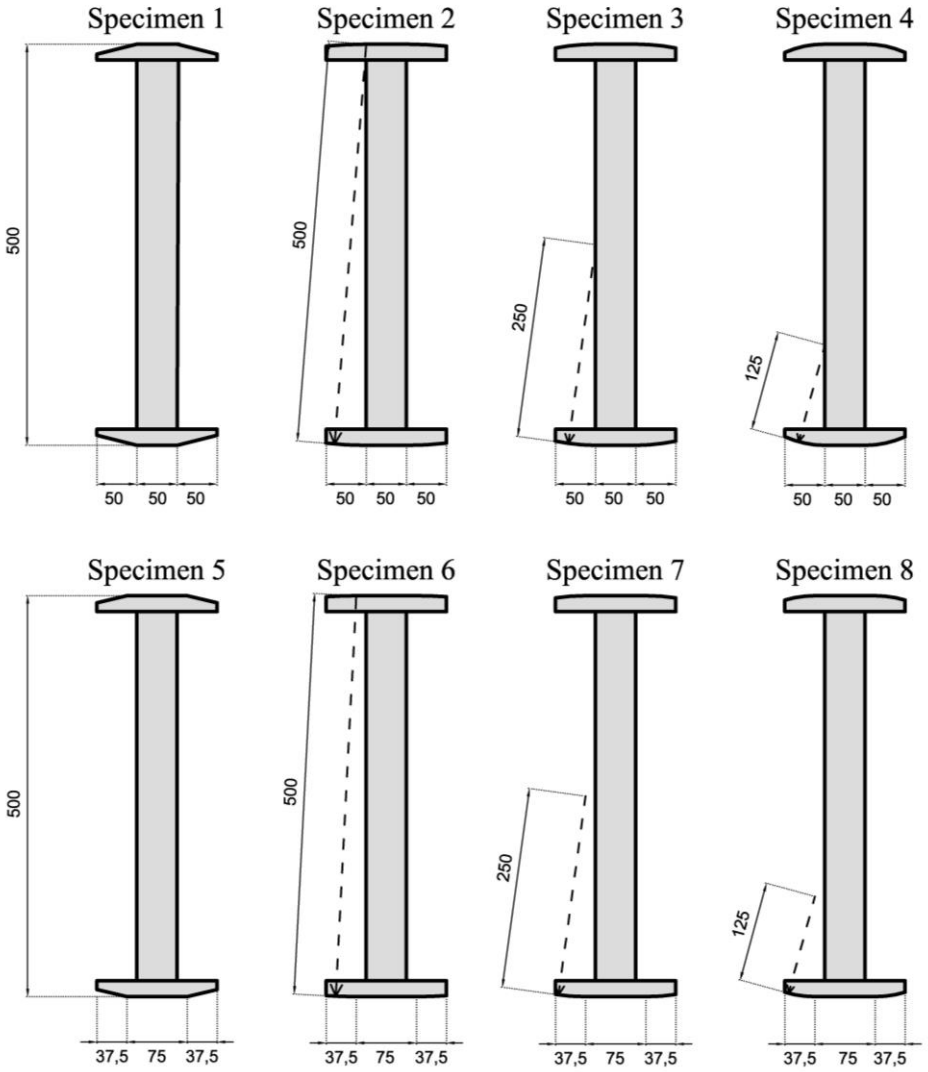

Figure 7. Geometric characteristics of the specimens.

4.2 Test Method

The specimens were tested on a flat, horizontal aluminium plate. They were tilted to an initial tilting angle and were let to move freely. The entire response time history was recorded, but in order to avoid experimental error due to potential unintended initial velocity, the time history was post processed and only the part after the maximum following the first impact was kept and later compared with the numerical solution.

4.3 Data Acquisition System

An Optotrak Certus System, manufactured by Northern Digital Inc., was used to track the position of the specimens during the tests. This system uses active infrared-emitting diodes as markers and a trinocular camera system to determine the position of the markers. In order to measure the tilt angle $\theta(t)$ and a potential slip on impact, four light-emitting diodes (LED) were used: two of them were placed on the rigid plate the structure was rocking on, a third one is positioned at the base, and the fourth one on top of the column (Figure 5). The NDI camera was able to compute the 3D angle between the LED 1-2 line and the LED 3-4 line as

well as the relative displacement between LED 1 and 3. The experimental design is shown in Figure 8.

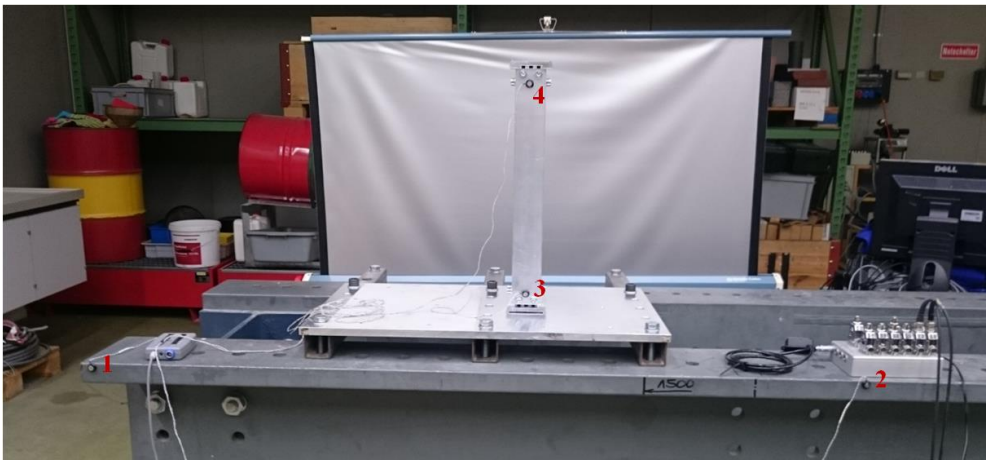

Figure 8. Experimental design

The accuracy of the system was determined by measuring the position of a marker at rest over a long period of time. In the x- and y-directions in the plane where rocking motion takes place, the accuracy was about 0.02 mm. In the z-direction, perpendicular to the plane of motion, the accuracy was about 0.10 mm. The position sampling frequency was 500 Hz.

4.4 Results and comparison with numerical solution

The objective of the experimental campaign was to validate the analytical model presented in the previous section. Each specimen was tested three times: 24 tests were performed. Figures 9-16 plot the time histories of the normalized tilt angle, θ/α. Three time histories are ploted in each plot: (a) the experiment results, (b) the numerical solution with the theoretical (Housner) coefficient of restitution, and (c) the numerical solution with an empirical coefficient of restitution. The empirical coefficient of restitution was obtained from the first 10 motion cycles assuming that energy dissipation takes place only at impact.

One can observe:

1) Hounser assumptions give a good estimate of the coefficient of restitution. For example, in Setup 1 the experimental value is ε_{emp}=0.990 while Housner assumptions would give ε_{th}=0.988. In terms of normalized energy loss per impact, the empirical coefficient would give $1-\varepsilon_{emp}^2 = 1.99\%$ while Housner would give $1-\varepsilon_{th}^2 = 2.39\%$. Considering the complicated nature of impact and damping, an accuracy of 20% is a good approximation.

2) Hounser-like coefficients of restitution slightly overestimate energy dissipation for the specimens without curved wedges (Specimens 1 and 5). In an effort to explore the source of this deviation, one has to explore Housner assumptions: (a) the impact is instantaneous, and (b) all the impact forces are concentrated on the new pivot point. Assumption (a) allows for the typical assumption that the non-impact forces (in this case the weight) can be neglected during the application of the impulse-momentum theorem. Assumption (b) leads to the Conservation of Angular Momentum Theorem (CAMT) applied about the new pivot point. Else, the CAMT should be applied about the point where the resultant of the impact forces is acting. Since

the bodies are rigid, the impact is expected to be instantaneous (and the weight is expected to be much smaller than the impact forces), at least for relatively large velocity impacts. On the other hand back-calculations for Specimen 1 show that the slight difference between the experimentally observed and the Hounser coefficient of restitution means that the point of action of the force should be 0.2mm away from the new pivot point. Missing the point of application of the resultant of the impact forces by only 0.2mm (which corresponds to 0.4% of the base) shows that Housner assumptions are valid and reasonable.

3) The addition of the curved wedges reverses the situation: Hounser assumptions underestimate the energy loss consistently (with the exception of Specimen 6). It seems that the addition of the wedges shifts the point of action of the impact forces away from the axis of symmetry, hence increasing the energy dissipation. However, apart from stating that qualitative result, it is impossible to quantify the increase.

4) In general, the coefficient of restitution decreases (implying a larger damping ratio) for low velocity impacts. This explains why a rocking block does not need infinite number of impacts to stop, as Hounser assumptions would predict [66] and is consistent with the results presented in [23]. Evidently, for smaller velocity impacts, the weight of the specimen is not negligible when compared to the impact forces and Hounser assumption (a) does not hold: The weight contributes to the impulse-momentum equation and slows down the motion.

5) Even though the coefficient of restitution is predicted relatively well, in many cases the numerical solutions diverge from the experiment data (e.g. become out of phase with the experiment data). Unlike elastic viscously-damped systems (where the period and the damping are only loosely related – $\omega_d = \omega_n \sqrt{1-\zeta^2}$) the „period“ or a rocking column (i.e. twice the time interval between two impacts) strongly depends on damping. This is attributed to the dependence of the period on the amplitude of vibration (hence on the coefficient of restitution). The above observation explains the difficulties in predicting the seismic response of a rigid block to a specific time history [56] and urges for a stochastic treatment of the rocking problem. It is evident that if deviations of 0.2mm in the prediction of the location of the impact point lead to different time history results, an error or 0.4% of the flat part of the foundation, then the deterministic treatment of the rocking problem is impossible.

5 CONCLUSIONS

Curved wedges are added to the flat base of a rocking rigid column in order to increase its overturning stability without significantly increasing the base moment. The equations of motion were derived and validated against free-vibration tests. It is shown that the theoretical values for the coefficient of restitution are numerically close to the experimentally obtained values. However, the response of the block is so sensitive to the exact coefficient of restitution value that a deterministic calculation of the response to a ground motion becomes practically impossible.

Keywords: Ancient Columns, Rocking Columns; Rocking Frames, Ground Motion Intensity Measures, Fragility Curves, Earthquake Engineering.

Abstract. *In this study the seismic response of free standing, rocking columns and frames is investigated taking into account different intensity measures (IMs) of the seismic excitations. The seismic vulnerability of the examined structural systems is based on the probabilistic seismic demand model (PSDM), in which the degree of uncertainty is depended on the IM used. Thus 23 different IMs are evaluated in order to extract the most optimal one. A performance based analysis is performed and fragility curves are generated conditional on uni-variable and bi-variable IMs considering the maximum rotation normalized to the slenderness as engineering demand parameter (EDP). The seismic assessment of these structures is evaluated using three limit states. Nevertheless, in this study, the effect of the beams' mass on the seismic rocking behavior of the frames is also examined. Finite element analysis models are used for the simulation of the structural members as deformable bodies while rigid contact elements are employed for the interfaces. Time domain analyses are performed using a set of 30 natural ground motions. Results in terms of correlation coefficients and dispersion values are first presented, indicated that the length scale of the excitation (Lm) and the vector value IM, PGV-Tm are the most optimal uni-variable and bi-variable IMs, for describing the rocking response. Further results in terms of peak rocking rotations and fragility curves shown that free standing frames are less vulnerable than the single columns. Moreover, as the beam mass increases, the developed rocking rotation of the frame tends to be reduced.*

1 INTRODUCTION

The investigation of the seismic response of ancient structural systems such as ancient columns and colonnades has received increasing attention during the last decades. These structural systems comprise the construction technique of Archaic, Classical, and Roman temples. Different types of columns with numerous variations in their geometrical characteristics can be found mainly in the Eastern Mediterranean region. In general, ancient columns are earthquake resistant, as proven from the fact that many monuments like these have survived many strong earthquakes over the centuries. This notable stability is displayed mainly due to the design method of these structures which is based on articulated mechanisms that demonstrate rocking behavior. Usually these are constructed of limestone or marble blocks (drums), which are placed on top of each other, without connecting mortar between them. These rigid-body assemblies display a very different dynamic response compared to modern structures. Their main difference as shown in Figure 1 is that the rocking behavior exhibits negative stiffness and low damping that occur only at the instant of impact in contrast with the modern design philosophy which is based on the positive stiffness of the structure and the ductility of the structural members [1]. Their response is composed primarily of rocking and sliding among the individual blocks of the structure and the ground. This behavior can be characterized as highly nonlinear due to the continuous changing of geometry and boundary conditions of the structural system during a strong earthquake.

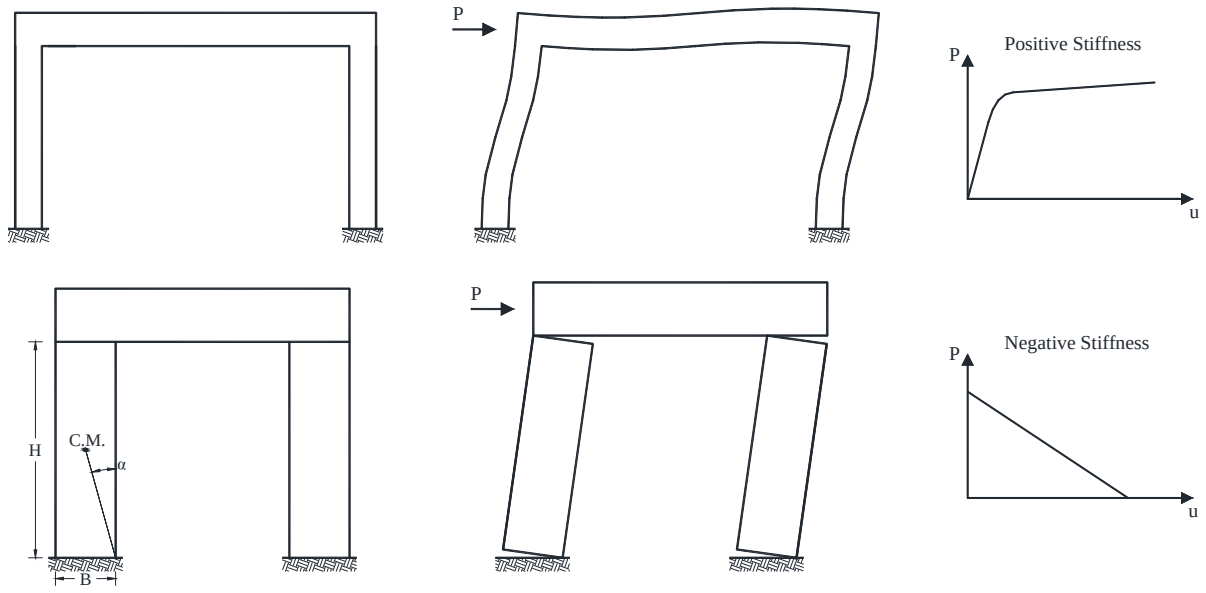

Figure 1: Response of a moment resistance frame versus a rocking frame.

Early work on the dynamics of the rocking column started analytically by Milne (1885) [2] while, Omori (1990) [3] was one of the first who performed experimental research on the seismic response of rectangular rocking columns. Subsequently, Kirkpatrick (1927) [4] presented a novel paper in which he relates the column size and the period of the excitation with the rocking response. It was Housner's (1963) [5] study that offers a solution for the dynamic behavior of a single block under pulse excitation, through the formulation of the inverted pendulum. Housner revealed both the size effect, which means that the larger block between two with the same aspect ratio exhibits greater stability under horizontal excitation, and the frequency effect which indicates that the frequency content of the excitation substantially affects

the rocking response, with long period excitations being more likely in causing overturning than the short period ones. His pioneer work constitutes the basis of the rocking analysis theory. After these studies several followed as researchers were motivated by the need to understand the rocking response, and they extended our previous knowledge, by revealing hidden aspects of rocking response [6-13].

Multi block rocking response has also been under investigation [14-18]. Sinopoli's work [14] has examined the impact problem between rigid bodies through a kinematic approach. Meanwhile, Psycharis [15] and subsequently Spanos et al. [16] proposed analytical solutions for the rocking response of two stacked rigid blocks assuming no sliding between them. Furthermore, Makris and Vassiliou [17] present the equivalence between a rocking frame and singular rocking blocks whereas, DeJong and Dimitrakopoulos [18] generalized it also for asymmetric rocking frames.

Extensive numerical investigation specifically on the response of ancient structural systems such as free standing single monolithic and multi-drum columns or columns connected to each other at the top level by architraves, which are usually consist the peristyles of ancient temples, has been presented by several researchers [19-25]. The numerical modeling of all these studies has been conducted using the Discrete Element Method (DEM). Using planar numerical modeling Psycharis et al. [19] investigated the seismic response of ancient columns. Moreover, Konstantinidis and Makris [20] also using a two dimension modeling, examined the effect of wooden poles installed in ancient times, but also of titanium poles which were installed during the restoration process, on the dynamic response of multidrum columns. Additionally, studies are presented on the seismic response of ancient columns and colonnades with epistyles using a custom-made software based on the DEM [23], [24]. On the other hand, Papantonopoulos et al. [21] and Psycharis et al. [22] performed numerical analyses in three dimensions. It was noticed that 2D analyses are capable of capturing the rocking phenomenon but without computing the out of plane oscillation, which makes the problem more complex. Thus is slightly underestimate the overall response. Experimental studies were also performed by Mouzakis et al. [26] Pena et al. [27] and Drosos and Anastopoulos [28] and confirmed the conclusion obtained from the numerical studies.

Due to the sensitivity of rocking response even to trivial changes of the ground motion characteristics or of the geometry of the model, Spanos and Koh [29] were the first to study the rocking response via a probabilistic framework. Afterwards, seismic vulnerability assessment of rocking columns and frames were presented by Psycharis et al. [30] and Dimitrakopoulos and Paraskeva [31].

In this paper, we present a numerical investigation of the seismic response of free standing columns and colonnades. Time domain analyses are performed with the use of 30 natural records. The scope of this study is to assess the seismic vulnerability of the examined rocking structures resulting in the most optimal intensity measures (IMs) [32] used for generating the probabilistic seismic demand model [33]. In addition, the difference of the colonnade with epistyle behavior against the single column response is studied while, the influence of the beams' mass on the rocking response is also examined.

2 NUMERICAL MODELING

For the purpose of this study, finite element models are utilized for the in space simulation of the members, in which the blocks are simulated as deformable elements and the ground as a rigid surface. Despite the structural members being modeled as 3D members, planar analyses were performed. Explicit dynamic analyses were employed as it is computationally efficient for discontinuous events like impact problems, using the central difference algorithm. Of particular significance for the simulation are the appropriate modeling of the contact between

the blocks and the base, and in the case of multi block models the contact between each block. Rigid contact is used to model the interfaces while a Mohr-Coulomb model is adopted to describe the mechanical behavior of the joints. For both normal and tangential direction of the contact element, the stiffness is assumed as infinite. In the normal direction no tensile strength is considered while the shear strength is governed by the Coulomb friction coefficient without considering cohesion. As mentioned by a thorough investigation made by Papantonopoulos et al. [21], damping affects the amplitude of the intense rocking response and thus, zero value of damping gives better results during the strong motion part of the excitation. Consequently both the mass proportional damping and the stiffness proportional damping coefficients are set zero for the analyses. The mechanical properties of the block material as well as the interface properties listed in Table 1 are assumed as typical values for marble blocks.

Material Properties	Density (kg/m^3)	2750
	Young's modulus (Gpa/m)	84.5
	Poison ratio	0.23
Interface Properties	Friction coefficient	0.70
	Cohesion (MPa)	0
	Tensile strength (MPa)	0

Table 1: Material and interface mechanical properties.

Column with 8m height and slenderness α=0.165rad is studied. The selection of the dimension was made to be in accordance with the size and the slenderness of recorded ancient columns. Specifically the columns of the Temple of Olympic Zeus and the Temple of Apollo in Syracuse have 8 m height. Additionally the Parthenon Pronaos columns have a slenderness of 0.16rad. Concerning the effect of the architrave existence, two varying geometry architraves are examined. The values of the beam (architrave) mass (m_b) are defined as a ratio over the columns mass (m_c), taking values $m_b/2m_c$=0.25, 0.5. The axial distance between the columns is 3m and is spanned with a single block architrave. Figure 2 shows the dimensions in meters of the examined rocking column and frames.

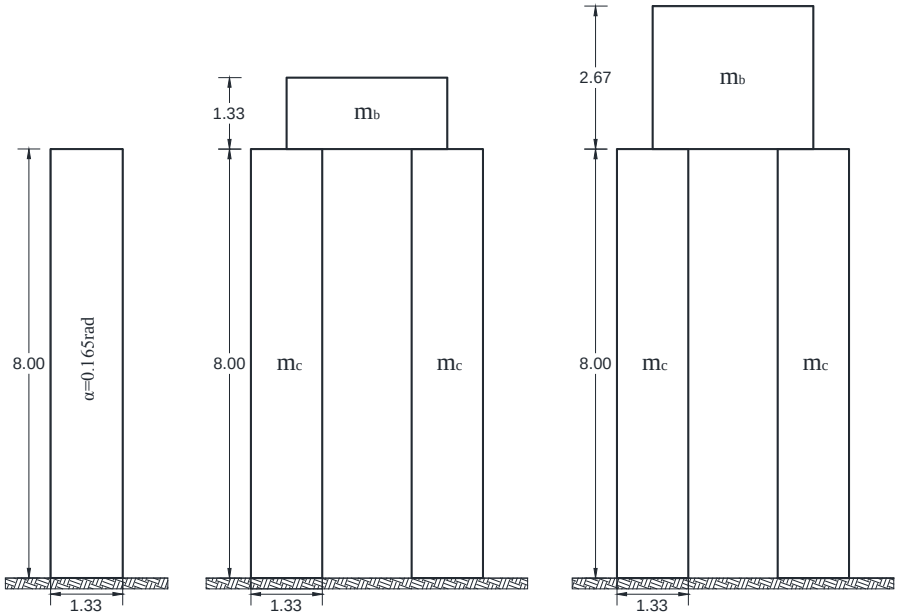

Figure 2: Examined cases of free standing column and free standing frames.

3 SELECTION OF NATURAL GROUND MOTIONS AND INTENSITY MEASURES (IMS)

3.1 Ground Motions

A set of 30 ground motion time histories is used as input ground motion for the analyses. What proved to be useful, for the selection was an extensive review of ground motion selection methods for dynamic analysis of structural systems presented by Katsanos et al. [34]. The events were chosen from worldwide well-known sites with strong seismic activity. Excitations generated from different types of fault types, with earthquake magnitudes (M_s) between 5.3 and 7.6, including both near fault and far fault records as the closest distance to fault rapture (R) varying from 0.6 to 115 km is employed in order to present a wide range of intensities and frequency contents. A further aspect which has been taken into consideration is the expected damage potential of the seismic excitation on the structure. Seismic excitations which provide a wide spectrum of structural damage, from negligible to severe, are taken into account. Based on the above assumption, a rigorous selection of ground motions carried out from the PEER [35] and the European [36] strong motion databases in order to use original records without any scaling. The complete list of the natural ground motions used for the analyses is shown in Table 2.

3.2 Intensity measures (IMs)

In order to designate the optimal earthquake intensity measures (IMs) for rocking response, a large number of seismic parameters is considered in the present study. Specifically 25 IMs were taken into account which can be classified into time history, energy, spectral, and frequency parameters. The definition of all the examined IMs is presented by Kramer [37]. Regarding the time history parameters, peak ground acceleration (PGA), peak ground velocity (PGV), peak ground displacement (PGD), sustain maximum acceleration (SMA), sustain maximum acceleration (SMV), and effective design acceleration (EDA) are taken under consideration. Additionally, with regard to the energy parameters the following were considered, root mean square of acceleration (A_{rms}), of velocity (V_{rms}), and of displacement (D_{rms}), characteristic intensity (I_c), Arias intensity (I_α), cumulative absolute velocity (CAV), specific energy density (SED), strong motion duration (T_D) and Fajfar index (I_F). The examined rocking structures do not possess natural modes in the classical sense [21] and so we do not use as intensity measures, spectral acceleration or velocity values for a certain period, although we consider the acceleration spectrum intensity (ASI), the velocity spectrum intensity (VSI) and the Housner Intensity (SI_H).

According to the frequency parameters, the period corresponding to the peak acceleration ($T_{p,A}$) and to the peak velocity ($T_{p,V}$) of the elastic response spectrum, are of the most extensively used frequency parameters in earthquake engineering. Nevertheless, none of these parameters represent the frequency content of a signal, except for the second one which seems to be a good approach to it. Mean period (T_m) [38] which is calculated by the Fourier spectra seems to be the best frequency parameter for excitations with arbitrary time-history shape. Moreover, the ratio PGV/PGA is related to the frequency content of the excitation, as for a harmonic motion this ratio is equal to $PGV/PGA=T/2\pi$. Finally, the characteristic length scale $L_p=v_p \cdot T_p$, which is introduced by Makris and Black [39] for pulse-type excitations and extended for non-distinct pulses by Dimitrakopoulos et al. [40], is considered too.

4 FRAGILITY ANALYSIS

4.1 Probabilistic seismic demand model

The vulnerability is assessed by estimating the conditional probability P where the seismic demand D measured to a specific engineering demand parameter (EDP), is higher than its capacity C, for a given value of a ground motion IM.

$$Fragility = P[D \geq C \,|\, IM] \tag{1}$$

The capacity is estimated by the proposed limit states while the demand is estimated using the relationship between the median structural demand Sd and each IM [33]:

$$S_d = aIM^b \tag{2}$$

where α and b are the linear regression coefficients for the logarithmic expression of the assumed scale law.

Assuming lognormal distribution for both the demand and the capacity of the structure and considering only demand uncertainties ($\beta_{D|IM}$), equation (1) can be rewritten in the following form:

$$P[D \geq C \,|\, IM] = \Phi\left(\frac{\ln(S_d / S_c)}{\sqrt{\beta_{D|IM}{}^2}}\right) \tag{3}$$

where Φ is the standard normal cumulative distribution function, Sc is the median value of the capacity which is estimated through the adopted limit states and $\beta_{D|IM}$ is the dispersion or logarithmic standard deviation for the demand conditioned the IM. For the calculation of the conditional standard deviation of the regression which is used to estimate the desperation, the following equation is utilized, where di is the i-th realization of the demands from the time history analyses.

$$\beta_{D|IM} \cong \sqrt{\frac{\sum(\ln(d_i) - \ln(aIM^b))^2}{N-2}} \tag{4}$$

In order to conclude in an intensity measure that could reduce even more the demand uncertainty ($\beta_{D|IM}$), also is examined vector IMs (couple of IMs) [41] to express the median demand as defined in the follow equation:

$$S_d = aIM_1^{b_1} IM_2^{b_2} \tag{5}$$

4.2 Definition of the engineering demand parameter

The introduced engineering demand parameter (EDP) has to get a clear physical meaning. Being aware of this principal, for the examined free standing structures, the best EDP that can be used has to be based on the rocking rotation as rocking is the dominant response of this structure. The absolute maximum developed rotation $|\theta_{max}|$ divided to the critical overturning rotation which is equal to the slenderness of the column α, was selected.

$$EDP = \frac{|\theta_{max}|}{\alpha} \tag{6}$$

4.3 Definition of the proposed limit states

Performance Based Earthquake Engineering has introduced the concept of acceptable performance levels. In vulnerability assessment analysis, capacity limit states (LS) are required to be defined, since the objective of the fragility analysis is to obtain the probability of exceedance the stated performance criteria. The capacity should be measured with the metrics of the EDP. Three performance levels, as presented in Table 3 are proposed for the current study. The first limit state (LS_I) corresponds to slight rocking of the structure, the second (LS_{II}) to moderate rocking which may cause local damage (imperfections) due to the impact and finally the third (LS_{III}) that corresponds to collapse due to rocking overturn.

Limit State	$\|\theta_{max}\|/\alpha$	Performance Level	Description
LS_I	0.20	Damage limitation	Lightly damaged structure.
LS_{II}	0.40	Moderate Damage	High likelihood of local damage due to impact.
LS_{III}	1.00	Near collapse	Rocking overturn of the structure.

Table 3: Proposed performance criteria.

5 RESULTS

5.1 Correlation analysis

To estimate the grade of interdependency between the intensity measures and the rocking response, the correlation coefficient according to Pearson is calculated. Pearson correlation coefficient shows how well the data fit to a linear relationship. The variables relationship is

based on the scale law of Equation (2). Figure 3 presents the correlation coefficient between the IMs and the EDP for the cases of a the free standing column and the free standing frame with masses ratio $m_b/2m_c=1/4$.

Examining Spearman's rank correlation coefficient of Figure 3, the maximum correlation of the adopted EDP with all the velocity based ground motion parameters is easily reconcilable. Specifically PGV and I_F is the IMs that has the strongest correlation with the EDP followed by the response spectrum IM SI_H. In addition, it is noted that the developed rocking rotation is influenced by the frequency parameters. The mean period of the excitation (T_m) and the ratio PGV/PGA exhibit the highest grade of interdependency, whereas between the predominant periods of the acceleration and the velocity elastic response spectrum, the second one has a higher value of correlation with the EDP. Finally the characteristic length scale of the excitation (L_m) displayed the strongest correlation among all the IMs.

On the other hand, the acceleration based parameters present the lowest grade of interrelationship with the rocking behavior. Additionally, the displacement based as the duration IMs show very low correlation levels with the EDP. Among the IMs which least affects the rocking behavior are the PGA the SMA and the TD.

From the results of the correlation analysis it can be concluded that the IMs associated with the velocity and the frequency content of the ground motion exhibit a far better correlation with the examined EDP. On the contrary, the IMs associated with the acceleration, the displacement and the duration of the excitation exhibit the lowest interdependency with the rocking rotation.

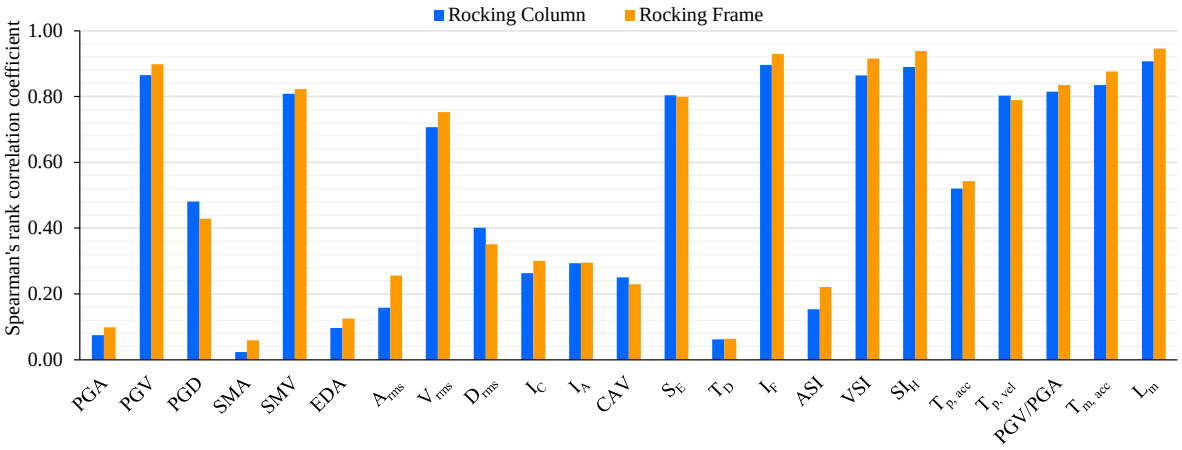

Figure 3: Correlation coefficients between the intensity measures and the engineering demand parameter.

5.2 Median seismic demand

The median demand models are generated from the linear regression analyses. Table 4 summarizes the expression of the median, the regression coefficient R^2 and the dispersion $\beta_{D|IM}$ of the seismic demand conditioned on a certain IM, for the cases of the free standing column. One of the main objectives of this paper is to estimate the most appropriate IM that reduces the uncertainty in the seismic demand model of rocking structures. The most efficient IMs are those that decrease the amount of the variation in the estimated median demand which means reduced uncertainty.

IM	PSDM	R^2	$\beta_{D\|IM}$
PGA	ln(0.202) + 0.256ln(IM)	0.01	1.31
PGV	ln(2E-4) + 1.729ln(IM)	**0.75**	**0.66**

Table 4: Seismic demands model for the examined IMs.

It is noted that as the coefficient of determination R2 reaches higher values, the dispersion $\beta_{D|IM}$ gets less. Indicated also from the correlation analysis the IMs that minimize the variation of the data in the median demand model, being in general, the velocity and the frequency based ground motion parameters. Specifically, as the performance of the IMs is evaluated regarding the reduction of the dispersion, the most efficient IMs are the PGV, the I_F, the T_m, and the Lm with dispersion values 0.66, 0.58, 0.72 and 0.55 respectively.

In order to achieve an even better intensity measure from the perspective of efficiency, we lead to examine also vector valued IMs. In this case a multilinear regression analysis was carried out (Equation (5)) in order to minimize the dispersion on the median demand model. Among all the probable IMs combinations, the couple PGV-T_m tends to be the best vector valued IM. The specific IM is generated from the combination of two individual IMs that are not directly interrelated, as the first one is an amplitude parameter and the second one a frequency ground motion parameter. The regression coefficients took values α=0.01, β_1=1.10 and β_2=0.85, the determination coefficient R^2=0.83 and the dispersion $\beta_{D|IM}$=0.54. In comparison with all the single IM models, the standard deviation has been reduced to the bi-variable one. Thus, the efficacy of the multivariable IM is shown in terms of uncertainty reduction.

5.3 Fragility curves

Fragility curves demonstrate the probability that the structure exceeds a certain capacity limit state, given a ground motion intensity level. The fragility curves of the rocking column resulting from the three most optimal IMs are presented in Figure 4.

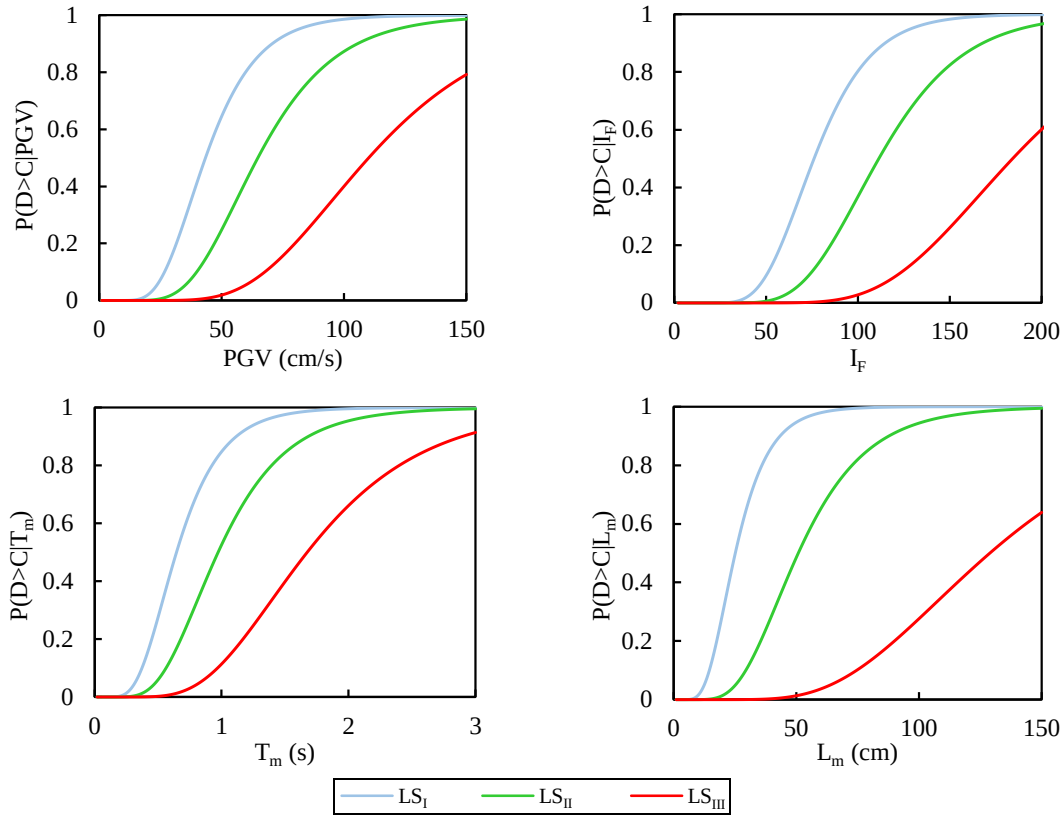

Figure 4: Fragility curves for the three most optimal IMs

The median values of the fragility curves using the PGV for the LS_I, LS_{II}, and LS_{III} are 43, 65 and 110 cm/s respectively whilst, for Farjfar index are 76, 112 and 184 cm/($s^{0.75}$). Using the T_m are 0.64, 0.98 and 1.68 s for the three limit states, and finally using the L_m as intensity measure, the median values of the fragility curves are 25, 51 and 129 cm for each limit state.

It is known that rocking structures exhibit an increased stability. This can also be observed from the fragility curves where the probability of exceeding the LS_{III} which corresponds to collapse by rocking overturn, are limited for intensity measure values that correspond to the majority of the ground motions. However, these structures which constitute some of the world's cultural heritage, have to be preserved undamaged throughout the years. Thus, if needed, we have to propose protection methods for these structures, in order to be preserved from seismic excitations of any magnitude.

Regarding the vector value IM, Figure 5 (a) depicts the surface fragility for all the limit states whilst, Figure 5 (b) shows the fragility curves of exceeding the LS_{II}, for the PGV and for the vector-valued IM which is the couple PGV-T_m. Comparing the single-variable with the bi-variable fragility curves for given Tm values, it is easily observed that as the mean period gets larger values, the vulnerability increases. In addition Table 5 lists the probability of exceedance the stated capacity for various pairs of the 2 IMs and for each IM individually. It is obvious that the bi-variable IM provided a more accurate approach on the definition of the structures' fragility as it can be shifted for even every simultaneous change of each of the two examined IMs. Comparing the probability values of Table 5, it can be seen that fragility curves generated using as uni-variable IM the mean period T_m seem to underestimate the probability of exceedance every stated performance level, especially when the mean period take low values.

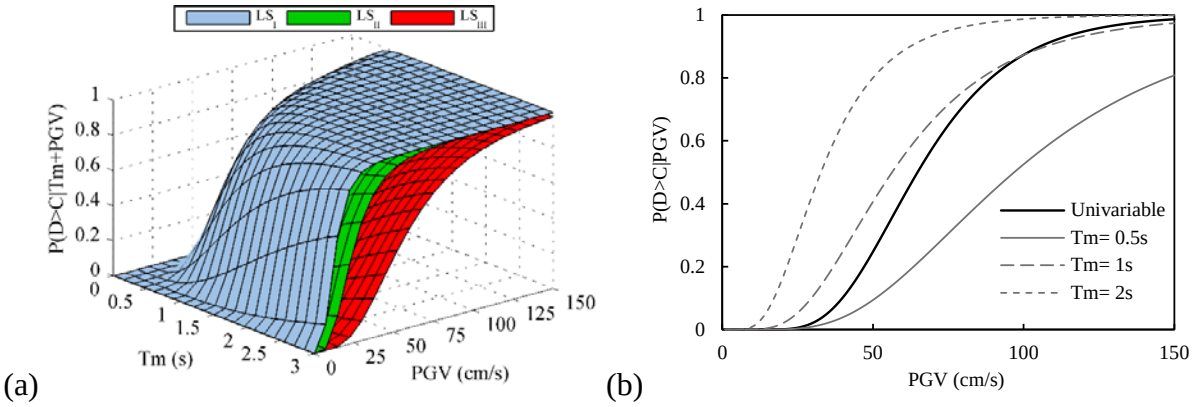

Figure 5: (a) Fragility surfaces using vector-value IM (T_m-PGV), (b) Compative results of univariable with bivariable fragility curves for given values of T_m.

Limit States	Velocity (cm/s)	Mean Period (s)			
		0.5	1	2	univariable
LS1	50	0.48	0.85	0.98	0.65
	100	0.91	0.99	1.00	0.99
	150	0.98	1.00	1.00	1.00
	univariable	0.22	0.85	0.99	-
LS2	50	0.09	0.44	0.80	0.25
	100	0.52	0.87	0.99	0.87
	150	0.81	0.97	1.00	0.98
	univariable	0.06	0.53	0.95	-
LS3	50	0.00	0.28	0.20	0.02
	100	0.05	0.30	0.71	0.40
	150	0.21	0.61	0.91	0.79
	univariable	0.00	0.11	0.66	-

Table 5. Probability values of exceeding the stated performance levels for both univariate and bivariate IMs.

5.4 Mass effect on the rocking response

In this section, the beams' mass effect on the rocking response is examined. The results in terms of peak developed rotation versus the most optimal uni-variable IM, which is the length scale of the excitation (L_m), are presented and compared between the different cases. Subsequently, to obtain results through a vulnerability perspective the fragility curves of exceeding the LS_{II} are displayed (Figure 6).

There are two rocking frames considered with differences of the ratio of the beam mass to the columns masses (Figure 2). From Figure 6 it can be noticed that the single free standing column presents larger values of rocking rotation in contrast with the rocking frames regardless of the rise of the gravity center of the cap beam. Moreover, comparing the seismic response of the frames, the one with the heavier beam exhibits increased stability. Both observations came into agreement with Papaloizou and Komodromos [23] and Makris and Vassiliou [17] conclusions. These remarks can easily be seen from the rotation versus the excitation length scale plot but also from the respective fragility curves.

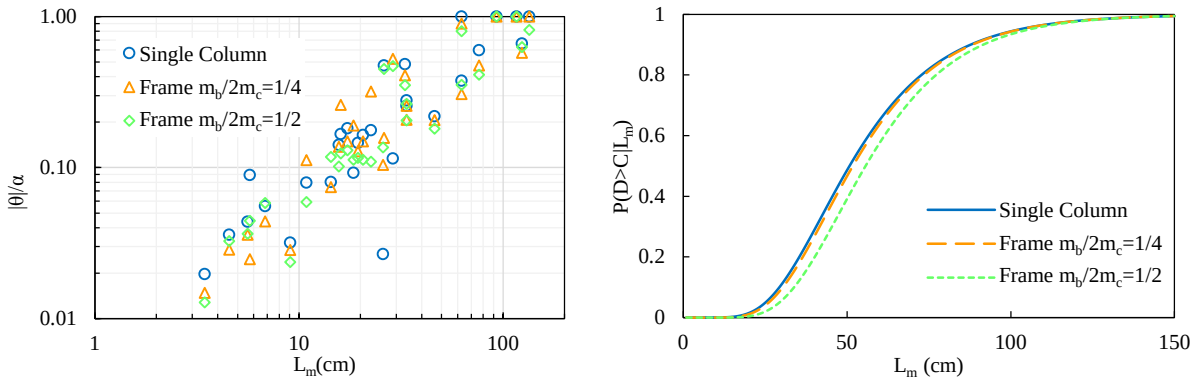

Figure 6: Comparative results of the maximum developed rocking rotation and the fragility curves of exceeding LS_{II}, between a single column and rocking frames with defferent beam masses.

6 CONCLUSIONS

The effect of the seismic excitations parameters on the rocking response of free standing columns and frames is numerically investigated in this paper, in order to conclude in an optimal uni-variable or bi-variable IM that reduces the uncertainties associated with the PSDM. Moreover, the influence of the size and the construction on the response of the structural systems is examined. The conclusion indicated by this study can be summarized as follows:

- Rocking behavior is primarily affected by the velocity based and the frequency content parameters of the ground motion. Specifically, the peak ground velocity (PGV), the Fajfar index (I_F), the mean period (Tm) and the length scale (Lm) of the excitation are the most optimal IMs.
- Vector valued IMs provided better approach on the determination of the fragility curves, than the uni-variable IMs. In addition, between the bi-variables IMs the couple PGV-Tm is the most efficient one.
- Rocking structures exhibit notable stability that can be seen also from the fragility curves in which the probability of overturning due to rocking is limited for IM values, which correspond to the majority of the ground motions.
- Free standing frames are less vulnerable than the single columns. Moreover, as the beam mass increases, the developed rocking rotation of the frame tends to be reduced.

Abstract. *We study the seismic response of rigid block structures against synthetic pulse-like ground motion records. A large number of synthetic ground motion records are systematically produced for various magnitude-distance scenarios. More specifically, we generate pulse-like ground motions for a grid of 56 receiver stations assuming a vertical strike-slip fault. The site conditions simulate a NEHRP Class D site, while for every combination of hypocenter, magnitude and receiver location, we generate 100 realizations consisting of low- and high-frequency components. The low-frequency component is based on a four-parameter wavelet, while the specific barrier model is used for the high-frequency component. The synthetic ground motions are used to study the seismic overturning of rigid blocks of various dimensions. The low-frequency pulse is described by four-parameters which refer to the amplitude, the prevailing frequency, the phase angle and the oscillatory character of the record, on top of which the high-frequency component is added. This description allows to parametrize the seismic response and thus improve our understanding on the effect of base motion characteristics on the overturning of rigid blocks.*

1 INTRODUCTION

Following the pioneering work of Housner (1963), the problem of rocking response and overturning of free-standing blocks to earthquakes, and especially to harmonic ground motion pulses, has been the subject of intense analytical and experimental research. Despite its apparent simplicity, the problem has proven to be a difficult task due to the nonlinear behavior introduced by the impact of the block with the base and the sensitivity of the response to even trivial changes of the problem parameters. Previous studies (e.g. Muto *et al.* 1960; Yim *et al*. 1980; Ishiyama 1982; Psycharis & Jennings 1983 & 1985; Priestley *et al*. 1983; Spanos & Koh 1984; Tso & Wong 1989; Cai *et al*. 1995; Anooshehpoor *et al*. 1999; Zhang & Makris 2001; Prieto *et al*. 2004; Peña *et al*. 2007; Purvance *et al.* 2008; Kounadis 2010 & 2013; Dimitrakopoulos & DeJong 2012, among others) have revealed the complex response, including certain counterintuitive trends such as: the stability of a block subjected to a particular ground motion does not depend monotonically on the size or the slenderness of the block; overturning of a block under a certain ground motion does not necessarily imply overturning for an increase in base excitation amplitude; the amplitude of the response does not always decrease with reduction in the value of the restitution coefficient.

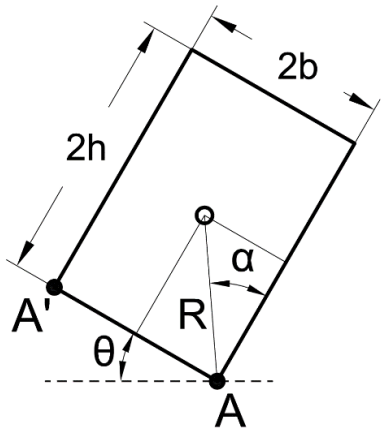

Figure 1. Rocking block geometry

In this paper, we investigate the seismic response of rigid blocks subjected to synthetic pulse-like ground motions. We consider rigid blocks of various dimensions which are subjected to pulse-like ground motions recorded at different locations with respect to the causative fault. The synthetic records consist of a low-frequency pulse, with known properties, and a high-frequency component. Following a systematic workflow, we investigate the sensitivity of the response of rigid blocks, and especially the overturning risk, to different problem parameters, such as the magnitude of the event, the distance, block dimensions and slenderness and other ground motion properties.

2 THE RIGID BLOCK PROBLEM

A rigid block of dimensions $2b \times 2h$ (Figure 1) oscillates about point A (or A'), provided that the coefficient of friction is large enough to prevent sliding. The block has weight W and moment of inertia I_0 about point A (Figure 1). Assuming that the block is homogeneous and thus

the center of gravity is located at height *h*, the block will start rocking only if the incipient ground acceleration exceeds the value of $(b/h)\cdot g$ or $g\cdot\tan(\alpha)$, where $\alpha = \text{atan}(b/h)$ is the block slenderness. Note that α together with the block size parameter $R = \sqrt{h^2 + b^2}$ fully define the geometry of the block. The equation of motion of the block (Housner 1963) thus becomes:

$$I_o\ddot{\theta}(t) + mgR\sin\left[\alpha\text{sgn}\theta(t) - \theta(t)\right] = -mg\ddot{u}_g(t)R\cos\left[\alpha\text{sgn}\theta(t) - \theta(t)\right] \quad (1)$$

where the angle of rotation θ is the only degree of freedom. The sign function is used to define the pivot point (A or A'), which depends on the sign of θ. Therefore, when A' is the pivot point, θ receives a negative value as implied by the sign function. For rectangular blocks, the moment of inertia becomes $I_0 = (4/3)mR^2$, while for small rotations θ, Equation (1) can be linearized:

$$\ddot{\theta}(t) = p^2\left[\text{-}\alpha\,\text{sgn}\left(\theta(t)\right) + \theta(t) - \ddot{u}_g(t)/g\right] \quad (2)$$

where *p* denotes the characteristic frequency of the rocking block and is defined as:

$$p = \sqrt{\frac{WR}{I_0}} = \sqrt{\frac{3g}{4R}} \quad (3)$$

Dimitrakopoulos and DeJong (2012) have shown that the frequency parameter *p* is equal to the oscillating frequency of the block if it is viewed as a pendulum with the rocking rotation point (A or A') being the pivot point. Damping is event-based, meaning that energy is lost only when the angle of rotation reverses and impact with the base occurs. The conservation of angular momentum just before and right after impact gives the coefficient of restitution η. This coefficient typically receives values between 0.6-0.9 and its theoretical value (Housner 1963) is:

$$\eta = \left[1 - \frac{3}{2}\sin^2\alpha\right]^2 \quad (4)$$

The equation of motion is solved numerically, while closed-form expressions for harmonic ground motions have been proposed by Dimitrakopoulos and DeJong (2012).

3 GENERATION OF BROADBAND SYNTHETIC GROUND MOTIONS

The hybrid method proposed by Mavroeidis and Papageorgiou (2003) is used to simulate broadband near-fault pulse-like ground motions. The incoherent (high-frequency) seismic radiation is synthesized using the specific barrier model (SBM) (Papageorgiou and Aki 1983). In the context of the SBM, the fault is visualized as an ensemble of non-overlapping circular subevents of equal diameter $2\rho_0$ that cover a rectangular fault with length *L* and width *W*. As the rupture front sweeps the fault plane with a rupture velocity *V*, a local stress drop $\Delta\sigma_L$ occurs on each subevent. The subevent rupture starts from its center and spreads radially outward with a constant spreading velocity until it is arrested by the barriers. The SBM has been calibrated to shallow crustal earthquakes of various tectonic regions (Halldorsson and Papageorgiou 2005). Given an earthquake magnitude and the tectonic region, the interdepend-

ence of other source parameters on the local stress drop $\Delta\sigma_L$ and the barrier interval $2\rho_0$ allows the causative earthquake fault to be constructed. Since the site of interest is considered to be in the "near field" of the ruptured fault, it is necessary to simulate time histories for each individual subevent of the SBM, rather than for the entire seismic event as an aggregate of subevents. The subevent time histories are subsequently summed up at the site with appropriate consideration of time delays.

On the other hand, the coherent (long-period) ground motion component is simulated using the mathematical model proposed by Mavroeidis and Papageorgiou (2003). The mathematical formulation for the representation of the near-fault velocity pulses is:

$$V(t) = 0.5A_p\left[1+\cos\left(\frac{2\pi f_p}{\gamma_p}(t-t_0)\right)\right]\cos\left[2\pi f_p(t-t_0)+\nu_p\right], \quad t\in\left[t_0-\frac{\gamma_p}{2f_p}, t_0+\frac{\gamma_p}{2f_p}\right] \tag{5}$$

where A_p controls the amplitude of the signal, f_p is the prevailing frequency of the signal, ν is the phase of the amplitude-modulated harmonic, γ_p is a parameter that defines the oscillatory character of the signal, and t_0 specifies the epoch of the envelope's peak. In addition, the pulse period T_p is defined as the inverse of the prevailing frequency f_p.

In what follows, we consider a vertical strike-slip fault in an interplate region and five scenarios with a distinct moment magnitude (M_w 5.5, 6.0, 6.5, 7.0, 7.5). The diameters of the subevents $2\rho_0$ are 2.9, 5.2, 9.2, 16.4 and 29.2 km for M_w 5.5, 6.0, 6.5, 7.0 and 7.5, respectively. According to the calibration of the SBM for interplate regimes (Halldorsson and Papageorgiou 2005), the total number of subevents that make up the SBM is typically 15. Consistent with realistic values of fault dimensions, the 15 subevents are arranged in a 5×3 pattern for events M_w 5.5, 6.0 and 6.5 (as illustrated in Figure 2), whereas for M_w 7.0 and 7.5 the subevents are placed in two rows with the upper and lower rows consisting of 8 and 7 subevents, respectively. The top edge of the fault is 0.1 km deep. The hypocenter is placed at $L/2$ along strike and $0.7W$ down dip whereas the rupture velocity is assumed to be 2.4 km/s.

The high-frequency ground motions are generated at a grid of 56 stations (Figure 2) at distances normal to the fault equal to 0.2, 1, 5, 10, 15, 20, 25 km. The spacing of the stations in the fault-parallel direction is: $-L/5$, 0, $L/5$, $2L/5$, $3L/5$, $4L/5$, $5L/5$, $6L/5$, where L is the fault length which is function of the moment magnitude M_w. The site characterization is assumed to be NEHRP site class D for all stations. We vary the seed number within the SBM so that 100 realizations are obtained for every combination of magnitude and receiver location. The long-period ground motion pulses are generated using the model input parameters as suggested by Mavroeidis and Papageorgiou (2003) and Halldorsson *et al.* (2011). The amplitude A_p is computed as A_p = 0.9 PGV, where the logarithm of PGV follows a normal distribution with the mean value provided by:

$$\log \mathrm{PGV} = 2.040 - 0.032 r_{rup} \tag{6}$$

and a standard derivation of 0.187. The distance measure r_{rup} is defined as the closest fault-to-station distance. The pulse period T_p scales self-similarly with earthquake magnitude, and the logarithm of T_p follows a normal distribution with the mean value determined by:

$$\log T_p = -2.9 + 0.5 M_W \quad (7)$$

and a standard deviation of 0.143. In addition, parameter γ_p follows a normal distribution with a mean value of 1.93 and a standard deviation of 0.47. This distribution is left-truncated to one to ensure that all γ_p values are greater than one. Finally, the phase angle follows a normal distribution with mean 1.83 and standard deviation of 0.98. Note that for every combination of magnitude and receiver location, 100 samples for each model parameter (e.g. A_p, f_p, ν_p and γ_p) are generated using Monte Carlo sampling. Finally, the long-period components of ground motion are superimposed on the high-frequency ground motions, with the initiation of the pulses aligned with time incident corresponding to 1% of the Arias intensity of the high-frequency motions.

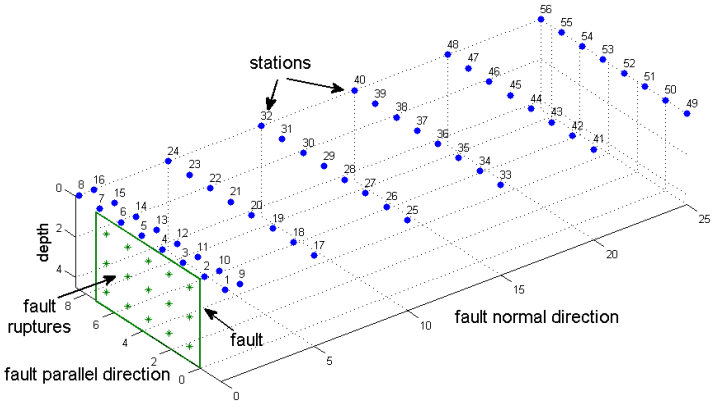

Figure 2 Fault geometry and grid of receivers (stations).

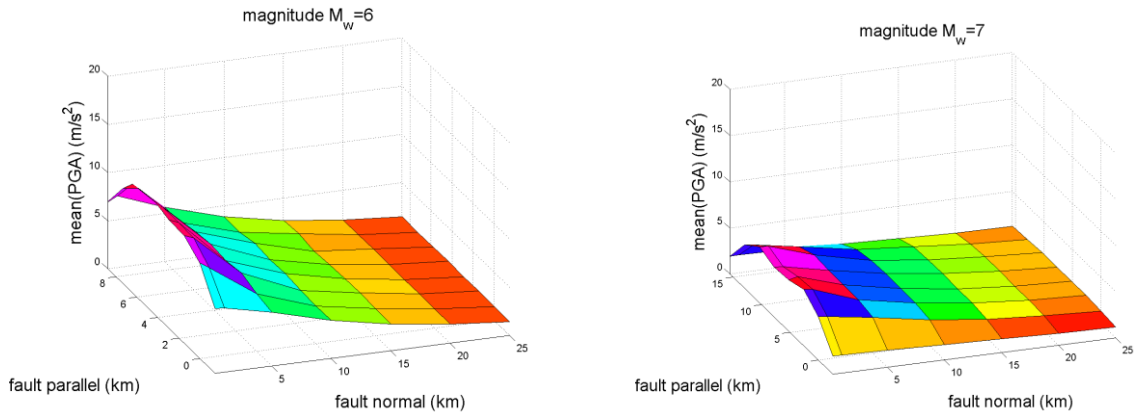

(a) (b)

Figure 3 Mean *PGA* values of the synthetic ground motion records for: (a) M_w = 6.0, (b) M_w = 7.0. Smaller M_w events produce larger PGA values.

Figure 3 shows the spatial distribution of the mean peak ground acceleration (*PGA*) of the synthetic broadband near-fault ground motions. For both M_w cases shown, larger mean *PGA* values are produced in the center of the fault-parallel direction that is closer to the epicenter, while the mean *PGA* attenuates as the distance in the fault-normal direction increases. Furthermore, the mean *PGA* values are larger for events of smaller magnitude (Figure 3). This

was first observed empirically by Somerville (2000), while Mavroeidis and Papageorgiou (2003) and Mavroeidis *et al.* (2004) discussed and explained mathematically that acceleration pulses generated by smaller earthquakes are typically stronger i.e., they have higher amplitude but shorter duration than acceleration pulses of larger earthquakes. However, once the high-frequency component is added to the pulse-type motions, this trend may be reversed.

4 PRELIMINARY RESULTS

4.1 Magnitude-distance plots

We consider twelve rigid block configurations with aspect ratio $\lambda = h/b$ equal to 2, 3, 5, 10 and characteristic frequencies p = 1.5, 2.5, 5.0. The grid consists of 56 receiver stations and, for every station and block configuration, we perform block response history analysis using 100 forward-directivity synthetic ground motions. Thus for every station, we perform 12000 rigid block response history analyses. Unless otherwise specified, all analyses refer to a fixed value of the coefficient of restitution η = 0.9.

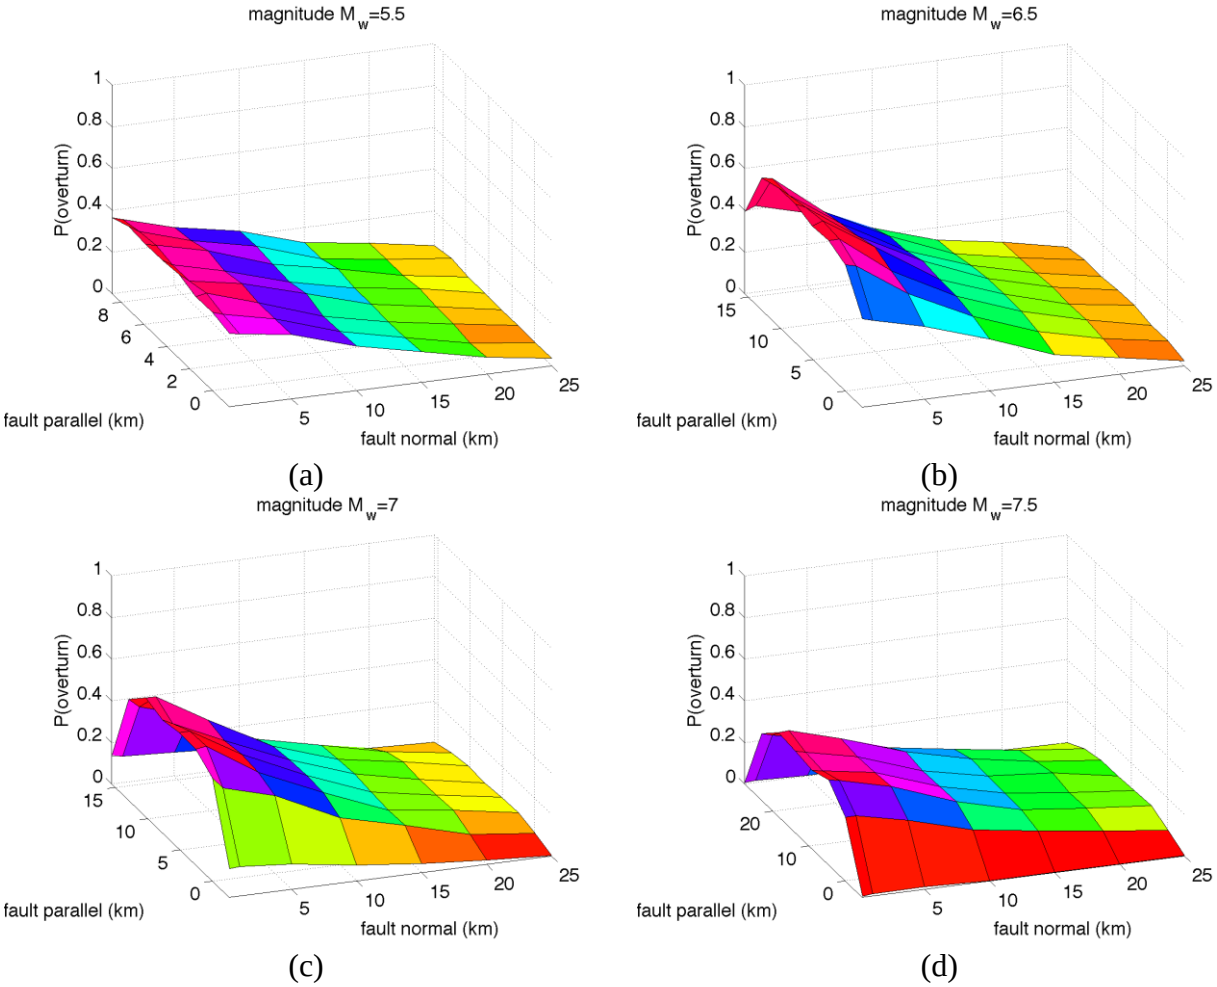

Figure 4 Probability of block overturning: (a) M_w = 5.5, (b) M_w = 6.5, (c) M_w = 7.0, (d) M_w = 7.5.

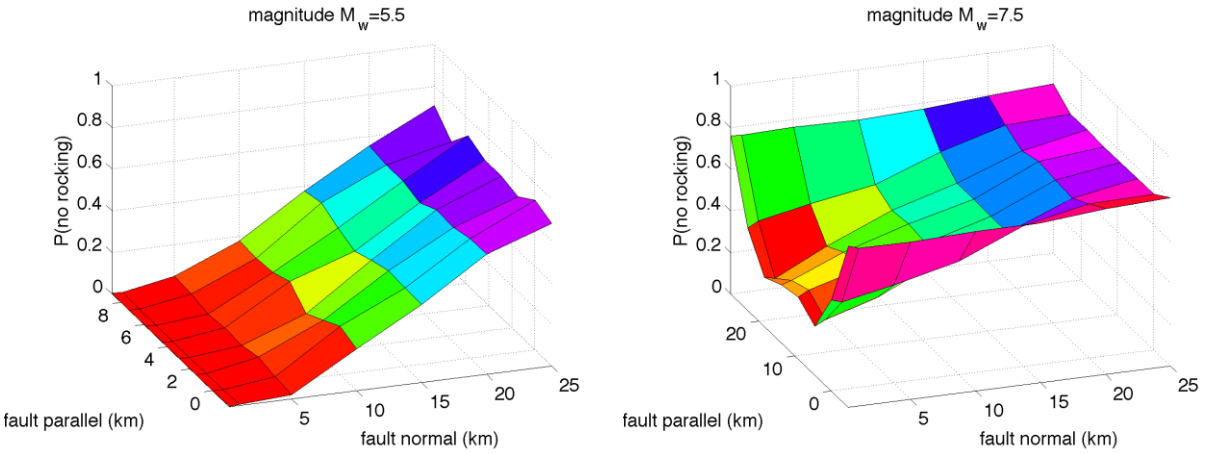
Figure 4 presents contour plots of the probability of block overturning. Four M_w scenarios, M_w = 5.5, 6.5, 7.0 and 7.5 are shown. The highest probabilities are observed for the M_w = 6.5 case,

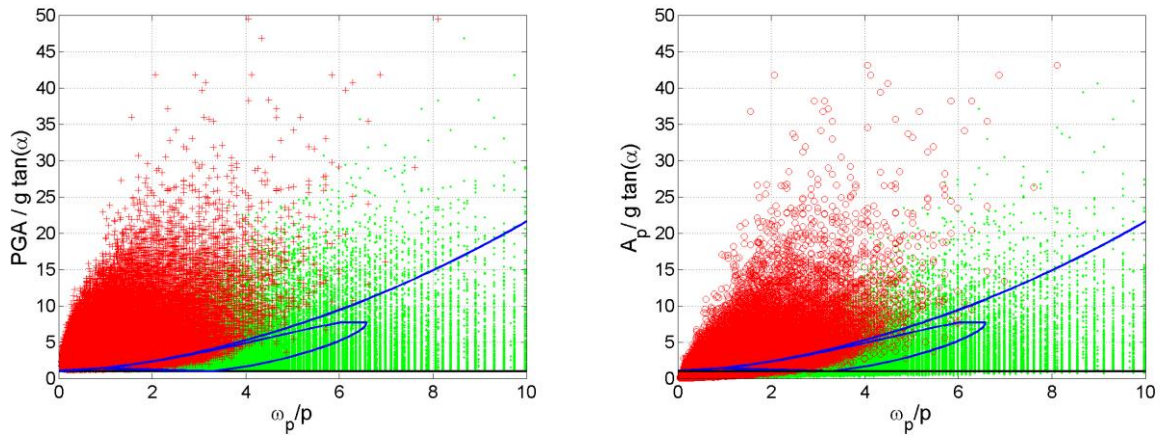
while smaller probabilities were obtained for the M_w = 5.5 and M_w = 7.5 ground motions. Compared to the PGA plots of Figure 3, the spatial distribution is the same, but the overturning probabilities decrease for large magnitudes. This is due to the fact that large magnitude events produce weaker and longer pulses although they have a longer duration and a stronger high-frequency component.



(a) (b)

Figure 5 Probability of not initiating rocking for the grid of stations: (a) M_w = 5.5, (c) M_w = 7.5.

Figure 5 shows the empirical probability that the ground motion is not strong enough to initiate rocking. It is reminded that a block starts rocking only if the *PGA* of the incipient ground motion exceeds $g \cdot \tan(\alpha)$. For the M_w = 5.5 case, practically all ground motions trigger rocking for small distances from the fault, while for stations far from the fault the probability that rocking is not initiated becomes very high. On the other hand, for the M_w = 7.5 case, the probability that no rocking is initiated is quite high even at sites very close to the fault (Figure 5b).



(a) (b)

Figure 6 PGA vs Ap. The blue lines refer to the closed-form expression of stable-unstable threshold for sine excitation according to Dimitrakopoulos and DeJong (2012).

4.2 Overturning spectra

The results are grouped in Figure 6 in stable-unstable plots in the acceleration-frequency domain. In Figure 6a, the normalized *PGA* with respect to the critical acceleration for the initia-

tion of rocking, $g \cdot \tan\alpha$, is plotted versus the normalized pulse period, ω_p/p, while in Figure 6b the normalized pulse acceleration, A_p, is plotted versus ω_p/p. Red points correspond to blocks that overturned and green points to blocks that did not overturn. Blocks that were not set to rocking motion are not shown; thus, $PGA/(g \cdot \tan\alpha)$ is larger than one for all points shown in Figure 6a. However, $A_p/(g \cdot \tan\alpha)$ can be smaller than one, as shown in Figure 6b.

These plots are referred as "overturning spectra", since the horizontal axis of Figure 6 measures frequency, while the vertical axis measures the intensity of the ground motion. Angle α controls the slenderness of the block (Figure 1), while parameter p accounts for the size of the block.

The two plots of Figure 6, which look similar, define the region in which the block might overturn. In both plots we also show, for comparison, with solid blue lines the closed-form solution of Dimitrakopoulos and DeJong (2012) that define the safe-unsafe threshold for a full sine pulse with amplitude equal to the PGA or the pulse amplitude A_p of our synthetic records and frequency ω_p equal to that of the low-frequency pulse. The sinusoidal ground motions are assumed symmetric (i.e. $v = 0$). The following observations can be made looking at Figure 6:

- $PGA/(g \cdot \tan\alpha)$ is preferable over $A_p/(g \cdot \tan\alpha)$, since it is easier to calculate and respects the condition that rocking will immense only if $PGA/(g \cdot \tan\alpha) \geq 1$.
- The use of a sinusoidal pulse is overall more conservative.
- As we move to the right side of each plot of Figure 6, the points shown refer to blocks that are either large (large R and small p) or are subjected to high frequency ground motions (large ω_p values). Therefore, these results show that overturning is rather improbable to occur in such cases. This seems to be true for ω_p/p larger than 8, independently of the amplitude of the normalized acceleration.
- On the left edge of the plots, specifically for values of ω_p/p smaller than about 2, corresponding to ground motions containing long-period pulses (small ω_p values) or to small-size blocks (large p values), overturning occurs for all ground motions capable to initiate rocking.
- The apparent limit between the safe and the unsafe region implies only that the blocks on the safe side do not overturn. In other words, there are many blocks on the "unsafe" region that did not overturn. In this sense, the threshold between the safe-unsafe regions corresponds to the minimum normalized ground acceleration $PGA/(g \cdot \tan\alpha)$ for each value of ω_p/p that could topple the block, without meaning that all excitations with larger values of $PGA/(g \cdot \tan\alpha)$ will cause overturning.
- Compared to our results, the sinusoidal ground motions are more conservative for ω_p/p values that exceed 6. Beyond this limit, our broadband simulations yield that the blocks do not overturn, as opposed to the case of sinusoidal pulse where the blocks are safe or their response does not depend on the $PGA/g \cdot \tan(\alpha)$ parameter.

5 SENSITIVITY ANALYSIS

5.1 Effect of distance and magnitude

In Figure 7, the probability of block overturning versus the magnitude of the event is shown for several distances. The black solid line denotes the average trend. It is evident that the probability of block overturning is affected by both magnitude and distance. Concerning the effect of distance, small distances result to higher probabilities of block overturning, as expected. However, concerning the effect of magnitude, it is seen that the overturning probability does not monotonically increase with magnitude as one would expect, since, for events of magnitude larger than $M_w = 6.5$, the overturning probability reduces as the magnitude increases. This counter-intuitive response is attributed to the saturation of the *PGV* for earthquakes with magnitude larger than 6.5 while the period of the pulse is increasing exponentially with the magnitude (Eq. (7)). As a result, the directivity pulse has small acceleration amplitude for large magnitudes, which is not capable to produce intense rocking.

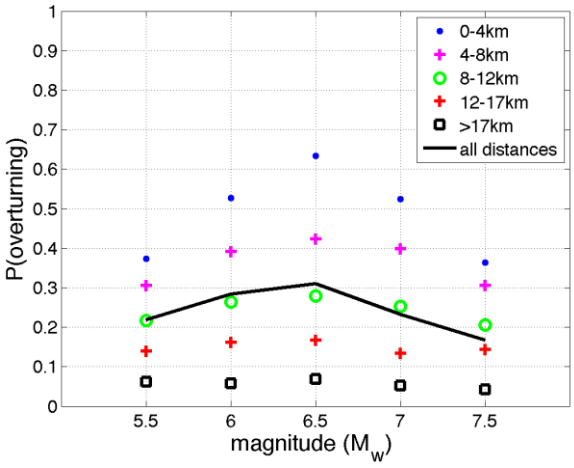


Figure 7 Variation of the probability of block overturning with magnitude and rupture distance. The black solid line denotes the average trend.

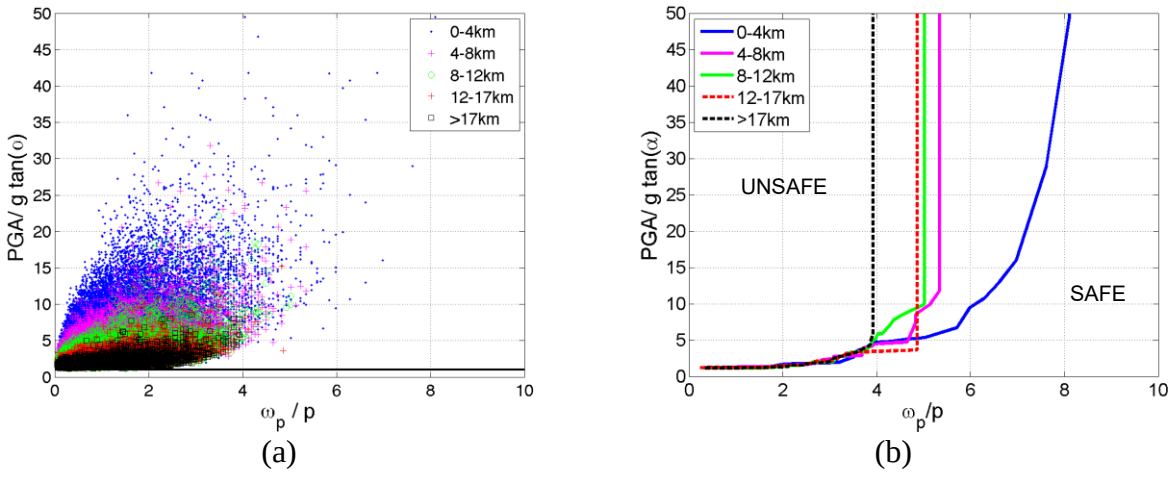

Figure 8 Clustering of the ground motions that caused block overturning with respect to the rupture distance: (a) all simulations; (b) envelope curves indicating the threshold between safe and unsafe regions.

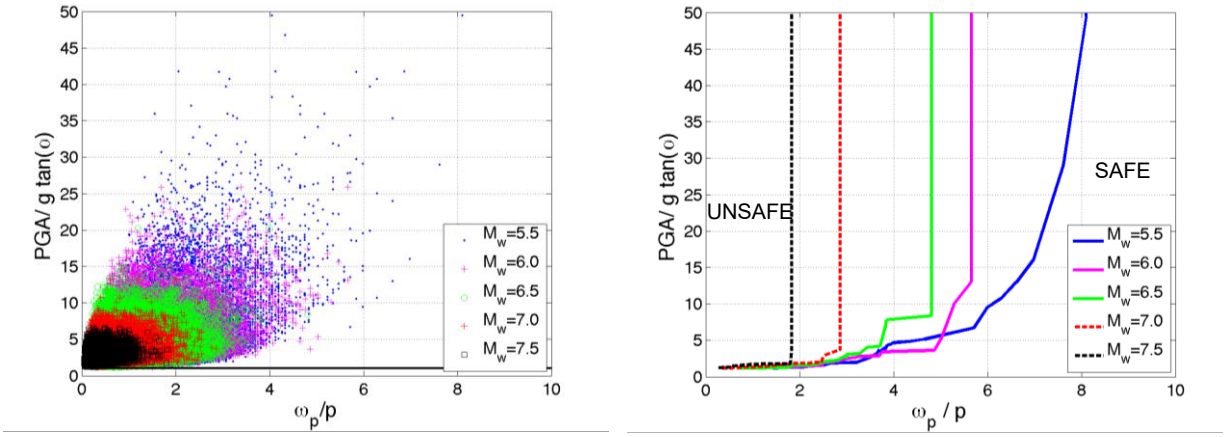
Further insight on the dependence of the block overturning probability with distance and magnitude is offered by Figure 8 and Figure 9, respectively. Figure 8 shows the effect of distance on the block overturning spectra. The left plot (Figure 8a) clusters the data depending on the distance, while Figure 8b shows the threshold curves that define the safe and the unsafe regions, allowing a better comparison. The number of blocks that overturn decrease with distance as also indicated by the overturning probabilities of Figure 7, which is attributed to the fact that the *PGA*s decrease at large-distances (Figure 3). However, as evident from Fig. 8b, the distance does not affect the safe-unsafe threshold for small values of ω_p/p, but only for blocks with $\omega_p/p \geq 4$, for which the unsafe region expands to the right for small-distant events.



(a) (b)

Figure 9 Clustering of the ground motions that caused block overturning with respect to moment magnitude Mw: (a) all simulations; (b) envelope curves indicating the threshold between safe and unsafe regions.

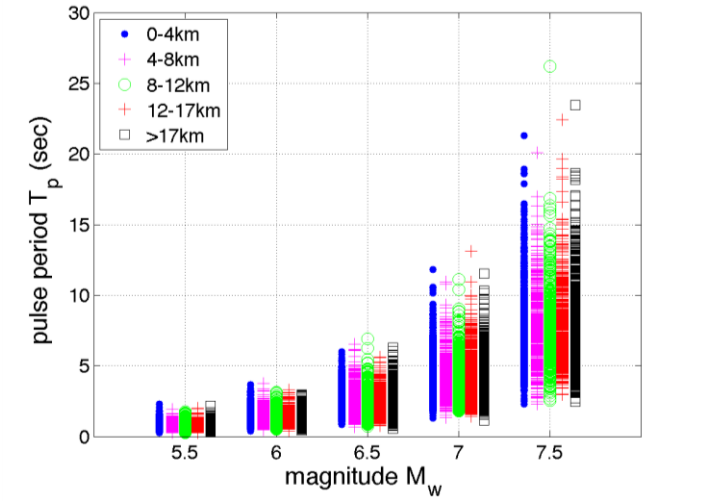


Figure 10 Relationship of the period T_p of the directivity pulse with moment magnitude M_w and distance. As M_w increases longer period values are obtained, while there is no dependence with respect to the distance.

Figure 9 shows the effect of moment magnitude M_w on the block overturning. The effect of M_w is strong, since the different magnitudes have distinct threshold curves (Figure 9b). This is due to the fact that both *PGA* and ω_p depend on the magnitude. As shown in Figure 3, events of small M_w (e.g. M_w=5.5) produce larger PGA values than larger magnitudes (e.g. M_w=6.5),

although the failure probabilities do not follow this trend (Figure 7). On the other hand, ω_p decreases quickly with amplitude due to the exponential increase of the pulse period T_p (Figure 10), which means that only small values of ω_p/p can be attained for large-magnitude events. In this sense, for a given block (given p), the normalized frequency ω_p/p decreases abruptly as M_w increases and, therefore, the safe-unsafe threshold moves to the left for the range of the block dimensions examined (block size is measured by parameter p).

Another interesting conclusion that can be drawn from Figure 9b is that, for values of $\omega_p/p < 3$ the minimum *PGA* required to overturn a block is almost equal or slightly larger to the one needed to set it on rocking motion, since $PGA/(g\cdot\tan\alpha)$ is close to unity. For events with large magnitude M_w (larger than 7.0), this means that, if the ground excitation is strong enough to trigger rocking, it will most probably cause overturning too. However, for events of smaller M_w, for which values of $\omega_p/p > 3$ can be attained, the minimum *PGA* required to overturn a block is significantly larger than the one needed to initiate rocking (equal to $g\cdot\tan\alpha$).

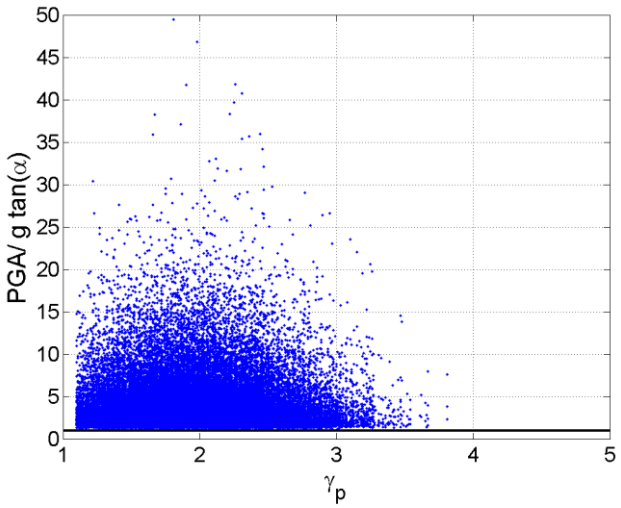

Figure 11 Distribution of the normalized PGA of the ground motions that caused overturning with the γp parameter that controls the oscillatory character of the ground motion.

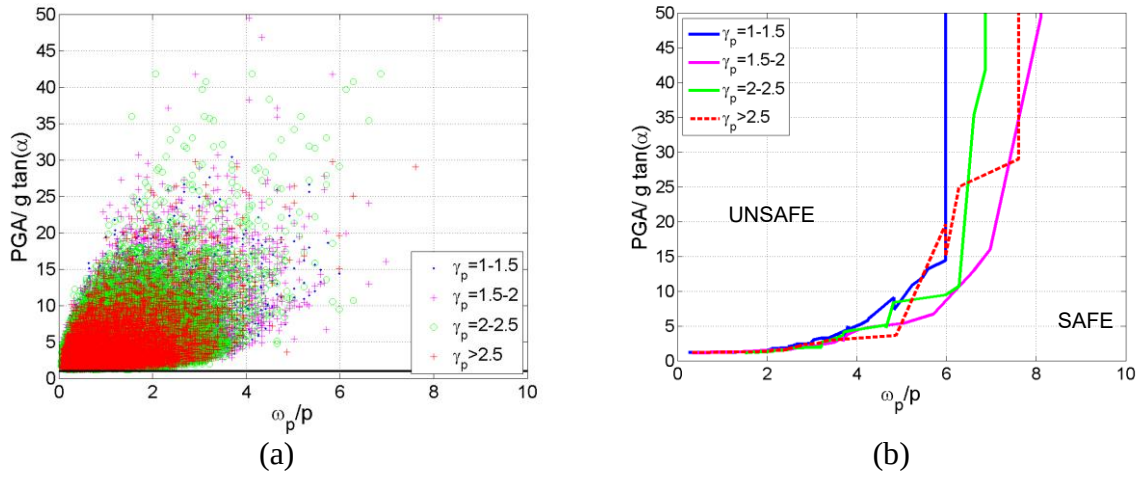

Figure 12 Clustering of the data with respect to γ_p: (a) all simulations that cause block overturning, (b) envelope curves indicating the threshold between safe and unsafe regions.

5.2 Effect of the oscillatory character of the directivity pulse (γ_p parameter)

The γ_p parameter is a constant of the wavelet proposed by Mavroeides and Papageorgiou (2003) that defines the oscillatory character (i.e. zero crossings) of the signal. This parameter was assumed normally distributed when the synthetic records were generated. Figure 11 shows the analyses that overturned the blocks as function of γ_p versus the normalized $PGA/(g \cdot \tan\alpha)$ intensity. The distribution of the analyses with respect to the values of γ_p resembles that of a normal distribution. Furthermore, Figure 12 shows the overturning spectra when the results are clustered with respect to γ_p. Both the cloud plots of Figure 12a and the threshold lines of Figure 12b indicate that γ_p has a small effect on the overturning of the blocks.

5.3 Effect of block properties

5.3.1. Sensitivity to the coefficient of restitution η

The coefficient of restitution η controls the damping of the rocking motion. Figure 13b shows the threshold curves of the overturning spectra (e.g. Figure 6a) for different values of the coefficient of restitution η, namely η = 0.7, 0.8 and 0.9. Practically there is no difference between η = 0.8 and 0.9, while η = 0.7 shifts the threshold curves slightly to smaller ω_p/p values. Therefore, the effect of η, in general, is small, although there are cases where this parameter may alter the results. This conclusion is compatible with the results of past studies based on pulse-like ground motions, as the ones shown in Figure 13b obtained with the aid of the closed-form relationships of Dimitrakopoulos and DeJong (2012). In this case, the coefficient of restitution affects only the closed-loop curves, which refer to block overturning after one impact, while the monotonically increasing upper curve, which corresponds to the threshold of overturning without impact, is independent of the coefficient of restitution.

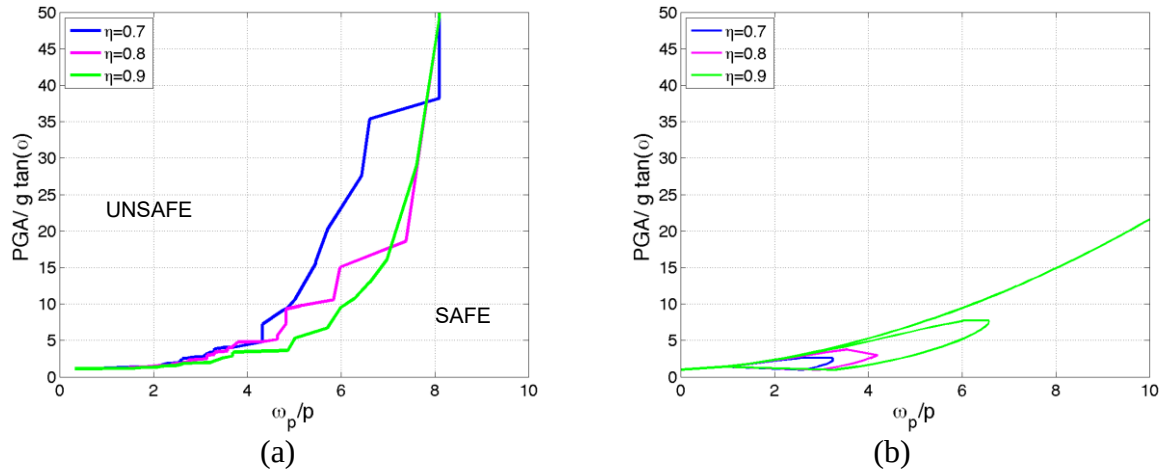

Figure 13 Effect of the coefficient of restitution η on overturning spectra: (a) this study; (b) obtained using sinusoidal pulses (Dimitrakopoulos & DeJong 2012).

5.3.2. Effect of block slenderness

Figure 14 shows the effect of the block slenderness ratio $\lambda = h/b$, i.e. the aspect ratio of the block. The h/b values considered are: 2, 3, 5 and 10, corresponding to slenderness angles α equal to 26.5, 18.4, 11.3 and 5.7 degrees, respectively. As expected, slender blocks are more

likely to overturn, as shown in Figure 14a, since they set to rocking motion for records with small enough *PGA*. Furthermore, slender blocks topple for significantly smaller angle of rotation than stocky ones, therefore, they are more vulnerable to small-period ground motions. This is the reason that the threshold curves of the overturning spectra move towards larger ω_p/p values as λ increases (Figure 14b).

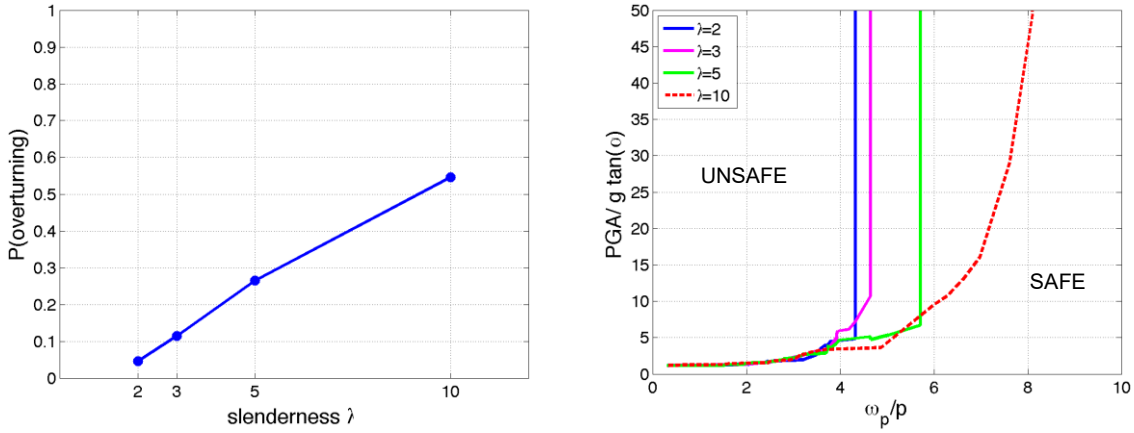

Figure 14 Overturning spectra for different values of the slenderness ratio λ of the blocks: (a) overturning probability versus λ; (b) overturning spectra.

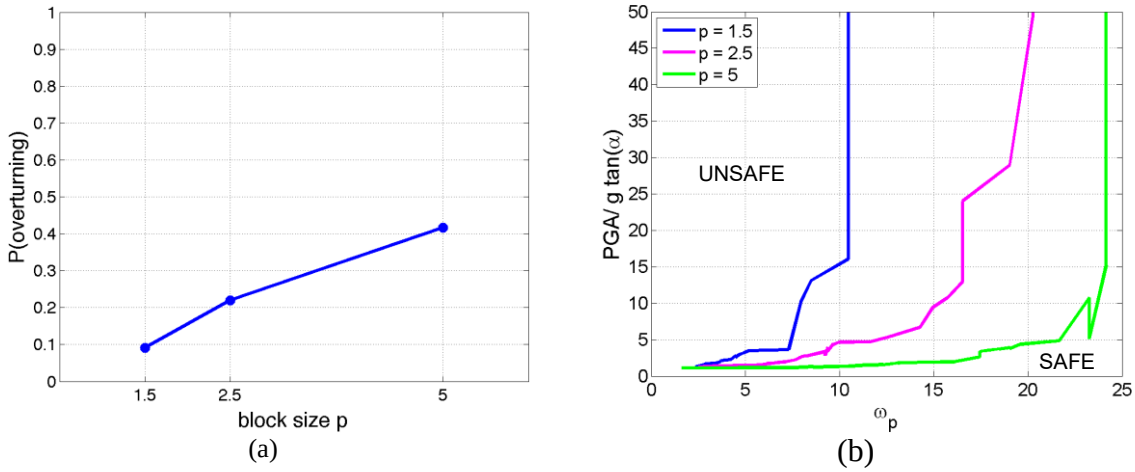

Figure 15 Effect of the frequency parameter p on the response of the block: (a) overturning probability versus p; (b) overturning spectra (note that the horizontal axis is not divided with p).

5.3.3. Effect of block size

In Figure 15, we examine the effect of the frequency parameter p which is used to measure the size of the block according to Eq. (3). We examine blocks with p = 1.5, 2.5 and 5, which correspond to blocks with half diameter R = 3.3 m, 1.18 m and 0.30 m, respectively. Figure 15a shows the scale effect on the probability of overturning, which was first observed by Housner (1963), with smaller blocks (larger p) been more vulnerable than larger ones (smaller p) of the same aspect ratio. This is also shown in Figure 15b, in which the safe-unsafe thresholds of the overturning spectra are shown w.r.t. the pulse frequency ω_p. It is evident that small blocks overturn even for high-frequency ground motions, for which large blocks of the same

aspect ratio are safe.

6 CONCLUSIONS

There are several parameters that control the seismic response of rigid block structures when subjected to pulse-like ground motion records. This paper offers a systematic investigation on the impact of several critical parameters through generating a large number of synthetic ground motion records and considering receiver locations at different places with respect to the fault. The response is post-processed in the form of overturning spectra, i.e. plots of the peak ground acceleration normalized by the critical acceleration required to trigger rocking ($PGA/g{\cdot}\tan\alpha$) versus the pulse frequency normalized by the characteristic frequency of the block (ω_p/p), from which the effect of various parameters on the threshold between the safe (no overturning) and unsafe (overturning) regions is investigated. The results show that the moment magnitude M_w is important, as it affects the pulse period T_p, while the effect of the distance is of lesser importance. Concerning the parameters of the directivity pulse, the oscillatory character of it (γ_p parameter) and the position of the hypocenter along the fault do not affect the results significantly. The same holds for the coefficient of restitution η, in contrast to the slenderness and the size of the block, which play an important role to the probability of overturning.

Keywords: Rocking, Macro-element, Non-linear analysis

Abstract. *In recent years, an increased interest in the use of rocking members for the design of earthquake resistant structures is observed. As described in the literature, the use of rocking members leads to more resilient structural systems, since, in contrast to conventional members which develop damage and residual deformations, rocking members have the ability to re-center without significant damage, leading to increased structural safety and lower repair costs after a seismic event, while their yield-like response restrains the seismic forces acting on the structure.*

Although much research has been conducted on the response of rocking members, mainly regarding analytical solutions for free-standing rocking bodies with rigid bases and simplified guidelines for the design of structural rocking members, it is believed that there is a need for simple computational models, which can describe the response of rocking flexible members in structural systems more realistically.

In this paper, a new approach that is able to take into account the deformation along the height of the body and along the contact areas, especially required for cases of constrained structural members, is applied for the development of a generalized macro-element, which can be used in the context of a finite element program. The theoretical formulation of the problem is based on the solution of the normalized semi-infinite strip problem with random loads on its free side. The new macro-element is demonstrated using typical example problems and the results are compared with corresponding results obtained with Abaqus, showing excellent agreement. Concerning the required runtimes, the macro-element runs significantly faster compared to conventional finite element codes.

1 INTRODUCTION

The complex mechanics of the rocking motion of rocking bodies and structural members have attracted attention from the scientific community in recent years, although the phenomenon is known from ancient times, as many ancient monuments were built with members allowed to rock.

The rocking motion occurs when a member is unrestrained or at least partially restrained at its base, so that tensile stresses cannot be transmitted, as considered in classical structural mechanics. Given that the imposed forces are large enough, the rocking body detaches from the ground and rotates about one of its corners. The vertical force acts as the restoring force that tends to bring the body back to its original equilibrium position.

The inclusion of rocking members in real structures is considered a promising solution to the design of resilient structures. Conventional structural elements are designed to gradually yield and develop damage and residual deformations during an earthquake. Such an approach means that, after a seismic event, costly and time-consuming repairs of the building may be necessary. In contrast, the motion of rocking members is a yield-like response, able to limit the forces transmitted to the structure during an earthquake, without however developing significant damage, while the residual deformations are virtually non-existent. As as result, fewer repairs are needed after a seismic event in comparison to the conventional design.

Up to date, rocking members have been applied in case of bridge piers (e.g. the Rangitikei Railway Bridge [1]), while extensive analytical and experimental work has been performed on rocking shear walls in precast structures (e.g. [2], [3], [4]). Guidelines addressing this alternative seismic design have been published by several organizations ([5], [6], [7]), while in Eurocode 8 (EN 1998-1) [8], rocking is anticipated for large lightly reinforced walls during strong earthquakes.

Although various analytic solutions exist regarding the motion of the rigid rocking block (e.g. [9], [10], [11], [12]), as well as approximate formulas for the design of controlled rocking systems, few models exist for modeling the response of deformable rocking bodies (e.g. [13], [14], [15], [16]). These studies, however, consider only the deformability of the rocking member along its height, while the lower face, along which the contact with the base takes place, is considered rigid. As a result, rocking occurs around the corners of the bottom side. The main attempts that have been presented including the flexibility of the base concern the rocking of rigid bodies on a flexible foundation (e.g. [17], [18], [19], [20], [21], [22], among others). Computational approaches taking into account the deformability of the base of rocking members include [23], [24], [25], [26], [27].

In this paper, a new macro-element formulation is proposed, able to take into account both the deformability of the rocking member along its height and along the contact area with the base mat. The main idea behind the proposed approach is to assume a stress distribution acting on the section of the rocking interface, depending on the resultant forces on this interface, and try to predict the displacements of the rocking element due to this partial loading. To this end, the similarity between the original problem of the flexible rocking body and that of a cantilever, partially loaded on its free side with normal and shear stresses that model the ones acting on the contact region of the body while rocking (Fig. 1) is used. More information on the applied technique can be found in [28].

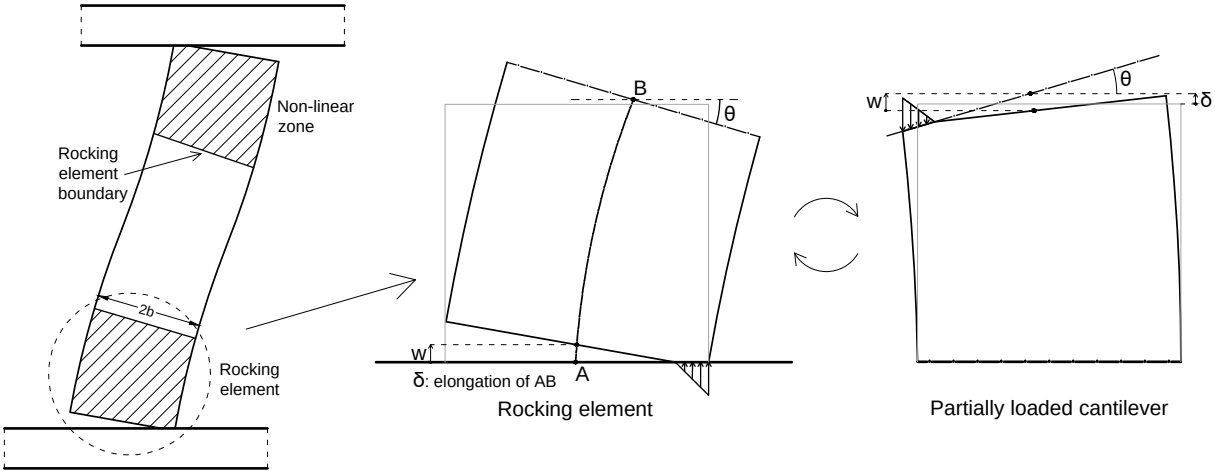

Figure 1: Rocking body and partially loaded cantilever analogy

2 NORMALIZED SEMI-INFINITE STRIP PROBLEM

In order to calculate the displacements of a cantilever due to partial loading on its free side, the spatial stress distribution near the loaded region has to be derived. From this stress distribution, an elongation profile across the member section can be found, from which the relative deformations of the element can be calculated.

The normal and shear stress distributions applied on the free side are separated into: *(i)* stresses produced by the resultant forces (axial force, shear force and moment); and *(ii)* self-equilibrating stresses. For the latter, since the effect of the self-equilibrating stresses is expected to vanish along the cantilever (rightmost diagram in Fig. 1), as the Saint-Venant assumption suggests, the easier semi-infinite strip problem is used instead. The stress distributions of the resultant forces are calculated according to the technical theory, so the use of a cantilever model is not necessary.

The general self-equilibrating stress problem for a semi-infinite strip of width $B = 2b$ is solved by first examining the normalized problem, which refers to a semi-infinite strip of $b = 1$ (Fig. 2).

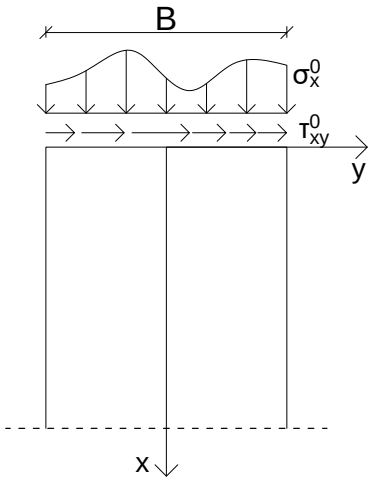

Figure 2: Semi-infinite strip normalized problem

The self-equilibrating stress distribution problem of the normalized semi-infinite strip is cal-

culated with the method developed in [29], using stress functions of certain form. The problem considered is that of a semi-infinite strip $x \geq 0$, $-1 \leq y \leq 1$ with generalized stress distributions on the free side, $x = 0$ (Fig. 2).

In the proposed macro-element, the results produced for specific load distributions of interest are approximated by polynomial expressions, which are easier and faster to implement.

The free surface of the semi-infinite strip is assumed to be loaded in the interval $[-1, p-1]$, representing a contact region of length p of the corresponding rocking body (Fig. 3). The self-equilibrating stress distributions assumed for the free surface of the semi-infinite strip originate from the following stress distributions, similar to the contact stresses at the interface between the rocking body and the base, after the removal of resultant forces:

Normal stresses which have a triangular distribution. The maximum value is s at the edge, $y = -1$, while it becomes zero after length p, that is at $y = p - 1$.

Shear stresses which are assumed to have a parabolic distribution. Its values are zero at $y = -1$ and $y = p - 1$, while its maximum value t occurs at $y = 0.5p - 1$

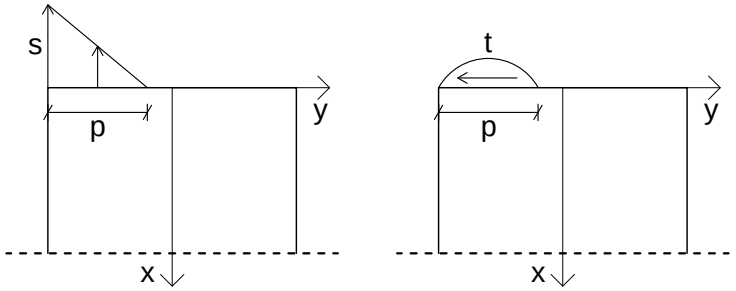

Figure 3: Semi-infinite strip normal (s) and shear (t) load distributions, for loaded region of length p

For the real problem, the interface between the body and the base mat remains flat. However, for the corresponding cantilever problem, the loaded region of the strip, although it remains close to flat, is not exactly flat. This causes problems when the elongation and the corresponding slope of a specific point on the loaded edge are used for the prediction of the axial elongation and the rotation of the body. For this reason, the elongation profile $u(y)$ of the fibers across the loaded region $[-1, -1 + p]$ is interpolated by a linear function $g(y) = \delta + \theta y$ (Fig. 1), in which δ and θ are the predicted axial elongation and the top rotation of the normalized problem, respectively, taking into account the gap existing between the loaded and non-loaded surfaces (Fig. 1).

It can be shown that for the stress distributions examined, the displacement vector $\boldsymbol{U} = [\delta, \theta]^T$ can be very well approximated by the following expressions:

$$\boldsymbol{U} = \begin{Bmatrix} \frac{1}{E} \left(s\boldsymbol{V}_s^T + t\boldsymbol{V}_t^T \right) \boldsymbol{P}_6 \\ \frac{1}{E} \left(s\boldsymbol{R}_s^T + t\boldsymbol{R}_t^T \right) \boldsymbol{P}_6 \end{Bmatrix} \tag{1}$$

where

$$\boldsymbol{P}_6 = [p^6 \quad p^5 \quad p^4 \quad p^3 \quad p^2 \quad p \quad 1]^T \tag{2}$$

$$\boldsymbol{V}_t = \boldsymbol{V}_{t0} + \nu \boldsymbol{V}_{td} \tag{3}$$

$$\boldsymbol{R}_t = \boldsymbol{R}_{t0} + \nu \boldsymbol{R}_{td} \tag{4}$$

E and ν being Young's modulus and the Poisson ratio, respectively, and the polynomial constant term $\boldsymbol{V}_s$ and $\boldsymbol{R}_s$ (for the normal stress contribution) and $\boldsymbol{V}_{t0}, \boldsymbol{V}_{td}, \boldsymbol{R}_{t0}, \boldsymbol{R}_{td}$ (for the shear stress contribution) vectors given in Table 1.

Also, the flexibility matrix of the normalized problem $\boldsymbol{F_t} = \partial \boldsymbol{U}/\partial \boldsymbol{R}$, with $\boldsymbol{R} = [p, s, t]^T$, is calculated by the following expression:

$$\boldsymbol{F_t} = \frac{\partial \boldsymbol{U}}{\partial \boldsymbol{R}} = \begin{bmatrix} \frac{1}{E}\left(s\boldsymbol{V}_s^T + t\boldsymbol{V}_t^T\right)\boldsymbol{dP}_6 & \frac{1}{E}\boldsymbol{V}_s^T\boldsymbol{P}_6 & \frac{1}{E}\boldsymbol{V}_t^T\boldsymbol{P}_6 \\ \frac{1}{E}\left(s\boldsymbol{R}_s^T + t\boldsymbol{R}_t^T\right)\boldsymbol{dP}_6 & \frac{1}{E}\boldsymbol{R}_s^T\boldsymbol{P}_6 & \frac{1}{E}\boldsymbol{R}_t^T\boldsymbol{P}_6 \end{bmatrix} \tag{5}$$

where

$$\boldsymbol{dP}_6 = [6p^5 \quad 5p^4 \quad 4p^3 \quad 3p^2 \quad 2p \quad 1 \quad 0]^T \tag{6}$$

The predicted displacements derived from the semi-infinite strip problem were compared against results obtained with Abaqus. Two cases for various cantilever heights were considered, with constant width $B = 2$: in the first one, the rocking member was loaded on its top with a concentrated moment, while in the second one it was loaded with a concentrated horizontal force. Figures (4) and (5) present the comparison results in relation to the different contact lengths, p, which show that, generally, there is very good agreement between the results of the two methods, especially for more slender members.

3 A MACRO-ELEMENT FORMULATION

By combining the self equilibrating stresses and the resultant force contributions (Fig. 6), a macro-element algorithm is developed which accounts for the total response of the rocking member.

For the rocking macro-element formulation, the concept of the simply supported beam natural system will be used, which is based on the geometrically non-linear force-based beam-column element formulation proposed by Neuenhofer and Filippou [30]. This coordinate system without rigid body modes demands only relative displacement values and not absolute ones, thus enabling the use of relative displacements presented previously for the self-equilibrating stresses contribution. The equations for the transformation of the displacements and forces to and from the simply supported beam natural coordinate system can be found in [30].

For the normalized semi-infinite strip problem discussed in section 2, given the load parameter vector $\boldsymbol{R} = [p, s, t]^T$, the displacements $\boldsymbol{U}$ and the flexibility matrix $\dfrac{\partial \boldsymbol{U}}{\partial \boldsymbol{R}}$ can be evaluated, which refer to the cantilever-like reference system of the semi-infinite strip. However, in order to combine these results with the resultant force ones, these quantities have to be converted from and to a reference system of a simply supported beam.

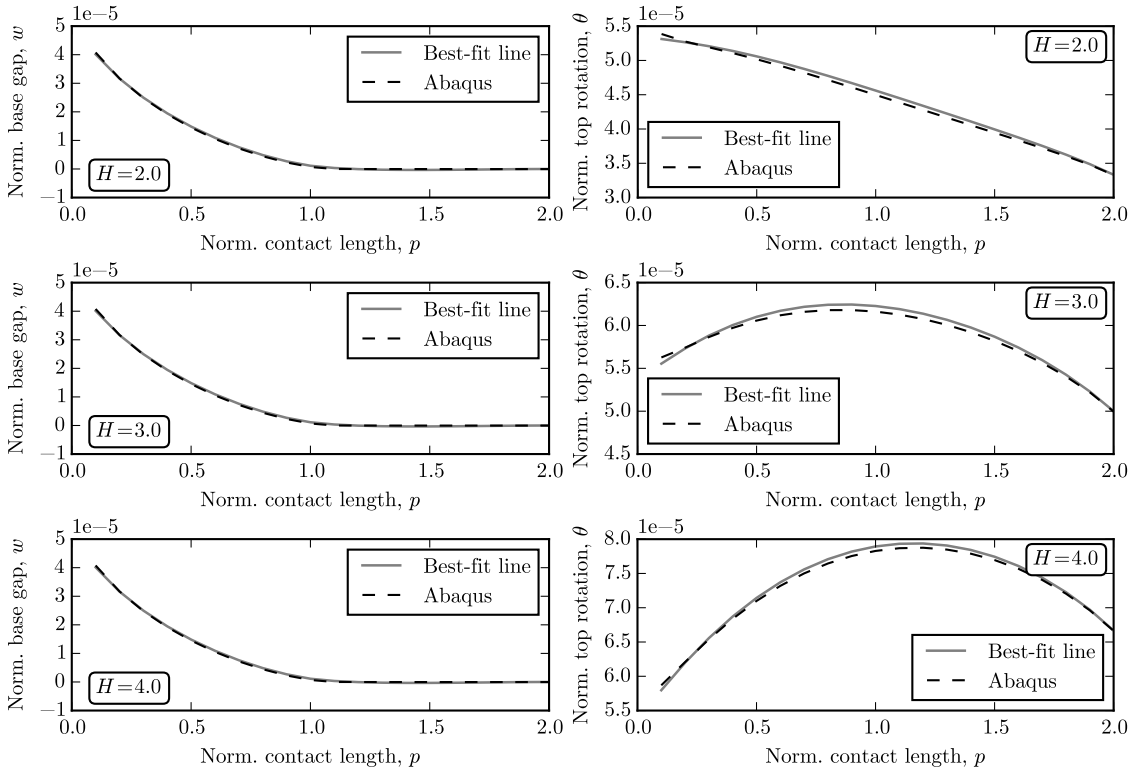

Figure 4: Rocking members with different heights loaded with a concentrated moment on their top: Central gap and top rotation versus the contact length at the bottom, p, and for $s = -1000, E = 30000000, \nu = 0.2$

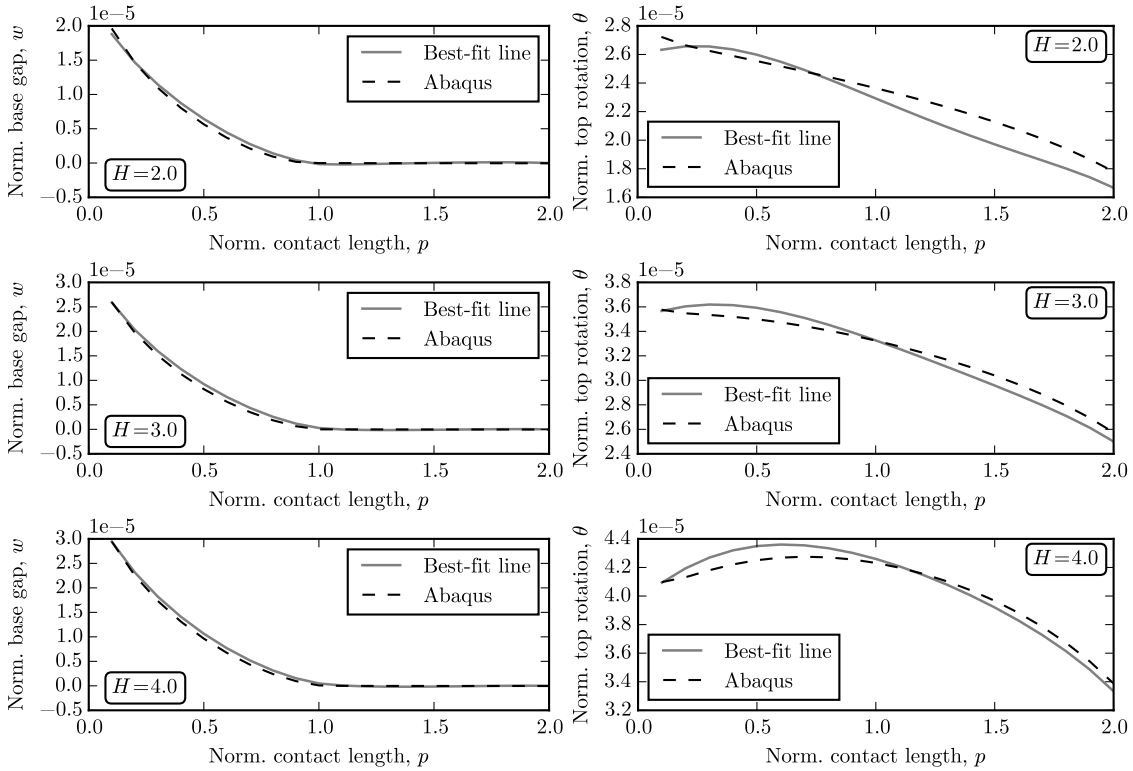

Figure 5: Rocking members with different heights loaded with a concentrated horizontal force on their top: Central gap and top rotation versus the contact length at the bottom, p, and for $s = -1000, E = 30000000, \nu = 0.2$

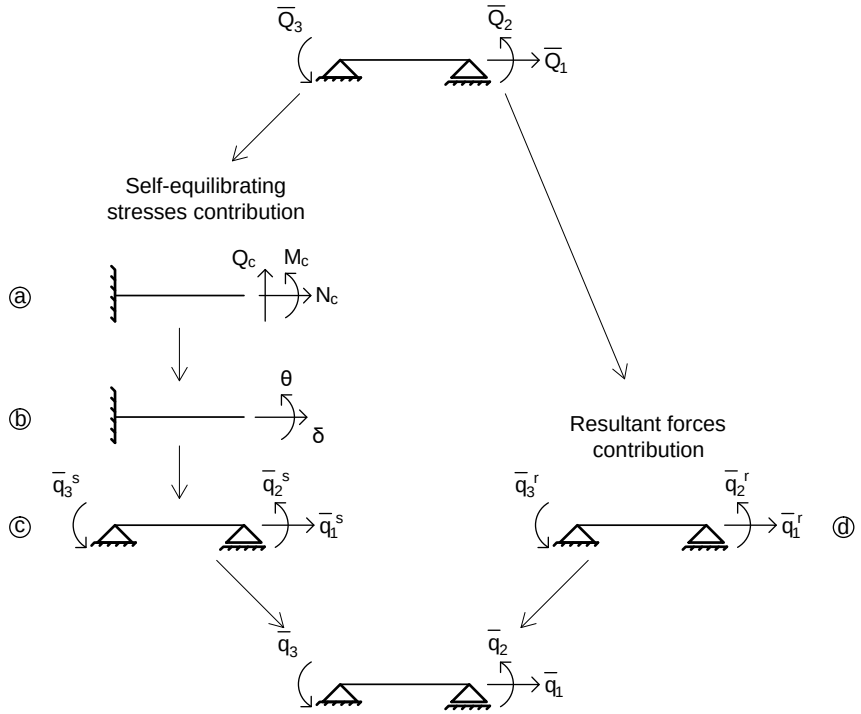

Figure 6: Schematic procedure used to calculate the combined displacements $\bar{\boldsymbol{q}}$ from the forces $\bar{\boldsymbol{Q}}$

Additionally, the problem that was formulated in section 2 referred to a semi-infinite strip of normalized semi-width $b = 1$, thickness $W = 1$ and stress distributions defined in the range $[-1, p-1]$. So, this problem has to be generalized to cover random width B, thickness W and load direction cases.

The conversion of the simply supported beam forces, $\bar{\boldsymbol{Q}} = [\bar{Q}_1, \bar{Q}_2, \bar{Q}_3]^T$, to the normalized problem cantilever ones, $\bar{\boldsymbol{Q}}_{\boldsymbol{c}} = [N_c, M_c, Q_c]^T$ (Fig. 6a), to the corresponding stress load parameters, $\boldsymbol{R}_{\boldsymbol{c}} = [c, s, t']^T$, and finally to normalized problem stress load parameters, $\boldsymbol{R} = [p, s, t]^T$, is described by the following equations:

$$\bar{\boldsymbol{Q}}_{\boldsymbol{c}} = \boldsymbol{S_1}\bar{\boldsymbol{Q}} \tag{7}$$

$$\boldsymbol{R}_{\boldsymbol{c}} = \begin{Bmatrix} 3\left(b + \dfrac{|M_c|}{N_c}\right) \\ \dfrac{2}{3}\dfrac{N_c}{b + \frac{|M_c|}{N_c}} \\ \dfrac{1}{2}\dfrac{Q_c}{b + \frac{|M_c|}{N_c}} \end{Bmatrix} \text{ with } N_c < 0 \tag{8}$$

$$\boldsymbol{R} = \boldsymbol{S_2}\boldsymbol{R}_{\boldsymbol{c}} \tag{9}$$

where

$$\boldsymbol{S_1} = \frac{1}{W}\begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & -\dfrac{1}{L} & -\dfrac{1}{L} \end{bmatrix} \quad \boldsymbol{S_2} = \begin{bmatrix} \dfrac{1}{b} & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & \rho \end{bmatrix} \text{ and } \rho = \text{sign}(M_c) \tag{10}$$

Similarly, after the calculation of the displacements $\boldsymbol{U} = [\delta, \theta]^T$ of the normalized problem (Fig. 6b), the conversion to the ones of the general simply supported beam problem, $\bar{\boldsymbol{q}} =$

$[\bar{q}_1, \bar{q}_2, \bar{q}_3]^T$ (Fig. 6c), is described by the equation:

$$\bar{\boldsymbol{q}} = \boldsymbol{S_3 U} \tag{11}$$

where

$$\boldsymbol{S_3} = \begin{bmatrix} b & 0 \\ 0 & \rho \\ 0 & 0 \end{bmatrix} \tag{12}$$

The self-equilibrating part of the rocking element is active only if a portion of the section supported on the ground is active, that is, only if

$$c < B \Rightarrow \left| \frac{M_c}{N_c} \right| > \frac{b}{3} \tag{13}$$

which means that the resultant normal force must be located outside the kern of the section.

Also, given the flexibility matrix of the normalized semi-infinite strip problem $\boldsymbol{F_t} = \dfrac{\partial \boldsymbol{U}}{\partial \boldsymbol{R}}$, the flexibility matrix in the simply supported beam coordinate system $\dfrac{\partial \bar{\boldsymbol{q}}}{\partial \bar{\boldsymbol{Q}}}$ is evaluated as follows:

$$\frac{\partial \bar{\boldsymbol{q}}}{\partial \bar{\boldsymbol{Q}}} = \frac{\partial \bar{\boldsymbol{q}}}{\partial \boldsymbol{U}} \frac{\partial \boldsymbol{U}}{\partial \boldsymbol{R}} \frac{\partial \boldsymbol{R}}{\partial \boldsymbol{R_c}} \frac{\partial \boldsymbol{R_c}}{\partial \bar{\boldsymbol{Q}}_{\boldsymbol{c}}} \frac{\partial \bar{\boldsymbol{Q}}_{\boldsymbol{c}}}{\partial \bar{\boldsymbol{Q}}} = \boldsymbol{S_3\ F_t\ S_2\ S_4\ S_1} \tag{14}$$

with

$$\boldsymbol{S_4} = \frac{\partial \boldsymbol{R_c}}{\partial \bar{\boldsymbol{Q}}_{\boldsymbol{c}}} = \begin{bmatrix} -3\dfrac{|M_c|}{N_c^2} & 3\dfrac{\rho}{N_c} & 0 \\ \dfrac{2}{3}\dfrac{b + 2\frac{|M_c|}{N_c}}{\left(b + \frac{|M_c|}{N_c}\right)^2} & -\dfrac{2}{3}\dfrac{\rho}{\left(b + \frac{|M_c|}{N_c}\right)^2} & 0 \\ \dfrac{1}{2}\dfrac{|M_c| Q_c}{(N_c b + |M_c|)^2} & -\dfrac{1}{2}\dfrac{\rho N_c Q_c}{(N_c b + |M_c|)^2} & \dfrac{1}{2}\dfrac{1}{b + \frac{|M_c|}{N_c}} \end{bmatrix} = \begin{bmatrix} -3\dfrac{|M_c|}{N_c^2} & 3\dfrac{\rho}{N_c} & 0 \\ \dfrac{4}{c} - \dfrac{6b}{c^2} & -6\dfrac{\rho}{c^2} & 0 \\ \dfrac{9}{2}\dfrac{|M_c| Q_c}{N_c^2 c^2} & -\dfrac{9}{2}\dfrac{\rho Q_c}{N_c c^2} & \dfrac{3}{2c} \end{bmatrix} \tag{15}$$

The contribution of the resultant forces can be calculated as usual. The flexibility matrix of the elastic simply supported beam, taking into account shear deformation effects, is (e.g. [31]):

$$\boldsymbol{F_r} = \begin{bmatrix} \dfrac{L}{EA} & 0 & 0 \\ 0 & \dfrac{L}{3EI} + \dfrac{\alpha}{GAL} & -\dfrac{L}{6EI} + \dfrac{\alpha}{GAL} \\ 0 & -\dfrac{L}{6EI} + \dfrac{\alpha}{GAL} & \dfrac{L}{3EI} + \dfrac{\alpha}{GAL} \end{bmatrix} \tag{16}$$

where α is the shear shape factor with $\alpha \approx 1.2$ for rectangular cross sections (shear deformations contribution can be neglected by setting $\alpha = 0.0$). So, the displacements at the nodes originating from the resultant forces (Fig. 6d) are given by

$$\bar{\boldsymbol{q}}_{\boldsymbol{r}} = \boldsymbol{F_r} \bar{\boldsymbol{Q}} \tag{17}$$

The general algorithm for the macro-element which combines these two contributions, based on the algorithm in [30], is presented in table 2, where index r refers to the resultant force problem and s refers to the self-equilibrating stress problem (extended semi-infinite strip algorithm).

Table 2: Rocking macro-element algorithm

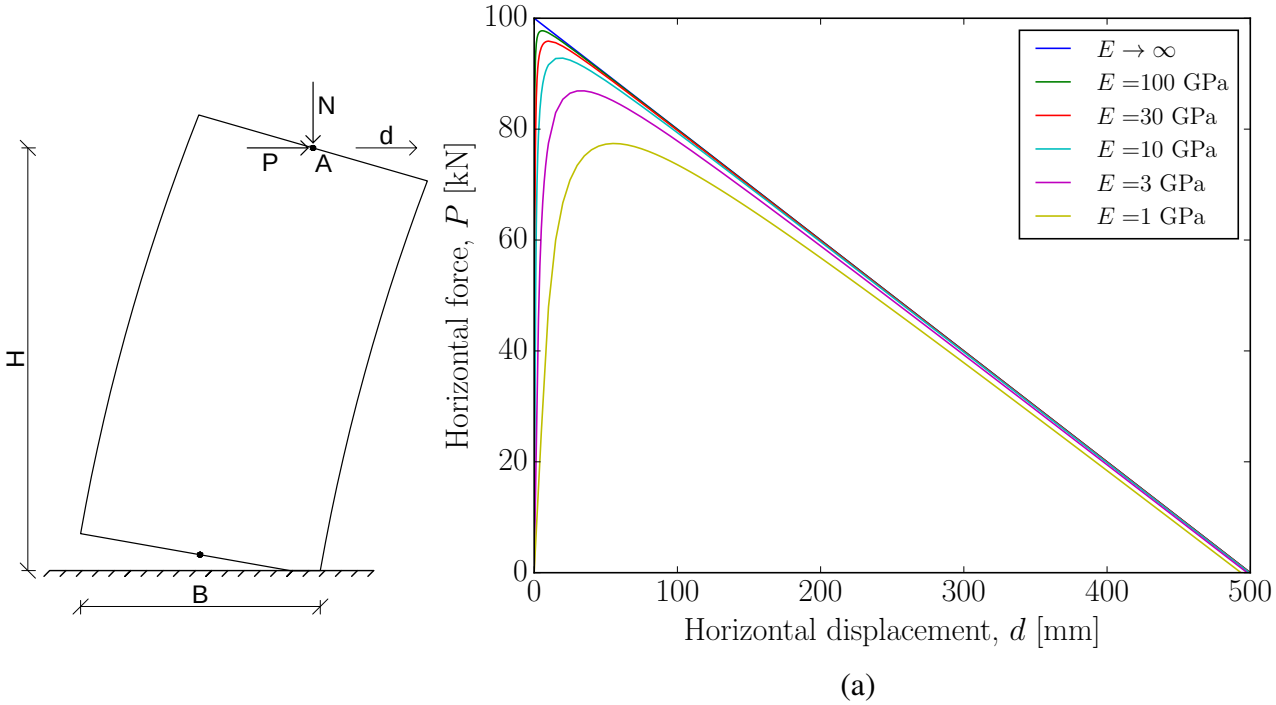
1. Elimination of rigid body modes	$\bar{\boldsymbol{q}}_i = \boldsymbol{T}_i \boldsymbol{q}_i$ $\Delta\bar{\boldsymbol{q}}_i = \boldsymbol{T}_i \Delta\boldsymbol{q}_i$
2. Nodal force increments	$\Delta\bar{\boldsymbol{Q}}_i = \boldsymbol{F}_{i-1}^{-1} \Delta\bar{\boldsymbol{q}}_i$
3. Nodal forces	$\bar{\boldsymbol{Q}}_i = \bar{\boldsymbol{Q}}_{i-1} + \Delta\bar{\boldsymbol{Q}}_i$
4. Flexibility matrix and Nodal displacements for the resultant force problem	$\bar{\boldsymbol{q}}_{\boldsymbol{r}}^{*} = \boldsymbol{F_r} \bar{\boldsymbol{Q}}_i$
5. Check whether there is rocking or not. If not, ignore steps (6)-(10) and set $\bar{\boldsymbol{q}}_{\boldsymbol{s}}^{*}$ and $\boldsymbol{F_s}$ to the zero matrices	$\left\lvert \frac{\bar{Q}_2}{\bar{Q}_1} \right\rvert > \frac{b}{3} \rightarrow$ Rocking
6. Force parameters for the self-equilibrating stresses problem	$\bar{\boldsymbol{Q}}_{\boldsymbol{c}} = \boldsymbol{S_1} \bar{\boldsymbol{Q}}_i$ $\boldsymbol{R_c} = \boldsymbol{R_c}(\bar{\boldsymbol{Q}}_{\boldsymbol{c}})$ $\boldsymbol{R} = \boldsymbol{S_2} \boldsymbol{R_c}$
7. Displacements of the normalized problem	$\boldsymbol{U} = \boldsymbol{G}\ \boldsymbol{L}$
8. Displacements in the simply-supported beam natural system	$\bar{\boldsymbol{q}}_{\boldsymbol{s}}^{*} = \boldsymbol{S_3}\ \boldsymbol{U}$
9. Flexibility matrix of the normalized problem	$\boldsymbol{F_t} = \frac{\partial \boldsymbol{U}}{\partial \boldsymbol{R}}$
10. Flexibility matrix in the simply-supported beam natural system	$\boldsymbol{F_s} = \boldsymbol{S_3}\ \boldsymbol{F_t}\ \boldsymbol{S_2}\ \boldsymbol{S_4}\ \boldsymbol{S_1}$
11. Combined displacements	$\bar{\boldsymbol{q}}_i^{*} = \bar{\boldsymbol{q}}_{\boldsymbol{r}}^{*} + \bar{\boldsymbol{q}}_{\boldsymbol{s}}^{*}$
12. Displacement residuals	$\boldsymbol{r}_i = \bar{\boldsymbol{q}}_i - \bar{\boldsymbol{q}}_i^{*}$
13. Combined flexibility matrix	$\boldsymbol{F}_i = \boldsymbol{F_r} + \boldsymbol{F_s}$
14. Extra nodal forces	$\bar{\boldsymbol{Q}}_i^{*} = \boldsymbol{F}_i^{-1} \boldsymbol{r}_i$
15. Updated nodal forces	$\bar{\boldsymbol{Q}}_i = \bar{\boldsymbol{Q}}_i + \bar{\boldsymbol{Q}}_i^{*}$
16. *(Optional)* Check convergence	$\frac{\lvert \bar{\boldsymbol{Q}}_i^{*} \rvert}{\lvert \bar{\boldsymbol{Q}}_i^{old} \rvert} >$ error $\Rightarrow$ return to step 4
17. Inclusion of rigid body modes	$\boldsymbol{Q}_i = \boldsymbol{T}^{*} \bar{\boldsymbol{Q}}_i$ $\boldsymbol{K}_i = \boldsymbol{T}_{1i} + \boldsymbol{T_i^{*}} \boldsymbol{F}_i^{-1} \boldsymbol{T_i^{*T}}$

4 EXAMPLES

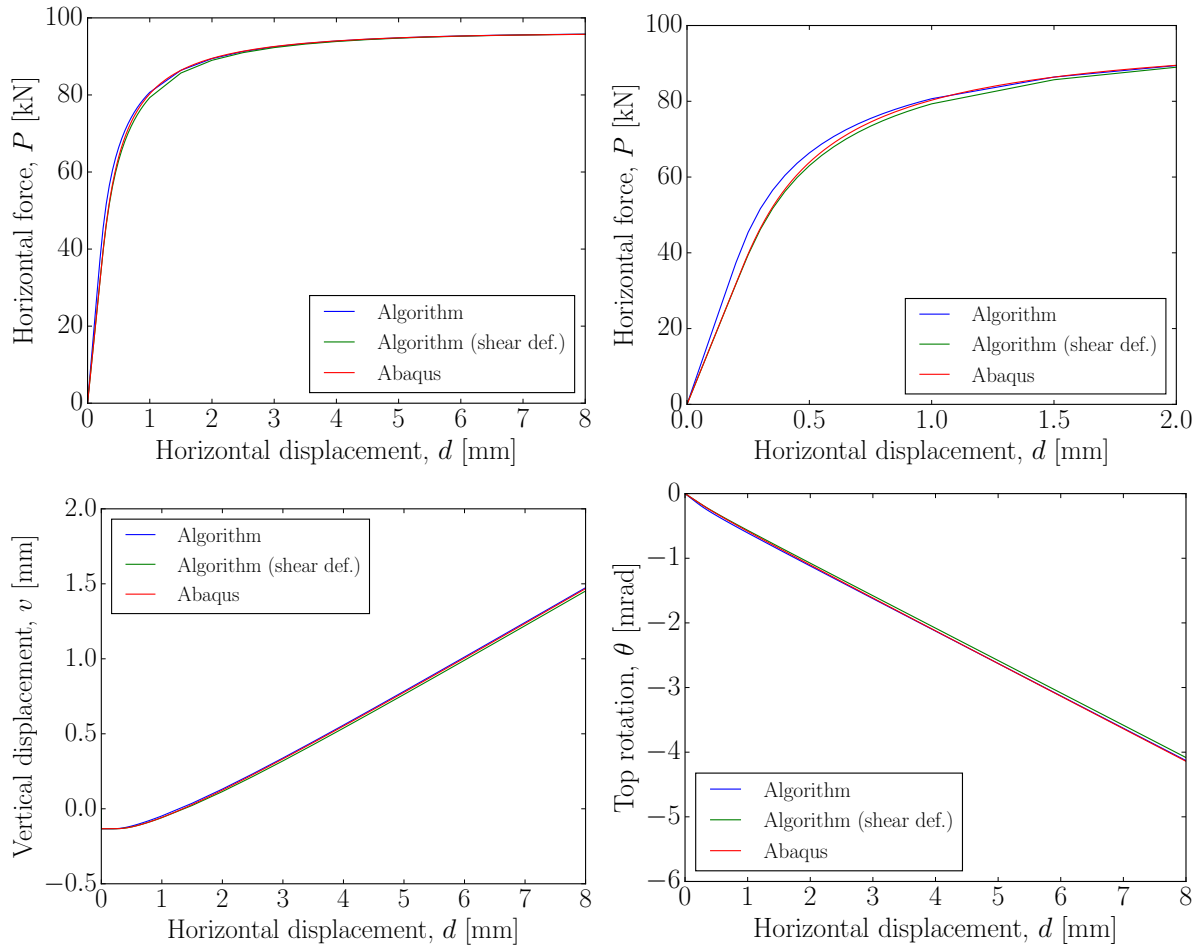
As a first example, the response of a simple cantilever model is calculated using the proposed macro-element. The results are compared with the results of the corresponding Abaqus model, consisting of 2D plane stress elements with contact properties at the base which allow only compressive stresses to develop.

In Fig. 7, a cantilever with height $H = 2$ m, width $B = 1$ m and thickness $W = 0.2$ m is examined, which is loaded with a vertical force $N = -400$ kN. In Fig. 7a, the pushover curves of such cantilevers with various E values and $\nu = 0.2$ are shown together with the theoretical rigid block case. It can be seen that, due to the non-linearity of the response, the maximum strength achieved decreases with decreasing E values.

In Fig. 7b, the response of the body with $E = 30$ GPa case is examined more thoroughly: apart from a magnification of the pushover curve in the initial region, the top rotation and the vertical displacement at the center of the body with and without shear deformation effects are presented. Comparison of the results with the ones of the corresponding Abaqus model shows



(a)



(b)

Figure 7: Example 1, $H = 2$ m panel loaded with vertical force $N = -400$ kN and horizontal force P at its top: (a) Pushover curves for different E values; (b) Pushover curves, top rotation and vertical displacement for the $E = 30$ GPa case, which is also compared with the corresponding Abaqus model

that, generally, the proposed macro-element can predict the response very accurately, especially if shear deformations are considered.

As a second example, the rocking body is examined with an elastic tendon with Young's modulus E_t and section area A_t installed along its center-line, imposing a prestress force with initial value $P_{t0} = 400$ kN. In this way, the vertical displacements are restrained after the onset of rocking, while the axial force originating from the tendon increases as its elongation increases.

The results are shown in Fig. 8 for typical values of tendon coefficients $E_t A_t$. It can be seen that the prestressing tendons force the pushover curve to be ascending instead of descending, offering stability to the system.

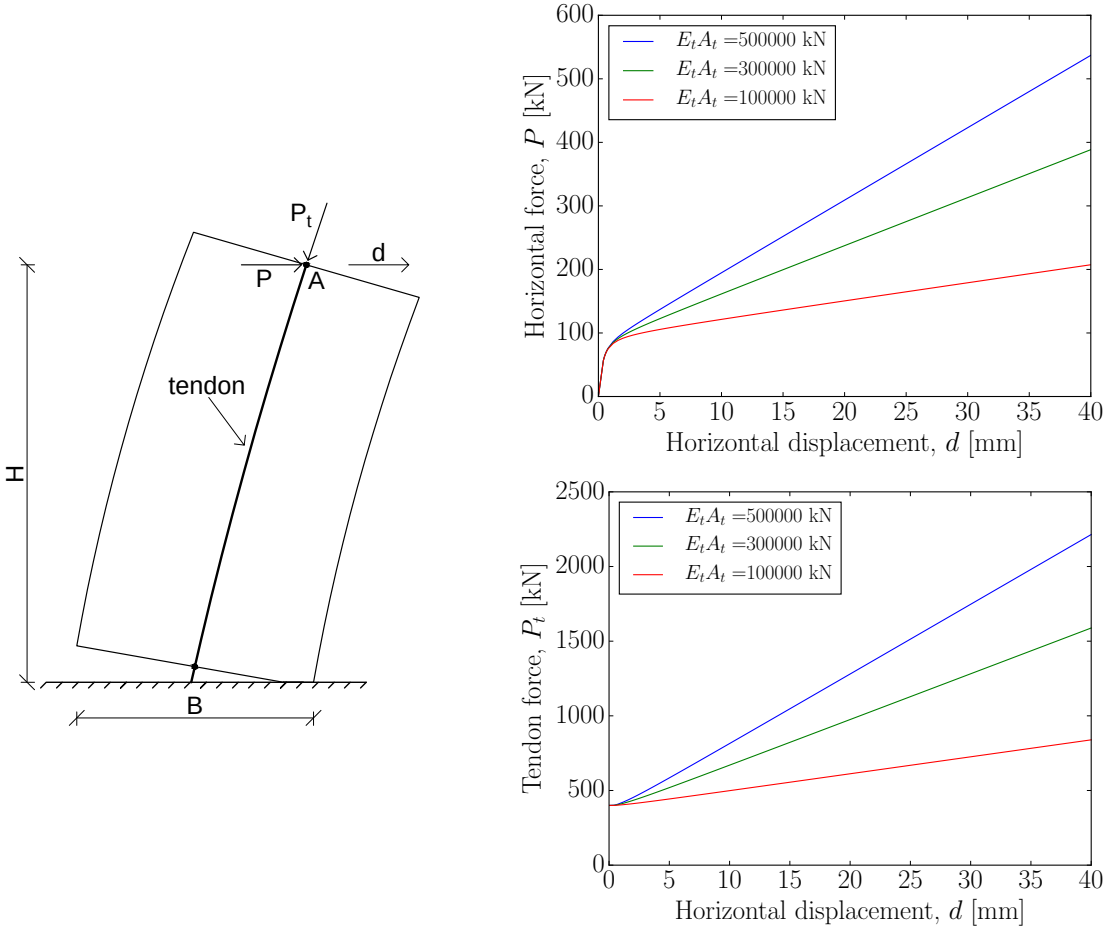


Figure 8: Example 2, $H = 2$ m panel with a horizontal force P at its top, constrained with a tendon with Young's modulus E_t, section area A_t and prestress force $P_{t0} = 400kN$: Pushover curve and tendon force

5 CONCLUSIONS

In this paper, a new macro-element algorithm is proposed, which can be used for the calculation of the rocking response of flexible bodies, also accounting for the deformability of their base. This is crucial in case of restrained rocking, when considerable axial forces develop. The formulation of the element is based upon the solution of the normalized semi-infinite strip problem, in order to account for the partial loading imposed on the rocking interface.

Two example problems are presented, showing typical cases where the proposed element can be used. Comparison of the results with ones obtained using equivalent Abaqus models

shows very good agreement between the two methods, while the proposed algorithm requires extremely low runtimes compared to conventional finite element codes.

Keywords: concrete infill walls, ductile design, experimental tests, shear studs, steel structures, steel and concrete hybrid systems.

Abstract. *Steel frames with reinforced concrete infill wall (SRCW) are characterized by an high stiffness that minimize the inter-storey drift and the associated damage to non-structural elements. They are however characterized by critical drawbacks, that limit their use, such as the low dissipative capacity of the concrete wall that causes high seismic force and high overturning moment at the wall base foundation. Within the present study, an innovative steel frame with reinforced concrete infill shear wall system is proposed. It consists of a reinforced concrete infill walls surrounded by a steel frame which contains energy dissipation replaceable elements within the columns. In this way the force transmitted to the other structural elements, and in particular to the foundations, are limited and an important portion of the seismic energy dissipated through plastic deformation. Within this paper the behaviour of the proposed system is investigated through nonlinear analyses based on advanced models supported by the experimental results on real scale specimens, highlighting advantages and drawbacks of the system.*

1 INTRODUCTION

Steel frames with Reinforced Concrete infill Walls (SRCWs) are structural systems that offer many advantages such as their high initial stiffness, able to reduce the building damage under low-intensity earthquakes, and potentially easy repairs after moderate damage through the use of epoxy resins on the cracked wall [1]. In this way, SRCW systems provide a promising structural solution potentially able to reduce the seismic risk in all its aspects, i.e., economic loss and fatalities, as for example contemplated in recent studies [2][3] following the 2012 Emilia earthquakes in Italy and highlighting the necessity of an adequate structural behaviour also for low-to-moderate seismic events [4].

In SRCWs three different resisting mechanisms to horizontal actions can be identified as depicted in Figure 1: 1) flexural behaviour of the steel frame; 2) direct interactions between the steel frame and the compression strut in the reinforced concrete (RC) infill walls; 3) interactions between steel frames and the RC infill walls through friction and shear connectors. The ratio of horizontal forces resisted by each of the load transferring paths depends on the mechanical properties and geometrical configuration of the considered system.

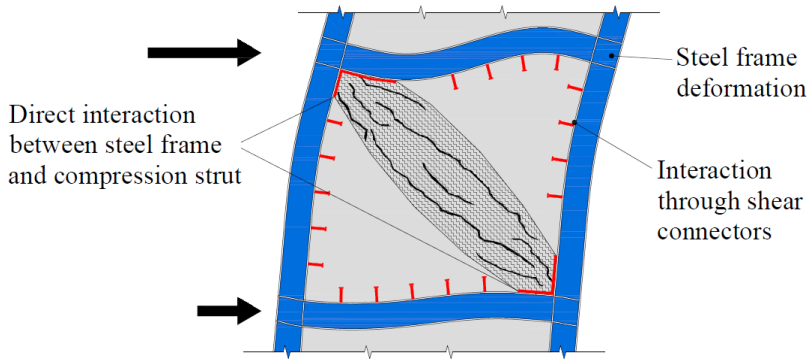

Figure 1: SRCWs resisting mechanisms to horizontal actions.

Despite all the available research studies carried out in the last decades, it is not easy to design a SRCW system in seismic areas due to the lack of specific capacity design rules that allow controlling the formation of a proper dissipating mechanism. Refined numerical analyses previously carried out on SRCW systems [5] designed according to the Eurocodes, in fact, pointed out an unsatisfactory fragile behaviour due to the severe damage occurring to concrete long before yielding of the ductile elements. The failure mechanism is generally characterised by yielding of the steel frame concentrated mainly in the elements near the bottom of the wall (more specifically at the connections of the horizontal to the vertical parts). The plastic deformation on the concrete infill walls concentrates in a diagonal path clearly highlighted by the distribution of cracking. In addition, localized plastic deformations are also present near the corners of the infill walls due to the local action of the first studs of the horizontal and vertical elements (Figure 2a). In order to overcome the observed critical aspects possibly affecting the considered structural system, an innovative approach for ductile design of SRCWs, recently studied during a European research project [5] that also involved innovative steel and concrete hybrid coupled walls [6], is presented in this work leading to the solution depicted in Figure 2b. The RC infill walls are not connected to the vertical elements where the energy dissipation is expected. The system is conceived to control the formation of diagonal struts in the infill walls and behaves as a latticed brace instead of a shear wall. The energy dissipation is expected to take place only in the vertical elements of the steel frame subjected mainly to axial forces without involving the reinforcements of the infill walls.

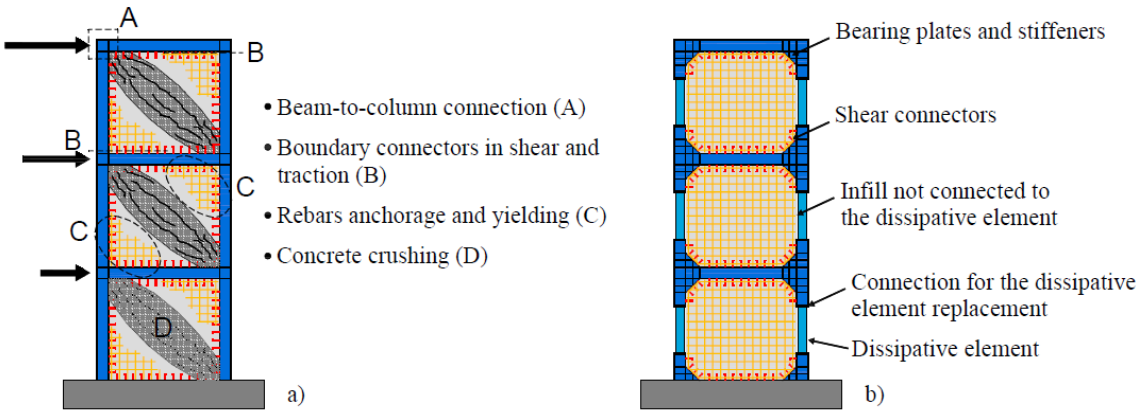

Figure 2: a) critical aspects in the behaviour of conventional SRCW systems; b) innovative SRCW system.

Detailing of the connection of the dissipating elements should allow their replacement and the presence of the infill wall limits the axial force in the compressed dissipative element avoiding its buckling. The formation of the diagonal strut is ensured by joint stiffeners and bearing plates. The joint may be welded in shops allowing speeding up the erection phases. The stud connectors are not required to transfer shear forces but they are mainly used to connect the infill and the frame together during the seismic shakings. A capacity design procedure, able to assure the desiderate energy dissipation mechanism, is proposed consistently with the Eurocode 8 [7] framework and explained in details. Sophisticated and simplified numerical models are then adopted to better understand the global behaviour of the system and to check the validity of the design procedure proposed. Finally, the results of an experimental campaign on two different 2/3 downscaled one-storey specimens are illustrated to validate the design procedure and to provide insight into the influence of the shear studs distribution on the behaviour of the proposed SRCW system.

2 DUCTILE DESIGN OF SRCW SYSTEMS

The proposed innovative SRCW is composed by elements with specific tasks according to the proposed capacity design. The design procedure consists of 9 steps, it is force-based and is applied by considering the simple statically determined scheme representing the limit behaviour of the SRCW depicted in Figure 3. The procedure is described hereafter.

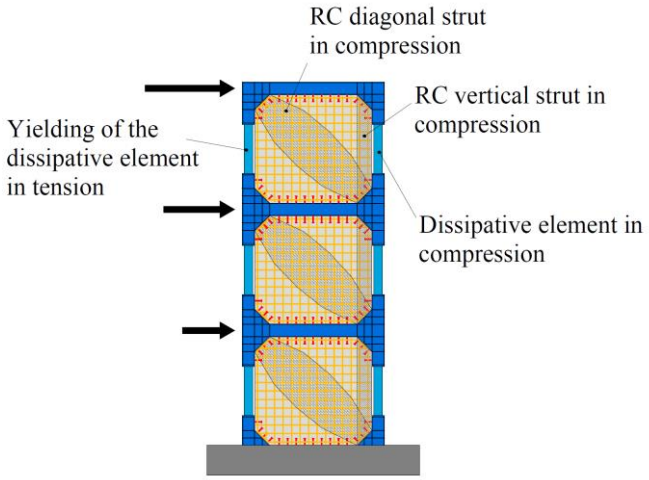

Figure 3: Limit behaviour under seismic action of the innovative SRCW system.

Step 1: definition of the static equivalent lateral loads and calculation of the truss actions.

A design spectrum reduced by a suitable behaviour factor is considered; the definition of the behaviour factor is rather delicate because the limit structural scheme adopted may not represent the behaviour of the system especially in the linear range for moderate earthquakes.

Step 2: design of the cross sections of the ductile boundary elements in traction.

These elements are subjected also to compression under the reversed loadings but they are not expected to yield in compression. Even if in principle no specific provisions are necessary, it is better to assure the element cross section being compact, e.g. at least class 2 according to Eurocode 3 [8].

Step 3: capacity design of the connection of the ductile elements and of the adjacent elements.

The design of the connection of the ductile elements and of the adjacent elements is performed with the formula

$$R_d \geq 1.1\gamma_{ov} R_{fy} \tag{1}$$

where γ_{ov} is the over-strength coefficient of the element with plastic resistance R_{fy} of the connected dissipative member based on the design yield stress of the material. The connection should be designed to resist the force in the linear range in order to reduce damage in the non-ductile elements and to permit the possibility to replace the ductile element after seismic damage. End-plates connections should be preferred to other types with the ductile element connected to the split plate by means of full penetration welding. The adjacent vertical elements to which the ductile elements are connected should be over-strengthened; this can be assured by using a different steel grade or by suitably enlarging the resisting cross section that should have width equal or greater than the infill wall thickness.

Step 4: calculation of geometric over-strength factors.

These factors are calculated as usual for steel structures by the ratio of the real plastic resistance of the ductile element and the relevant design force

$$\Omega = min\left\{\Omega_i = \frac{N_{pl,Rd,i}}{N_{Ed,i}}\right\} \tag{2}$$

To guarantee yielding of the edge steel elements at the different levels, and to avoid formation of soft storeys, the maximum over-strength Ω_i should not differ from the minimum value by more than 25%. At the higher levels, this condition may difficultly be satisfied. In such a case, the yielding takes place only at a limited number of storeys and the ductile elements should be designed to guarantee the global ductility, e.g. [9][10][11].

Step 5: calculation of axial forces in non-ductile elements by combining the effects of gravity loads with those of the seismic action suitably magnified.

These forces are calculated by suitably magnifying the seismic design component accounting for the material and geometric over-strength of the ductile elements with the usual formula

$$N_{Ed} = N_{Ed,G} + 1.1\gamma_{ov}\Omega N_{Ed,E} \tag{3}$$

Step 6: capacity design of the reinforced concrete infill against concrete crushing (definition of wall thickness t_w and width of the bearing plate l_b).

This step is crucial as it assures the good performance of the system that should not be affected by the wall failure (concrete crushing). As previously described, bearing plates are placed at the beam-to-column nodes to control the formation of the diagonal strut within the wall (Figure 4a).

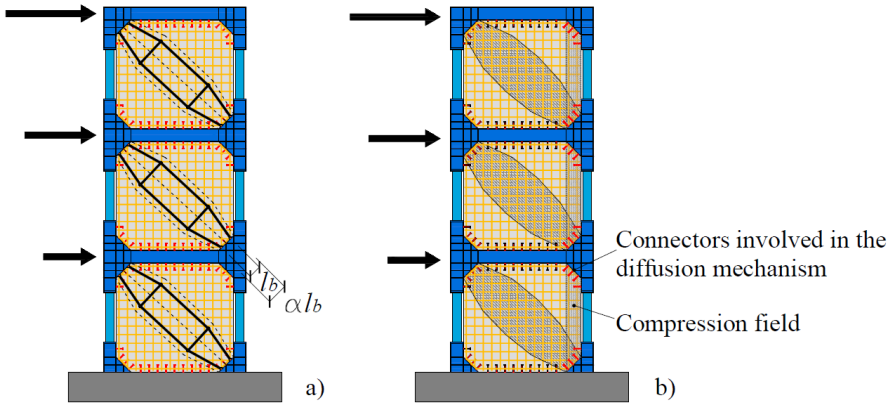

Figure 4: (a) diagonal struts within the infill walls; (b) compression fields involved to resist the axial force in the case lateral elements failed due to instability.

A fan-shaped stress field is expected at the bearing plate; the effective width of the wall should be equal to the bearing plate width l_b at the diagonal ends whereas the effective width is imposed by a coefficient $\alpha > 1$ at mid diagonal. The design formula

$$\left\{0.85\frac{f_{ck}}{\gamma_c}t_w l_b;\ 0.85\frac{f_{ck}}{\gamma_c}\nu\left(1-\frac{f_{ck}}{250}\right)\left(\alpha t_w l_b\right)\right\} \geq N_{Ed,G} + 1.1\gamma_{ov}\Omega N_{Ed,E} \tag{4}$$

is derived from Eurocode 2 (paragraph 6.5) [12]; the second value of the strut strength takes into consideration the transverse tension ($\upsilon = 0.6$ may be assumed) whereas the first value considers a simple compression field. The two design parameters l_b and coefficient α can be determined with a trial procedure or by imposing a tentative value for α. The bearing plate should be then proportioned and stiffened to avoid stress localization in the concrete.

The wall reinforcements should be checked to guarantee the diffusive mechanism that depends on the choice of the parameter α; for this purpose rules for partial discontinuity regions suggested in Eurocode 2 (paragraph 6.5.2) [12] are considered. In this case, tractions to be resisted by reinforcements is evaluated by means of the formula

$$T = \frac{1}{4}\left(1-\frac{1}{\alpha}\right)N_R \tag{5}$$

Two different reinforcement layouts may be adopted (Figure 5), the former is constituted by two sets of orthogonal reinforcements whereas the latter is constituted by a set of specific transverse (with respect to the strut direction) reinforcements. In the first case, vertical and horizontal reinforcements should fulfil the conditions

$$\frac{T^2}{f_{yd}^2} = A_{sl}^{v\,2} + A_{sl}^{h\,2} \qquad \frac{A_{sl}^h}{A_{sl}^v} = \frac{L}{h} \tag{6}$$

It is worth noting that the first reinforcement layout is simpler but possibly less stiff than the second, which instead requires a third order of reinforcements that can be placed only in the case of sufficiently thick walls.

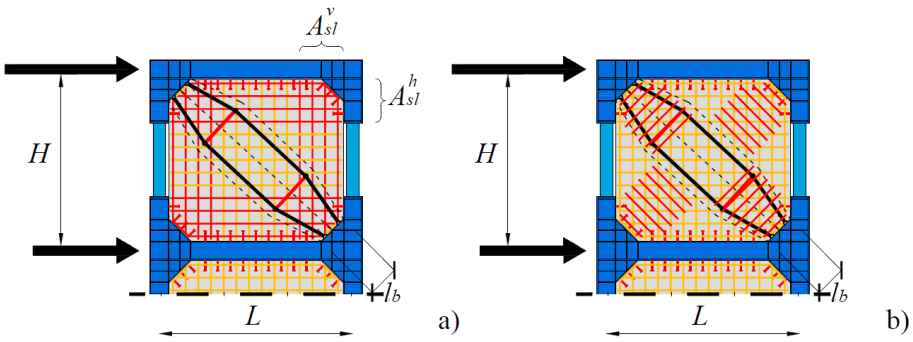

Figure 5: (a) reinforcements constituted by orthogonal rebar layout; (b) reinforcements constituted by additional stirrups.

Step 7: design of the beams in traction.

These elements are designed to resist magnified axial forces. To improve the system feasibility, it is better that their width is compliant with the wall thickness.

Step 8: check and possible re-design of the compressed edge elements.

The ductile elements are checked for instability by using the formula

$$\frac{Af_y\chi}{\gamma_{M1}} \geq N_{Ed,G} + 1.1\gamma_{ov}\Omega N_{Ed,E} \tag{7}$$

The effective length of the element can be selected to be equal to the distance between beam-to-column intersection nodes taking into account the real dimension of the enlarged zone necessary for realizing the bearing plate. In the case the verification is not satisfied, it is expected that the adjacent strip of the concrete wall collaborates to bear the compression force (Figure 4b); in such a case, the following points (8-1 and 8-2) have to be carried out.

Step 8-1: design of the shear connection between the wall and the frame.

The shear connection is designed to transmit to the adjacent RC wall the force in excess with respect to the bearing capacity of the ductile element given by

$$\upsilon_{Rd} \geq N_{Ed,G} + 1.1\gamma_{ov}\Omega N_{Ed,E} - \frac{Af_y\chi}{\gamma_{M1}} \tag{8}$$

In this case, shear connection has to be placed at the vertical elements. It has to be designed by taking into account that possible splitting failure mechanisms of the wall may occur instead of the usual failures due to concrete crushing and yielding. For this purposes, rules suggested by Eurocode 4 Part 2 (paragraph 6.6.4 and Annex C) [13] may be considered.

Step 8-2: check of the vertical strut developing in the wall.

This element withstands the same force calculated with equation (8) and has to be suitably reinforced with confinement stirrups. The same detailing rules suggested in Eurocode 8 (paragraph 5.4.3.4.2) [7] for RC walls may be adopted.

Step 9: calculation of the length of the dissipative element, in order to ensure the compliance between local and global ductility.

For this purpose, formulas derived by considering simplified mechanisms (Figure 6) can be adopted. To a first approximation, the following formula may be used:

$$H' = \frac{(\mu_s - 1)}{(\mu_m - 1)} \frac{\delta_{el} L}{\varepsilon_y \sum_{i=1}^{N} (z_N - z_{i-1})} \tag{9}$$

where μ_s and μ_m are the ductility of the structure and of the material of the dissipative element respectively; the summation is extended only to the N elements that fall in the $\Omega \div 1.25\ \Omega$ range, δ_{el} is the structure elastic displacement evaluated for the static equivalent loading inducing the first yielding; δ_{pl} is the structure plastic displacement evaluated considering only the elements expected to yield.

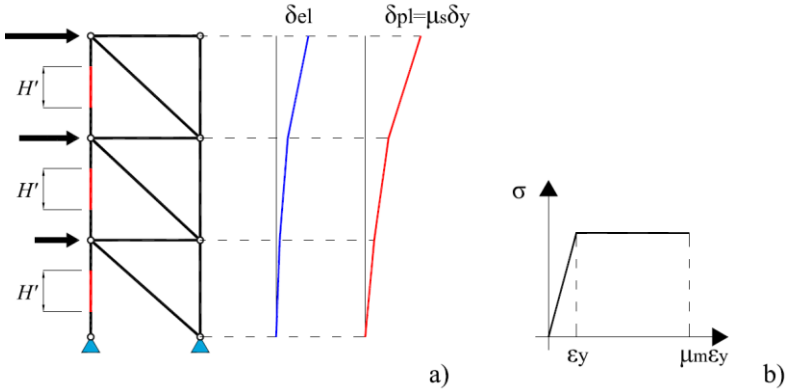

Figure 6: a) Elastic and plastic deformations of the SRCW; b) material stress-strain relationship.

3 NONLINEAR ANALYSIS OF THE INNOVATIVE SRCW SYSTEM

3.1 Finite element model

High fidelity finite element models are developed with the computer program ABAQUS for a preliminary analysis of the behaviour of the presented design approach for SRCW systems. A 4-storey system is considered and designed according to the procedure previously described. Details on the design parameters (i.e. geometry, vertical and horizontal loads, material properties) are reported in [5]. The geometry of the system is closely reproduced by using shell finite elements both for the steel frame and for the concrete infill walls (Figure 7); these are assumed to be connected to the frame only at the inclined bearing plates where stud connectors are placed. In particular, 4-node linear shell elements with 5 degrees of freedom per node (reduced integration, small membrane strains) are used. Wall reinforcements are considered by introducing two layers of reinforcements according to the construction drawings. A coarse mesh (mean size of 0.5 m) is adopted for the concrete walls to avoid numerical convergence problems, whereas a more refined mesh (mean size of 0.1 m) is adopted for steel members.

The behaviour of the concrete is described adopting a smeared cracking model with full shear retention. The concrete behaviour is assumed to follow Mander's law in compression and a linear elastic law in tension up to cracking, followed by a softening tract as later illustrated. Cracking is assumed to occur when the stress reaches a failure surface defined by a linear relationship between the equivalent pressure stress and the Mises equivalent deviatoric stress. When a crack is detected, its orientation is stored for subsequent calculations. Subsequent cracking at the same point is restricted to being orthogonal to this direction because stress components associated with an open crack are not included in the definition of the failure surface used for detecting the additional cracks. The behaviour of cracked concrete is modelled with a strain-softening branch that allows to simulate the interaction between rein-

forcements and concrete (tension stiffening); in particular, it is assumed a linear strain softening with zero stress at a total strain of about 10 times the strain at tensile failure. Elastoplastic-hardening models are considered for the reinforcements and the steel frame. The yielding point, the material plastic hardening and the ultimate stress for each steel grade considered are defined according to the mechanical characteristics of materials adopted in the design.

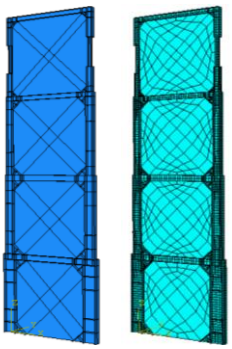

Figure 7: SRCW finite element model.

3.2 Results

Figure 8a; shows the yielding pattern of the steel frame for three displacement levels measured at the top level. It is observed that plastic strains are attained only at the ductile elements consistently with the dissipating mechanism assumed in the proposed design procedure. The resisting mechanism adopted in the design is also corroborated by the stress field in the wall (Figure 8b) that clearly depicts the formation of the diagonal struts in the concrete panels. The values of the principal stresses do not increase with the overall displacement demonstrating that the wall is protected against crushing due to yielding of the side fuses.

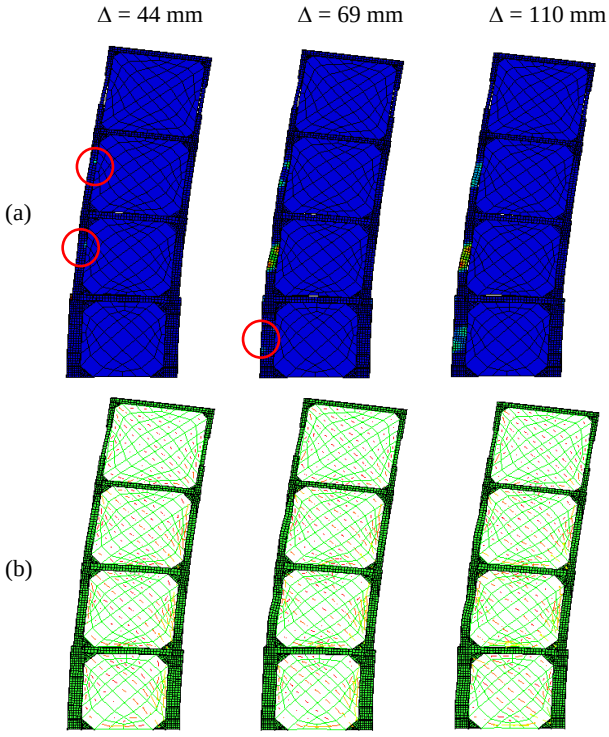

Figure 8: Results of finite element analysis: a) yielding pattern in the steel frame; b) stress field in the wall.

4 EXPERIMENTAL BEHAVIOUR OF THE INNOVATIVE SRCW SYSTEM

4.1 Introduction

An experimental campaign was carried out on two two-third downscaled specimens in order to validate the predicted behaviour of the proposed SRCW, evaluate possible problems related to the realization of such system, and highlight the influence of different shear stud distributions along the steel frame perimeter. The specimens, respectively named S1 and S2 are shown in Figure 9. S1 is characterized by the presence of shear studs only in the steel frame corner zones while S2 has shear studs distributed all along the steel frame perimeter (excluded the dissipative zones). In both cases the RC wall is 12 cm thick.

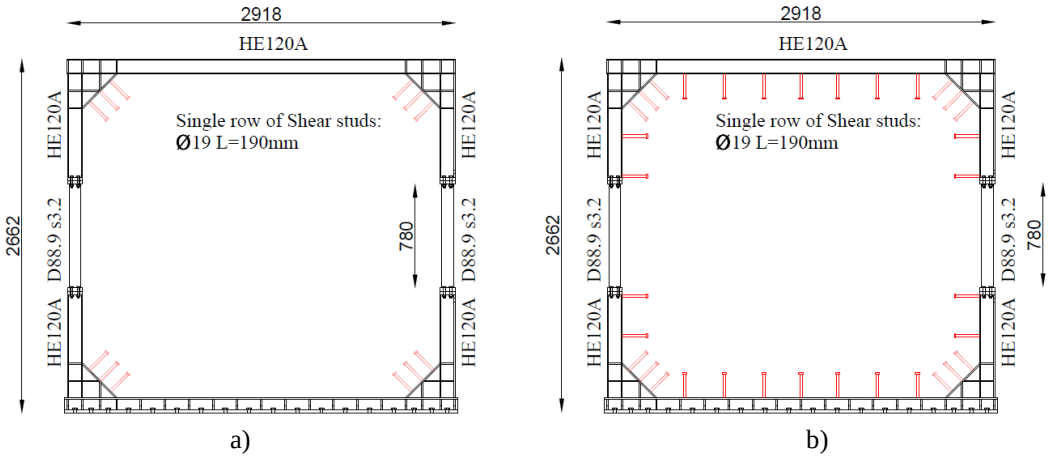

Figure 9: SRCW Steel frame specimens: a) Specimen S1 with shear studs only in the corner; b) Specimen S2 with shear studs all along the perimeter (excluded the dissipative zones).

4.2 Test setup

The SRCW specimen is bolted to a steel base firmly connected to the strong floor by means of an anchoring system and horizontal reaction system (Figure 10), while a lateral stabilizing system avoids transversal displacements of the wall.

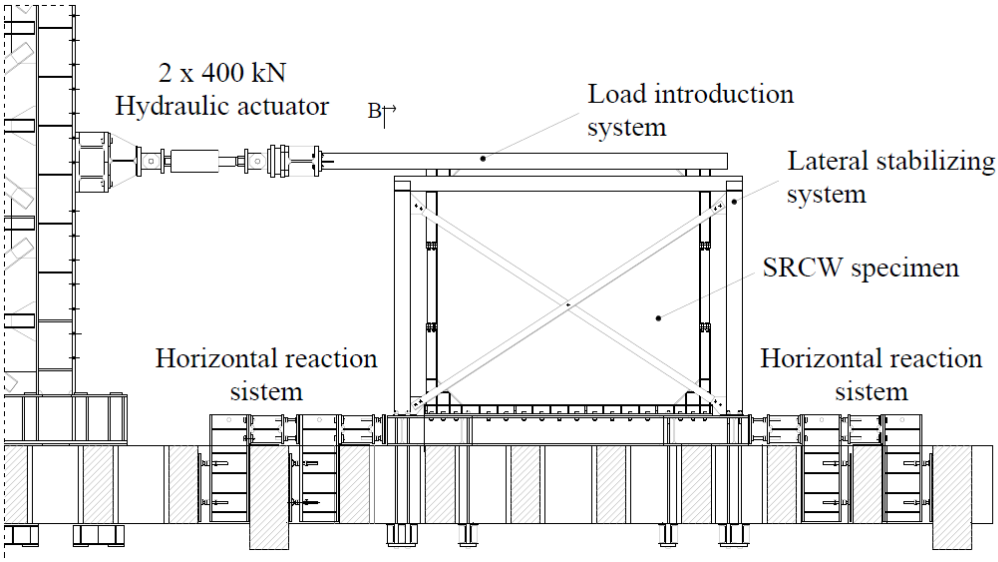

Figure 10: Global test setup.

The system is connected to the wall specimen by ten friction connections and it is independent from the lateral supporting system, allowing so the free tensile deformation of the dissipative elements. The displacements of the wall, the force applied, the deformation of dissipative elements and of the load introduction system are recorded by several sensors placed as shown in Figure 11.

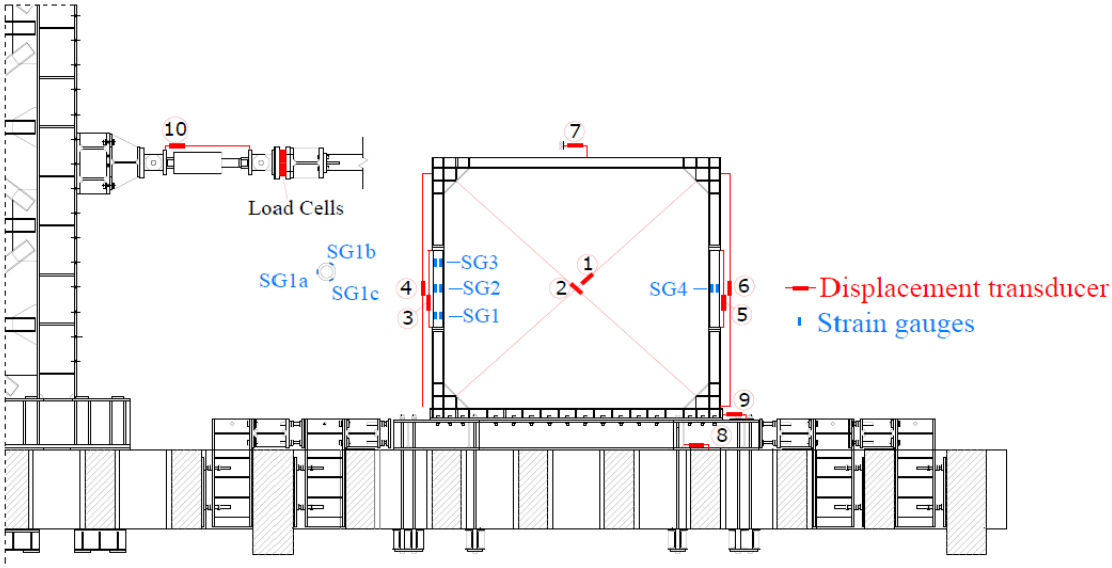

Figure 11: Sensors position.

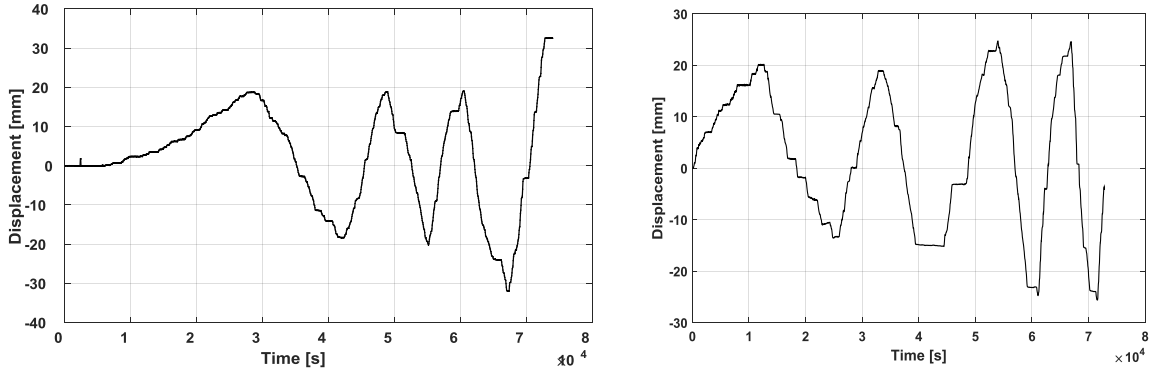
The tests are carried out in displacement control and the displacement history imposed to the jacks end is reported, for both tests, in Figure 12. An initial maximum displacement equal to 20 mm is imposed cyclically in order to assess a displacement ductility equal at least to 3 (during the test a yield displacement equal to about 6 mm is observed). The imposed maximum displacement is then raised to about 30 mm.



a) b)

Figure 12: Loading history of tests on a) specimen S1 and b) specimen S2.

4.3 Experimental results

In Figure 13 the experimental cyclic behaviour of specimen S1 is shown. The first loading cycle highlights a relatively "fat" hysteretic behaviour, while pinching phenomena, with the maximum resistance that remains practically constant, is exhibited during the subsequent cycles. The first semi-cycle shows that the system is characterized by a behaviour very close to an ideal elastoplastic one with a displacement ductility equal, at least, to 3.

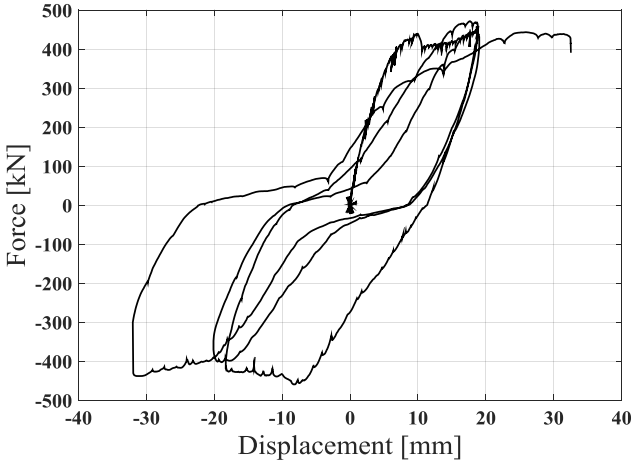


Figure 13: Specimen S1: cyclic force-displacement curve.

At the end of the first unloading phase, the concrete wall exhibits practically no damage, exception made for a little detachment from the lateral steel boundary elements. It can be inferred that, mainly due to the low number of shear studs connecting the RC wall to the steel boundary elements, the wall behaves as a rigid body within the steel frame, avoiding any damage, except for the corner zones. Due to the continuous accumulation, cycle after cycle, of the vertical displacements in the lower edge, the force application point of the compressed concrete diagonal strut changes and causes the failure of the specimen due to an excessive shear deformation of the non-dissipative vertical steel element (Figure 14a). At the same time, the spalling of the concrete on the opposite lower corner of the infill wall and the complete detachment of the infill wall from the steel frame occurs (Figure 14b). Practically no other damages are visible within the RC wall.

a) b)

Figure 14: Lower corners of S1 after failure: a) shear failure of the non-dissipative zone and b) spalling of the concrete and complete detachment by the steel frame.

Specimen S2 shows a behaviour similar to the one of specimen S1 as can be seen in Figure 15, with evident pinching phenomena but with an higher resistance. The diffused presence of the shear studs all along the perimeter of the steel frame allows the transmission of horizontal forces also through shear mechanism, as testified by the diffused diagonal cracking observed

within the wall. The more efficient connection between the wall and the boundary steel elements causes the propagation of a main crack from the base of the dissipative element in tension, as illustrated in Figure 16, avoiding any detachment phenomena between the RC wall and the steel frame. Due to the displacement accumulation, the vertical and horizontal reinforcing bars crossing the main crack break (Figure 16), causing the loss of some horizontal forces carrying capacity.

5 CONCLUSIONS

A new steel frame with reinforced concrete infill wall (SRCW) is proposed and its actual behaviour assessed through experimental tests. The system is characterized by the presence of a dissipative element within the boundary steel columns that allows the activation of a proper dissipative mechanism. Consequently, the force transmitted to the other structural elements, and in particular to the foundations, are limited and an important portion of the seismic energy dissipated through plastic deformation. To allow the activation of the dissipative mechanism and in order to optimize the design of non-dissipative elements, a force-based capacity design method, applied by considering the simple statically determined scheme representing the lim-

it behaviour of the SRCW, is proposed. Rules and indications are supplied for the design of each element composing the system, selecting and adapting the design philosophy and the indications of the Eurocodes. The real behaviour of the proposed system is then studied through an experimental campaign on two 2/3 downscaled specimens, characterized by a different shear stud distribution. Both specimens results highlighted a good monotonic displacement ductility and cyclic pinching phenomena, a practically constant maximum resistance and a tendency to accumulate tensile plastic deformation on the dissipative elements. The specimen with shear studs only on the corners failed due to excessive shear damage to the non-dissipative zone of the column and the spalling of the concrete on the opposite lower corner of the infill wall. The failure was probably caused primary by the uplifting of the concrete infill wall and the consequent uplifting of the contact point between the concrete strut and the steel frame. The other specimen, with shear studs distributed all along the non-dissipative steel boundary elements, failed due to the tensile failure of concrete wall reinforcements. It showed the same tendency to accumulate vertical displacement, but the accumulation took place on the main crack formed on the RC wall, while no detachment was observed between the wall and the steel frame. While the first specimen exhibited a latticed structural behaviour, the second specimen highlighted also a shear resistance mechanism of the shear wall, with a consequent initial lateral resistance higher than the one of first specimen. Further researches are however needed for better understanding of the shear studs distribution influence and to study the effects on the failure mechanism of the vertical forces transmitted by the dead and live load to the SRCW systems. The presence of the vertical loads could, in fact, modify the effective failure mechanism, avoiding the accumulation of the vertical displacements. In this way, the re-centring capability, today accepted as one of the most important features for limiting the structural damage due to the earthquake actions [14][15], would be demonstrated also for SRCW systems.

Keywords: Passive Seismic Protection, Linear Viscous Dampers, External Seismic Retrofit, Dissipative Towers.

Abstract. *This paper deals with the seismic protection of existing buildings using external viscous damper systems to increase the energy dissipation capacity. Dampers and bracings can be arranged in very different configurations and the possible solutions can be grouped into different categories, depending on the specific kinematic behavior. The study analyzes a recent solution called "dissipative tower", which, for the dampers activation, exploits the rocking motion of a stiff steel truss hinged at the foundation level. A state space formulation of the dynamic problem is presented in general terms and some issues concerning the influence of the bracing properties on the behavior of a case study consisting of a building coupled with a dissipative tower are investigated. The results presented concern both the influence of the external dissipative bracings on the most important modal properties of the system, and the global effect on the seismic response, evaluated via the modal decomposition method. It is shown that the addition of the towers yields a regularization of the drift demand along the building height, but it can also induce significant changes in the distribution of internal actions in the existing frame. Moreover, the contribution of higher order modes can be important for the internal actions evaluation, while it is negligible for the displacement estimation. The results obtained by considering the coupled system are compared with the corresponding results obtained by considering two limit cases: the bare frame, and the frame equipped with an infinitely stiff dissipative tower.*

1 INTRODUCTION

Passive control systems have proven to be very efficient solutions for new constructions and for seismic retrofitting of existing structures [1-4]. Viscous dampers are traditionally installed within a building frame in either diagonal or chevron brace configurations connecting adjacent storeys and there are many studies concerning both the dynamic properties of the damped system and the methods for the design [*e.g.*, 5-10]. However, this type of damping system may present some disadvantages, particularly when employed for retrofitting existing buildings. Usually, the addition of dissipative diagonal in existing frames provides an increment of axial forces in the columns and this may lead to premature local failures [11]. Furthermore, there may be some feasibility limits on the strengthening of the existing foundations at the base of the bracing system. Also, the indirect costs related to the interruption of the building utilization during execution of the retrofit can be very demanding, in particular for strategic buildings, such as hospitals or schools.

These problems can be efficiently resolved by considering external damper configurations, i.e., by placing the dissipative bracings and the relevant foundations outside the building frame. External dampers and bracing components can be arranged in very different configurations and the possible solutions can be grouped into three main categories, characterized by substantially different kinematic behaviors, but all permitting the control of both the total amount of the dissipated energy and the frame deformation at the various storeys. A possible solution can be obtained by placing the dampers horizontally at the storey level, between the frame and an external stiff structure [12]. This way, the links are activated by the floor absolute displacements. A similar configuration can be obtained by placing the dampers between adjacent buildings, though this solution is efficient if the two buildings have strongly different dynamic properties [13-16]. An alternative solution can be obtained by coupling the frame with an external shear deformable bracing structure. The new and existing structures are connected at the storey level and the dissipative devices are activated by the relative displacements between adjacent floors, as in the more traditional case of bracings placed within the existing structure [3].

Recently, some applications have been developed by proposing a new configuration exploiting the rocking motion of a stiff brace hinged at the foundation level [17, 18]. In this configuration, known as "dissipative tower" (Figure 1) [19], the dampers are activated by the base rotation of the tower.

This work focuses on the coupling between an existing frame and a rocking dissipative configuration shown in Figure 1; the purpose is the investigation of the modal properties and the seismic response of the coupled system by means of a problem formulation presented in general terms. The dynamic behavior and seismic performance of the system is compared against that of two other limit cases, the first one being the bare building, the second the building coupled with an infinitely stiff dissipative tower.

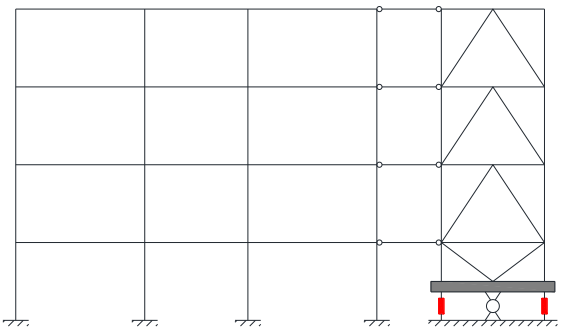

Figure 1: Dissipative Tower.

2 PROBLEM FORMULATION

In the first part of this section, the equation of motion and the state variables of the considered problem are presented by assuming that both the building and the external damping system exhibit a linear response. The limit case of stiff tower is also presented and the balance equations of the reduced single-degree-of-freedom (SDOF) system are obtained by introducing a constraint in the structure motion.

2.1 Equation of motion

The equations of motion for the system can be expressed as follows:

$$\mathbf{M}\,\ddot{\mathbf{u}}(t) + \mathbf{C}\,\dot{\mathbf{u}}(t) + \mathbf{K}\mathbf{u}(t) = \mathbf{M}\mathbf{p}\,a_g(t) \tag{1}$$

where $\mathbf{u}(t) \in R^l$, is the vector of nodal displacements, the dot (·) denotes time-derivative; $\mathbf{p} \in R^l$ is the load distribution vector, l denotes the total number of degrees-of-freedom, and $a_g(t)$ is the external scalar loading function describing the seismic base acceleration. The time invariant matrices $\mathbf{M}$, $\mathbf{K}$, $\mathbf{C}$ describe the mass, stiffness and damping operators $R^l \to R^l$; they result from the sum of the contribution due to the existing frame and the one coming from the external dissipative bracing system. The damping contribution of the frame and of the dissipative system are denoted respectively as $\mathbf{C}_F$ and $\mathbf{C}_D$. Generally, the external bracing system notably influences the stiffness and damping operators while it contributes only marginally to the mass operator. The displacement vector $\mathbf{u}(t)$ collects both the displacements required for the description of the frame response and the displacements involved in the bracing deformations.

In order to study the dynamic response of the system it is useful to separate the displacements associated with the masses, and thus involving inertial forces, from the displacements describing the internal degrees of freedom, related to stiffness and damping forces only. Accordingly, the total displacement vector $\mathbf{u}(t)$ can be split into the active components collected in the vector $\mathbf{x}(t) \in R^m$ and the other components $\mathbf{y}(t) \in R^n$ ($l = m + n$). The matrices describing the linear operators and the distribution vector can be consequently partitioned as follows

$$\begin{vmatrix} \mathbf{M}_{xx} & 0 \\ 0 & 0 \end{vmatrix} \begin{vmatrix} \ddot{\mathbf{x}} \\ \ddot{\mathbf{y}} \end{vmatrix} + \begin{vmatrix} \mathbf{C}_{xx} & \mathbf{C}_{xy} \\ \mathbf{C}_{yx} & \mathbf{C}_{yy} \end{vmatrix} \begin{vmatrix} \dot{\mathbf{x}} \\ \dot{\mathbf{y}} \end{vmatrix} + \begin{vmatrix} \mathbf{K}_{xx} & \mathbf{K}_{xy} \\ \mathbf{K}_{yx} & \mathbf{K}_{yy} \end{vmatrix} \begin{vmatrix} \mathbf{x} \\ \mathbf{y} \end{vmatrix} = \begin{vmatrix} \mathbf{M}_{xx} & 0 \\ 0 & 0 \end{vmatrix} \begin{vmatrix} \mathbf{p}_x \\ 0 \end{vmatrix} a_g \tag{2}$$

As usual, only the masses related to the horizontal floor displacements are considered in order to reduce the dimension of the dynamic problem and to simplify the interpretation of the results.

The distribution of the damping in the structure and, in particular, the location of the concentrated dampers of the external bracings, leads to a non-classically damped system. For its solution it is convenient to formulate the problem by introducing the vector $\mathbf{v}(t) = \dot{\mathbf{x}}(t)$ and the state vector $\mathbf{z}(t)$ collecting the displacements and the velocities of the active displacements and the displacements of the internal nodes:

$$\mathbf{z}(t) = \begin{vmatrix} \mathbf{x}(t) \\ \mathbf{v}(t) \\ \mathbf{y}(t) \end{vmatrix} \tag{3}$$

Eqn. (1) can be reduced to a first-order state space form:

$$\dot{\mathbf{z}}(t) = \mathbf{A}\mathbf{z}(t) + \tilde{\mathbf{p}}\, a_g(t) \tag{4}$$

where:

$$\mathbf{A} = \begin{vmatrix} \mathbf{0} & \mathbf{I} & \mathbf{0} \\ -\mathbf{M}_{xx}^{-1}\left(\mathbf{K}_{xx} - \mathbf{C}_{xy}\mathbf{C}_{yy}^{-1}\mathbf{K}_{yx}\right) & -\mathbf{M}_{xx}^{-1}\left(\mathbf{C}_{xx} - \mathbf{C}_{xy}\mathbf{C}_{yy}^{-1}\mathbf{C}_{yx}\right) & -\mathbf{M}_{xx}^{-1}\left(\mathbf{K}_{xy} - \mathbf{C}_{xy}\mathbf{C}_{yy}^{-1}\mathbf{K}_{yy}\right) \\ -\mathbf{C}_{yy}^{-1}\mathbf{K}_{yx} & -\mathbf{C}_{yy}^{-1}\mathbf{C}_{yx} & -\mathbf{C}_{yy}^{-1}\mathbf{K}_{yy} \end{vmatrix} \tag{5}$$

Vector $\tilde{\mathbf{p}}$ is defined as:

$$\tilde{\mathbf{p}} = \begin{vmatrix} 0 \\ \mathbf{M}_{xx}^{-1}\mathbf{p} \\ 0 \end{vmatrix} \tag{6}$$

2.2 Free vibrations and modal properties

The free vibration problem can be solved by assuming a solution of the form $\mathbf{z}(t) = \boldsymbol{\varphi} e^{\lambda t}$, where $\lambda, \boldsymbol{\varphi}$ are a eigenvalue-eigenvector pair of $\mathbf{A}$, such that:

$$\mathbf{A}\boldsymbol{\varphi} = \lambda\boldsymbol{\varphi} \tag{7}$$

Complex eigenvalue has the following form:

$$\lambda_i = -\xi_i\omega_{0i} + i\omega_{0i}\sqrt{1-\xi_i^2} \tag{8}$$

and contains information regarding both the damping ratio ξ_i and the corresponding undamped circular frequency ω_{0i} of the *i*-th mode. These information can be extrapolated as follows:

$$\begin{aligned} \omega_{0i} &= |\lambda_i| \\ \xi_i &= -\mathrm{Re}(\lambda_i)/|\lambda_i| \end{aligned} \tag{9}$$

Known the modal properties, the problem solution can be obtained as a linear combination of the single mode contributions. Let $\boldsymbol{\Lambda}$ be the diagonal matrix containing the complex eigenvalues and $\boldsymbol{\Phi} = |\boldsymbol{\varphi}_1, \boldsymbol{\varphi}_2, ..., \boldsymbol{\varphi}_{2m+n}|$ the complex eigenmatrix containing the eigenvectors, such that the orthogonality property $\boldsymbol{\Lambda} = \boldsymbol{\Phi}^{-1}\mathbf{A}\boldsymbol{\Phi}$ holds.

2.3 Seismic response via modal decomposition method

The motion can be obtained as a linear combination of modes:

$$\mathbf{z}(t) = \boldsymbol{\Phi}\mathbf{q}(t) \tag{10}$$

where $\mathbf{q}(t)$ is a vector collecting the modal coordinates. The orthogonality property leads to the diagonal problem:

$$\dot{\mathbf{q}}(t) = \boldsymbol{\Lambda}\mathbf{q}(t) + \boldsymbol{\gamma}\, a_g(t) \tag{11}$$

where $\gamma_i = \left[\boldsymbol{\Phi}^{-1}\tilde{\mathbf{p}}\right]_i$ is the *i*-th (complex-valued) modal participation factor.

Introducing the normalized complex modal response vector $\mathbf{s}(t)$ such that: $q_i(t) = \Gamma_i s_i(t)$, the problem can be written in a normalized form:

$$\dot{\mathbf{s}}(t) = \mathbf{\Lambda s}(t) + \mathbf{I}a_g(t) \tag{12}$$

Assuming that the system is initially at rest, the solution can be obtained by the Duhamel integral:

$$\mathbf{s}(t) = \int_0^t \mathbf{h}(t-\tau)a_g(\tau)d\tau \tag{13}$$

where the components $h_i(t) = e^{\lambda_i t}$ are the solutions related to an impulsive unitary input.

2.4 Generalized SDOF system approximation

The dissipative tower consists of an external bracings system that activates the dampers located at its base through its rocking motion. In the case of an infinitely stiff tower all the degrees of freedom of the system (active displacements of the frame and displacements involved in the bracing deformations) are governed by the base rotation φ. This means that the displacement vector $\mathbf{u}(t)$, shown in eqn. 1, can be expressed as

$$\mathbf{u}(t) = \mathbf{L}\varphi \tag{14}$$

in which **L** is a vector collecting the heights of the frame. The D'Alembert Principle for the problem at hand can be expressed by introducing a virtual velocity field $\hat{\eta} = \mathbf{L}\hat{\varphi}$, in which $\hat{\varphi}$ is an arbitrary base rotation. Eqn. 1 can be rewritten for any time instant *t* as

$$\mathbf{M}_b\ddot{\mathbf{u}} \cdot \hat{\eta} + \mathbf{C}_F\dot{\mathbf{u}} \cdot \hat{\eta} + \mathbf{C}_D\dot{\mathbf{u}} \cdot \hat{\eta} + \mathbf{K} \cdot \hat{\eta} = \mathbf{M}_b\mathbf{p} \cdot \hat{\eta}a_g \qquad \forall t \tag{15}$$

where the matrices $\mathbf{M}_b$, $\mathbf{K}_b, \mathbf{C}_F$ describe the mass, stiffness and damping of the frame and where $\mathbf{C}_D$ is the dissipative contribution of the dampers located at the tower base. This way, the tower influences only the damping operator and the shape of the virtual displacement field. Eqn. 15 can be rewritten as

$$\tilde{m}\ddot{\varphi} + (\tilde{c}_F + \tilde{c}_D)\dot{\varphi} + \tilde{k}\varphi = m^* a_g \tag{16}$$

where $\tilde{m} = \mathbf{M}_b\mathbf{L} \cdot \mathbf{L}$, $\tilde{c}_F = \mathbf{C}_F\mathbf{L} \cdot \mathbf{L}$, $\tilde{c}_D = \mathbf{C}_D\mathbf{L} \cdot \mathbf{L}$, $\tilde{k} = \mathbf{K}_b\mathbf{L} \cdot \mathbf{L}$, $m^* = \mathbf{M}_b\mathbf{p} \cdot \mathbf{L}$ are the scalar parameters describing the properties of the system reduced to a SDOF, and $\cdot$ denotes the scalar product. By solving Eqn. 15, the time-history of the base rotation is known, and the vector of nodal displacements of the MDOF system is determined by considering Eqn. (14).

3 CASE STUDY

3.1 Case study description

The application of the proposed approach is illustrated by considering a r.c. frame structure, with limited ductility, typical of many buildings designed during the 80s in Italy without any specific seismic detailing. Along the longitudinal direction, the structure consists of two external frames with 6 spans and a central one with 7 spans (Figure 2). The building has 5 storeys plus the roof.

The presented results concern three configurations, the bare existing frame (*As is*), the r,c, frame coupled with dissipative tower hinged at the foundation level and equipped with linear viscous dampers located at the base (*Retrofit*), and the r.c. frame coupled with an infinitely stiff dissipative tower (*Stiff*).

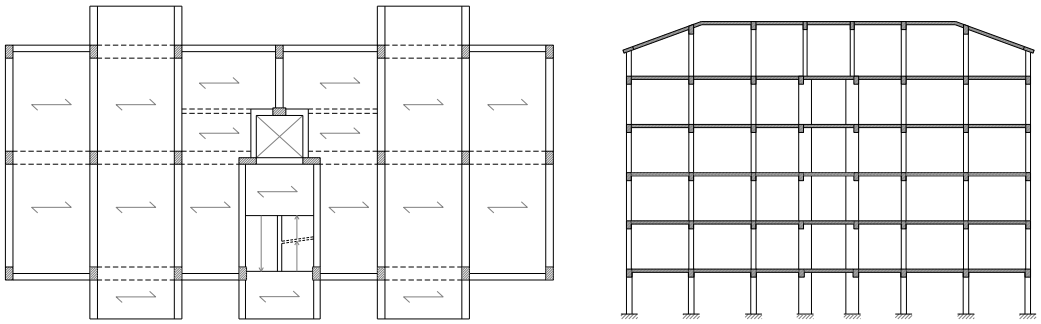

Figure 2: Planar view and longitudinal section of the bare building.

First, the previously described formulation is employed to investigate the influence of the external bracing properties on the overall dynamic properties of the coupled system, such as the modal displacement profile, the relevant internal action distribution and the modal damping ratios. Successively, the global effect of the retrofit on the seismic response is evaluated by solving the seismic problem with the modal decomposition method for the first two configurations (*As is* and *Retrofit*) and with a direct integration method for the last one (*Stiff*).

The dynamic system is described by considering only the motion along the longitudinal direction. The floors are assumed to be rigid in the horizontal plane and the masses are concentrated at the storey levels so that the vector of active degrees of freedom $\mathbf{x}$ collects the five storey motions only.

3.2 Modal properties of the undamped system

The bracing system influences both the stiffness and the damping properties of the coupled system, while its contribution to the masses is negligible. It is useful to separately analyze the variations on stiffness and damping and, for this purpose, the case of the added tower without dampers is considered separately from the case of the tower with dampers.

Table 1 reports, for the five modes of the bare building (*As is*), the vibration periods, the undamped natural frequencies and the participant mass ratios, defined as $M_i^* = (\mathbf{M}\mathbf{p} \cdot \boldsymbol{\psi}_i)^2 / \mathbf{M}\boldsymbol{\psi}_i \cdot \boldsymbol{\psi}_i$ where $\boldsymbol{\psi}_i$ are the eigenvectors of the undamped system.

T_i [s]	ω_0^2	M_i^*	ΣM_i^*
1.021	6.18	0.787	0.787
0.300	21.03	0.117	0.904
0.153	41.26	0.052	0.956
0.097	65.51	0.03	0.985
0.074	86.05	0.015	1

Table 1: Modal analysis results - *As is* configuration.

The modal analysis results of the coupled system in the *Retrofit* configuration are summarized in Table 2, where it can be observed that the first two vibration modes involve the 95% of the total mass and the second period reduces to about half the value obtained with the *As is* configuration. The third case, i.e. the existing frame coupled with an infinitely stiff tower (*Stiff*), is characterized by one vibration mode only (T=0.925 s) as it behaves like a SDOF system governed by the tower rocking motion.

T_i [s]	ω_0^2	M_i^*	ΣM_i^*
0.964	6.52	0.806	0.806
0.147	42.84	0.138	0.945
0.073	86.24	0.035	0.980
0.051	124.17	0.015	0.995
0.041	151.63	0.005	1

Table 2: Modal analysis results – *Retrofit* configuration.

Figure 3 reports and compares the values of the interstorey drifts along the building height corresponding to the first three modes of vibration for the *As is* and the *Retrofit* configurations. It can be observed that the addition of the towers yields a regularization of the drift demands along the building height, even though a higher value of the drift is required at the first level.

Figure 4 reports the distributions of the total shear forces in the *As is* and *Retrofit* cases for the first three modes, whereas Figure 5 shows, for the *Retrofit* configuration only, the storey shear demand for the building and the tower. It is worth to note that the shear contributions of the existing frame and the towers could have different signs at some levels and, for the considered case, the first mode shear forces acting on the existing frame is higher than the total shear force at the first level.

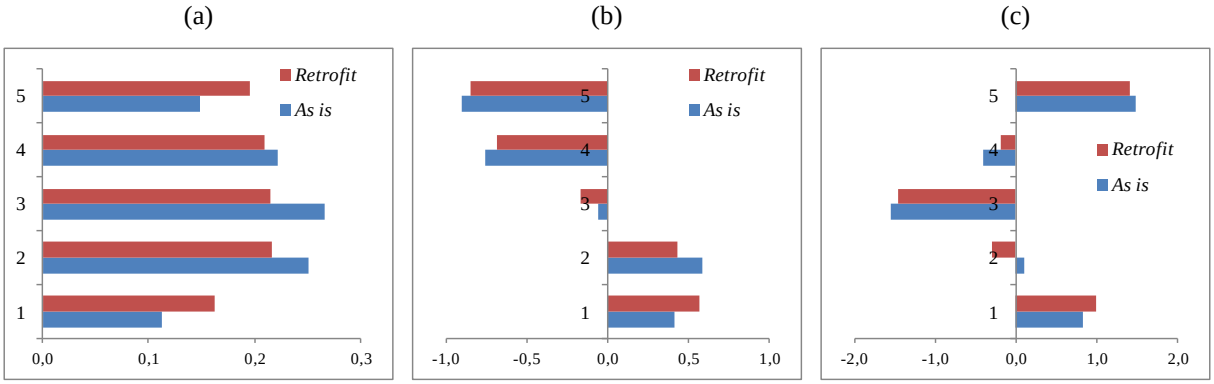

Figure 3: Interstorey drifts along the building height for mode 1 (a), mode 2 (b) and 3 (c).

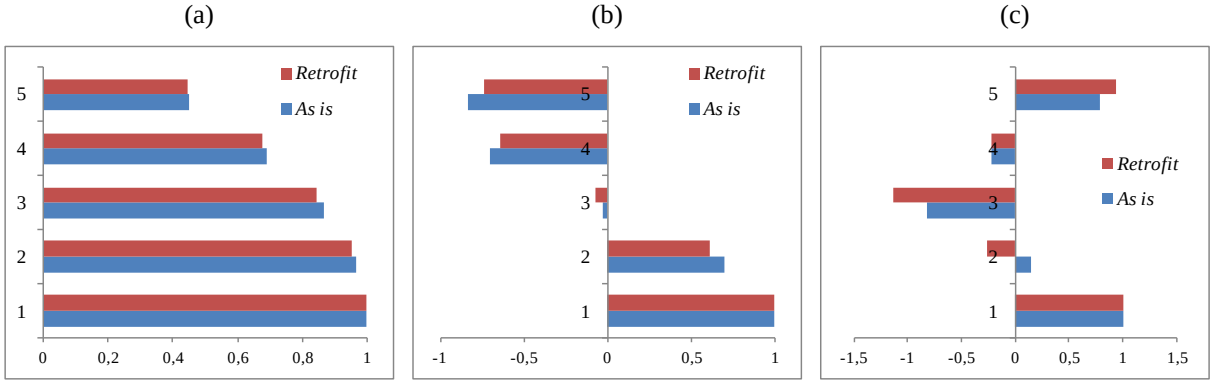

Figure 4: Total shear force comparison for mode 1 (a), mode 2 (b) and 3 (c).

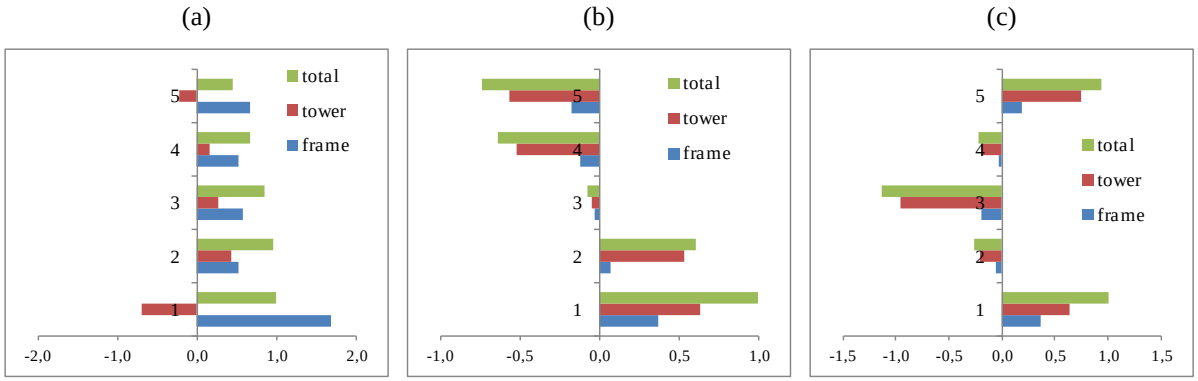

Figure 5: Shear force distribution for mode 1 (a), mode 2 (b) and 3 (c) – *Retrofit* configuration.

3.3 Modal properties of the damped system

The damping of the system is the sum of two contributions $\mathbf{C} = \mathbf{C}_F + \mathbf{C}_D$, the former is described by a Rayleigh damping matrix $\mathbf{C}_F = \alpha \mathbf{M} + \beta \mathbf{K}$, related to the existing frame, providing a inherent damping ξ=0.05 at the first two vibration modes. The latter contribution is due to the dampers and it is directly related to their displacements produced by the rocking motion.

A reference value of the damper dimensions is obtained by fixing a target total amount of the effective damping ratio β_{eff} =0.25 (0.05 due to the building and 0.20 due to the dampers), and by using the expression reported in ASCE/SEI 41-13 (2013)

$$\beta_{eff} = \beta + \frac{\sum_j W_j}{4\pi W_k} \tag{17}$$

where β is the damping in the structural frame (0.05), W_j the work done by j-th device in one complete vibration cycle and W_k is the maximum strain energy in the frame.

The retrofit configuration consists of two dampers placed as in Figure 1, whose viscous constant values are designed by employing eqn. (17) assuming that the system deforms according to its first undamped vibration mode. The total amount of added damping is measured by C_0=135020 kNs/m, which is the sum of the viscous damping constant of the two devices.

By means of the complex modal analysis it is possible to identify the damping ratio ξ_i corresponding to each one of the vibration modes, as shown in eqn. (9); moreover, by introducing a damper multiplier c for the total added damping C_0, it is possible to evaluate the variation of the modal properties at different damping levels, defined by the parameter c.

Figure 6(a) shows the influence of c on the vibration periods of the first three modes. The first three natural periods of the undamped system (dashed line in Figure 6) are 0.964 s the first period (blue line), 0.147 s the second (red line), and 0.073 s the third period (green line). The vibration periods of the coupled system decreases for increasing damping. For c=3.0, the first period attains the value 0.595 s, the second 0.141 s and the third 0.072 s. Thus, the amount of damping introduced influences significantly only the first vibration period of the system. Figure 6(b) shows the variation, with the total added damping c, of the damping ratio of the first, second and third vibration modes, ξ_1, ξ_2 and ξ_3. It also reports the variation of the estimate of the damping ratio β_{eff}, obtained by employing the approximate formula of Eqn.(17), for increasing values of c.

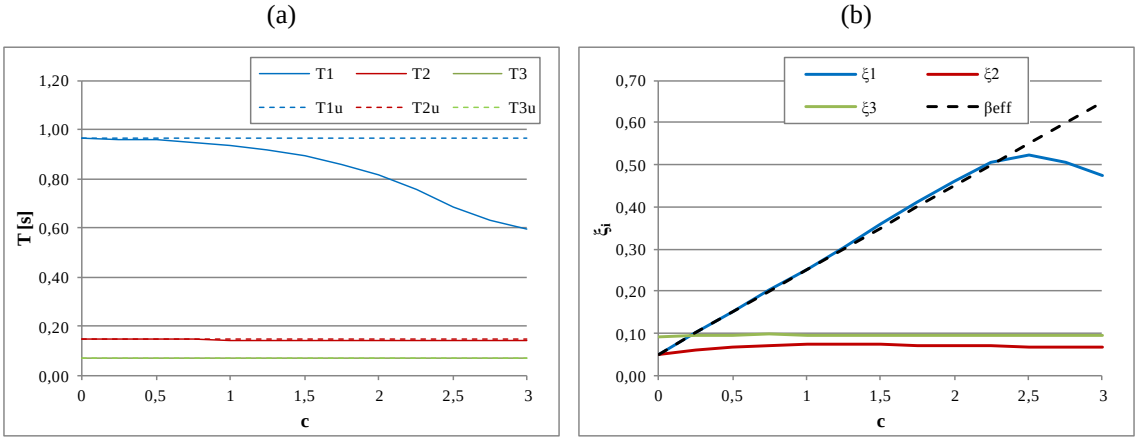

Figure 6: First three period trends (a) and first three modes damping trends (b) for increasing damping levels.

The first modal damping ratio ξ_1 is well approximated by the design formula of Eqn. (17) for ξ values up to 0.50 (c=2.25); for increasing values beyond this limit the amount of the effective damping decreases. As already observed for the periods, the influence of the damper dimensions on the second and third mode is negligible; the damping ratio varies in the range 0.050-0.067 with a maximum 0.074 when c=1.25 for the second mode, while for the third mode the range is 0.091-0.094 with a maximum value of 0.097 when c=0.75.

Due to the fact that all the dampers are concentrated at the tower base the system is notably non-classical damped and the extent of non-classical damping is synthetically quantified by the coupling index ρ (Claret e Venancio-Filho 1991), expressed as:

$$\rho = \max \left| \frac{\Xi_{ij}^{2}}{\Xi_{ii}\,\Xi_{jj}} \right| \quad (i,j=1,2,\ldots,m)\ i \neq j \tag{18}$$

where $\Xi_{ij} = \mathbf{C}_{xx}\boldsymbol{\psi}_i \cdot \boldsymbol{\psi}_j$ is the modal damping matrix component, $\mathbf{C}_{xx}$ and m are defined in section 2.1 and $\boldsymbol{\psi}_i$ are the eigenvectors of the undamped system. The index assumes the value 0 for classical damped systems and it spans the range [0,1] in the case of non-classical damping. Figure 7(a) shows the coupling index trend for increasing damping levels, while Figure 7(b) shows the values of ρ obtained for the damping target value c=1. In the latter case the maximum value of ρ is equal to 0.35 and corresponds to the coupling among the first and the second mode.

3.4 Seismic response

This section reports some results concerning the response of the three system configurations to a seismic input. The seismic action is determined by assuming the building located in Camerino (MC, Italy), with soil category C and topographical one T1, according to Italian code [20]. Seven artificial earthquakes, generated in accordance with Italian Standards, are considered. The results reported concern the most interesting parameters, i.e., the displacements, interstorey drifts, shear action distribution and the absolute accelerations; the values of these parameters reported below are the mean of the maximum values obtained for each of the seven time-histories analyses. The results related to the coupled systems (*Retrofit* and *Stiff* configurations) correspond to a total added damping multiplier c =1.

Table 3 reports the floor displacements and the interstorey drifts for the three configurations analyzed. The maximum top displacement, normalized with respect to that of the bare frame, is 54% for the *Retrofit* case and 58% for the *Stiff case*. Figure 8(a) and (b) show the distribution along the height of the building displacements x_i and interstorey drifts θ_i, for i=1,2,..,5. The reported values are normalized by dividing them by the corresponding values obtained at the 5th level in the *Stiff* configuration.

level	*As is*		*Retrofit*		*Stiff*	
	x_i [m]	θ_i [m]	x_i [m]	θ_i [m]	x_i [m]	θ_i [m]
1	0.013	0.013	0.008	0.008	0.009	0.009
2	0.040	0.028	0.019	0.011	0.018	0.009
3	0.068	0.029	0.029	0.011	0.027	0.009
4	0.092	0.026	0.040	0.011	0.036	0.009
5	0.109	0.019	0.050	0.010	0.046	0.009

Table 3: Floor displacements and drifts results

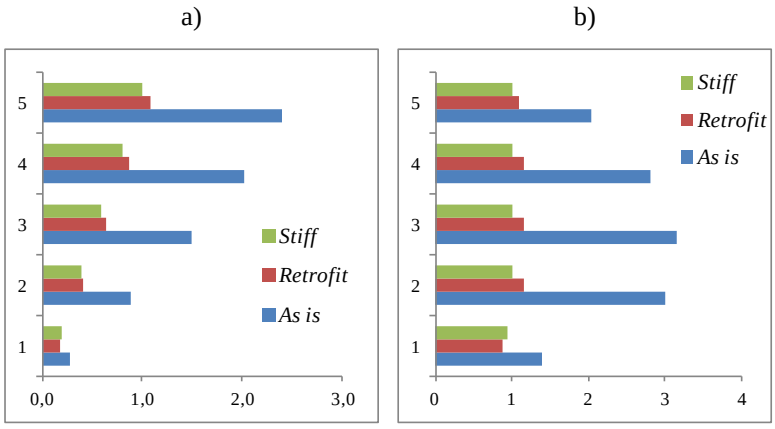

Figure 8: Displacements (a) and interstorey drifts (b) distributions for the three configurations.

It is noteworthy that the coupling with an infinitely stiff tower leads to a linear distribution of the displacements along the height. Moreover, the displacement demand at the first level is higher in the *Stiff* case than in the *Retrofit* case, while an opposite trend is observed at the top. This means that the regularization of the frame displacement distribution is achieved with the tower interacting with opposite forces at the base and at the top of the frame.

Having employed the complex mode superposition approach to solve the seismic problem, the contribution of the higher vibration modes to the response can be estimated by comparing the full response accounting for all the modes to the response obtained by considering the contribution of the first mode only. Table 4 reports the displacement response for the *As is* and the *Retrofit* case. Figure 9 comparises the displacement responses of the *As is* and *Retrofit* cases. In both the cases, the first mode contribution nearly controls the total response, while the effect of higher order modes is negligible.

level	*As is*		*Retrofit*	
	x_{full} [m]	x_1 [m]	x_{full} [m]	x_1 [m]

2	0.0405	0.0392	0.0188	0.0187
3	0.0684	0.0680	0.0295	0.0294
4	0.0918	0.0920	0.0399	0.0399
5	0.1092	0.1081	0.0497	0.0496

Table 4: Floor displacements and drifts results.

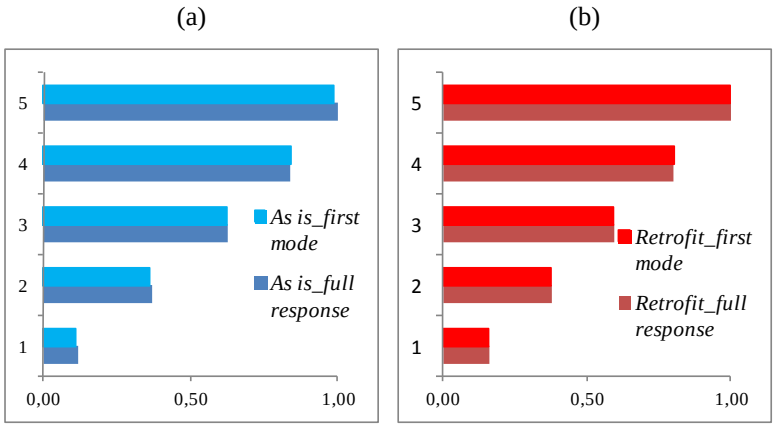

Figure 9: Contribution of the first mode to the full response of the (a) *As is* and (b) *Retrofit* cases.

Table 5 reports the shear actions resisted by the frame in the three configurations; for the *Retrofit* case the shear actions resisted by the tower and the total shear actions are also reported. It is noteworthy that the maximum shear for the tower and the frame may not occur at the same instant of time for all the records considered. As already discussed for the displacements, also the global shear demand decreases, but in a less significant way. The relative reduction of the maximum base shear acting on the frame, with respect to the bare frame, is nearly 19% for the *Retrofit* case and 6% for the *Stiff* one.

Figure 10(a) shows the shear actions distribution along the height of the frame, normalized after dividing them by the value of the base shear in the *Retrofit* configuration. Figure 10(b) shows the shear forces in the frame and the tower for the *Retrofit* case; the values are normalized with respect to the total base shear, obtained as the sum of the building plus the tower one.

level	*As is*	*Retrofit*			*Stiff*
	$V_{i,\text{frame}}$ [kN]	$V_{i,\text{frame}}$ [kN]	$V_{i,\text{tower}}$ [kN]	$V_{i,\text{total}}$ [kN]	$V_{i,\text{frame}}$ [kN]
1	5215.67	4232.33	2661.26	3544.64	4877.47

5	2755.01	1740.77	1020.58	1819.51	1643.12

Table 5: Shear actions results.

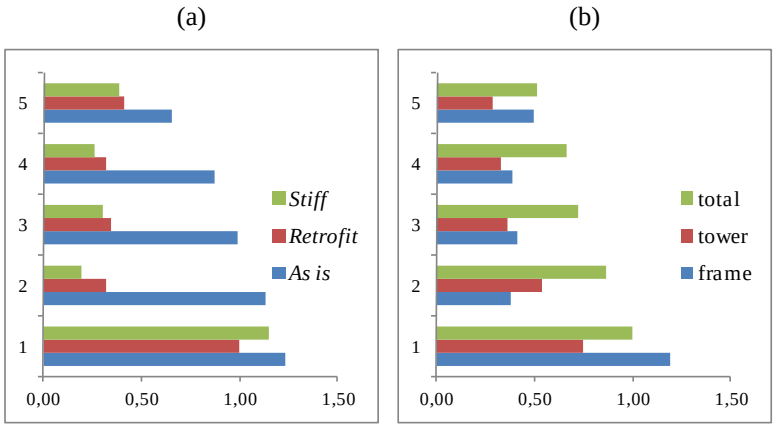

Figure 10: (a) Shear actions resisted by the frame in the three configurations and (b) shear actions resisted by the tower, the building and the frame compared to the total shear in the *Retrofit* case.

The complex mode superposition is also employed to estimate the contribution of the higher order modes of vibration on the shear actions before and after the retrofit. Table 6 reports the shear actions distribution resisted by the frame in the *As is* case and the contributions of both the frame and the tower in the *Retrofit* one, due to the full response and the first mode. Differently from the case of the displacements, the contribution of higher order modes is important as the values of both the total shear response and the tower shear response are higher than the corresponding values obtained by considering the first mode only. However, the building response appears to be still dominated by the first mode of the coupled system. These observations, together with the fact that the increase of damping ratio after the retrofit is lower for the higher modes than for the first mode, could explain why the reduction of the displacement demand is higher than that of the base shear.

level	*As is*		*Retrofit*

Figure 11(a) depicts the first mode contribution to the full shear response of the frame in the *As is* case, normalized by the value of the total base shear. Figure 11(b) shows the same comparison for the *Retrofit* configuration. Figure 12 a) and b) depicts the first mode contribution to the full shear response of the tower and of total system for the *Retrofit* case.

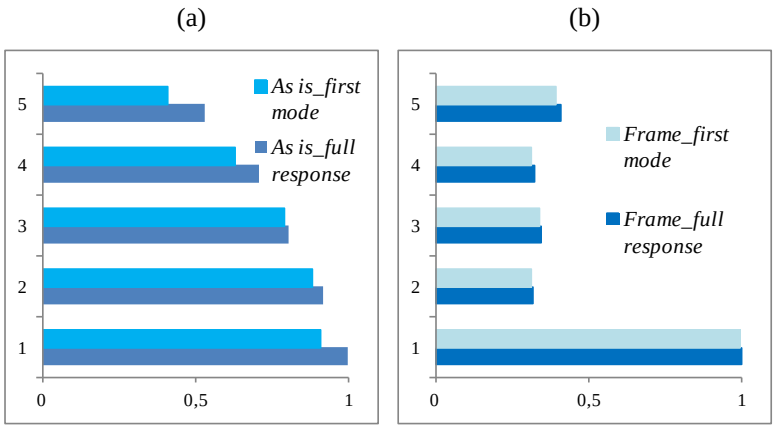

Figure 11: First mode contribution on the total shear response of the frame in the (a) *As is* case and (b) *Retrofit* configuration.

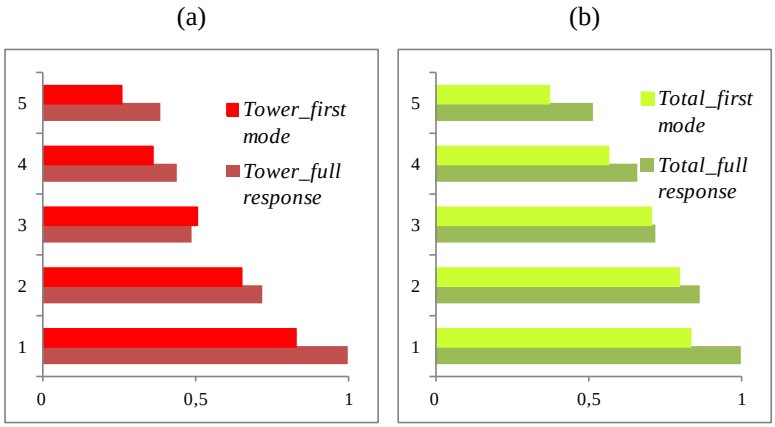

Figure 12: First mode contribution in the *Retrofit* case (a) on the total shear response of the tower and (b) on the overall response.

Table 7 contains the absolute acceleration values observed at the various levels of the building for the configurations investigated..

level	*As is* $\ddot{x}_i$ [m/s^2]	*Retrofit* $\ddot{x}_i$ [m/s^2]	*Stiff* $\ddot{x}_i$ [m/s^2]
1	2.98	2.77	2.10
2	3.86	3.36	1.80
3	4.58	3.02	1.70
4	4.14	2.34	1.97
5	5.27	3.49	2.69

Table 7: Absolute accelerations.

The coupling of the building with the external dissipative system induces a relative reduction of the maximum absolute acceleration values with respect to the values observed in the *As is* case. This result is noteworthy especially for all the non structural elements (e.g. medical devices) that could be hosted in a structure. Figure 13 shows the values of the absolute acceleration distribution along the height of the normalized by the value at the 5th floor observed for the *Stiff* case. The relative reduction of acceleration is nearly 34% for the *Retrofit* case and 48% for the *Stiff* case

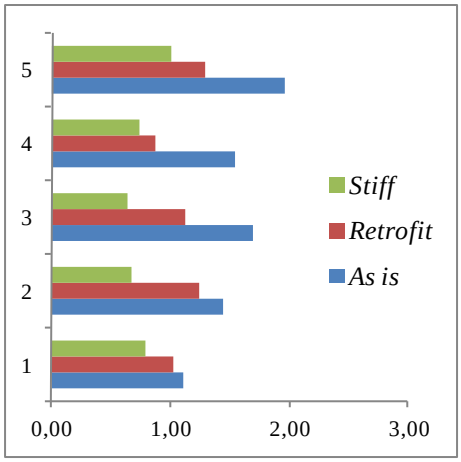

Figure 13: Absolute acceleration distribution along the height.

4 CONCLUSIONS AND FURTHER STUDIES

This paper presents and analyzes three alternative categories of external viscous dampers retrofitting system which exhibit a different kinematic behavior. Among them, the dissipative tower configuration is deeply investigated, in terms of modal properties and seismic response of the coupled system.

A problem formulation concerning the dynamic behavior of the coupled system is presented in general terms. The results include also two limit configurations, the bare building and the coupling with an infinitely stiff dissipative tower.

The case study results reveal that the addition of the towers leads to a regularization of the drift demand along the building height. After the retrofit, the shear force distribution in the existing frame could significantly change and the system is notably non-classical damped due to the fact that all the dampers are concentrated at the base of the tower. Moreover, from the dynamic response it appears that higher order vibration modes have a notable influence on the internal actions demand, while are almost negligible for the displacement response.

The *Stiff* configuration highlights the benefits and drawbacks of the dissipative system. This limit configuration provides the best distribution of the inter-storey drifts but provides high shear forces in the frame, which are larger than the forces observed in the *Retrofit* case and similar to the forces observed in the *As is* case.

A deeper and wider investigation is still necessary for a full comprehension of the problem, and should be oriented to understand the optimal stiffness range of the dissipative tower.

Keywords: masonry; holonomic model; closed form solution; non-linear static analysis; non-linear dynamic analysis.

Abstract. *A simple total displacement homogenization model suitable for the non-linear analysis of in and out of plane loaded masonry walls is presented. In the model, a running bond rectangular elementary cell is discretized into few triangular elastic constant stress elements representing bricks and non-linear holonomic with softening mortar joints reduced to interfaces. The unrefined discretization adopted allows dealing with a homogenization problem ruled by few displacement variables, where homogenized stress-strain relationships can be found in semi-analytical form.*

The approach proposed is validated at a cell level in both the elastic and inelastic range, exhibiting excellent numerical stability and accuracy.

It finally allows a straightforward implementation at a structural level on a commercial code, where entire walls are modelled by means of rigid elements and non-linear homogenized interfaces. Some example of technical relevance are analyzed in both the non-linear static and dynamic range and compared with those achieved using alternative numerical procedures. To this aim a first set of simulation is performed on a deep beam tested by Page while the second series of analyses are conducted on a church façade subjected to dynamic excitation.

1 INTRODUCTION

Masonry is a traditional composite material obtained by the assemblage of bricks and mortar. The elastic behavior is quite limited because masonry is typically characterized by a reduced, almost vanishing tensile strength and either macro- or micro-modeling strategies are adopted over elasticity.

Macro-modeling [1]-[3] substitutes bricks and mortar with a homogeneous, sometimes orthotropic material with softening. It allows studying even large scale structures without the need of meshing separately bricks and mortar. It is therefore very convenient where efficient computations on engineering structures are needed. Nevertheless, the calibration of model parameters is typically done by means of comprehensive experimental campaigns. Theoretically, such approaches may be capable of adequately estimate the non-linear masonry behavior along any load combination, even if some meaningful limitations occur in specific cases but in practice the needed experimental data fitting would require –at least in principle- new calibrations case by case.

The alternative micro-modeling is simply characterized by a distinct modelling of mortar joints and blocks at a structural level. The reduction of joints to interfaces [4][5] helps in limiting variables, especially in the non-linear range, but the approach still remains computationally very demanding, because bricks and mortar are meshed separately. In order to obtain sufficiently reliable solutions in terms of displacements and stresses, constituent materials should be meshed with more than one element, with the consequent grow of the number of non-linear equations to deal with, even for small masonry panels. Furthermore, the preprocessing phase regarding the model generation is not straightforward. Partitioning methods have been recently proposed to overcome such computational limitations and speed up structural analyses.

For the previous reasons, it can be affirmed that macro-scale computations with FEs still remain preferable when non-linear analyses for engineering structures are needed.

In this framework, homogenization [5]-[16] is for sure much more suitable than both micro- and macro-modelling, because it allows in principle to perform non-linear analyses of engineering interest without a distinct representation of bricks and mortar, but still considering their mechanical properties and the actual pattern at a cell level.

Homogenization is roughly an averaging procedure performed at a meso-scale on a representative element of volume (REV), which generates the masonry pattern under consideration by repetition. A Boundary Value Problem BVP is formulated, allowing an estimation of the expected average masonry behavior to be used at structural level. As a matter of fact, the resultant material obtained from meso-scale homogenization turns out to be orthotropic, with softening in both tension and compression.

Instead of using refined FE discretization within the REV, in this paper a simplified homogenization two-step model is proposed for the non-linear structural analysis of masonry walls in- and out-of-plane loaded. The first step is applied at the meso-scale, where the assemblage of bricks and mortar in the REV is substituted with a macroscopic equivalent material through a so called compatible identification. The unit cell is meshed by means of 24 triangular constant stress (CST) plane stress elements (bricks) and interfaces for mortar joints. Triangular elements are assumed linear elastic, whereas the mechanical response of the interface elements is holonomic and non-linear, including two dominant deformation modes, namely peel (mode I) and shear (mode II) or a combination of two (mixed mode). Both a piecewise linear and an exponential law formally identical to an improved version of the Xu-Needleman law and proposed in another context [17]-[19] are implemented.

The second step, performed at a structural level, relies into the implementation of the homogenized stress-strain relationships into a rigid element approach (RBSM) where contiguous rigid elements are connected by shear and normal non-linear homogenized springs. The extension of the model to the out-of-plane mechanisms has been achieved by on-thickness integration of the homogenized stress-strain relationships obtained in the first step, thus adopting suitable out-of-plane interface laws at a structural level, whose behavior is formulated in order to describe flexural and torsional failures.

The procedure is quite efficient and reliable because it is not necessary to discretize with refined meshes the elementary cell (only three kinematic variables are needed at the meso-scale) and hence it is possible to drastically speed up computations. In addition, the holonomic laws assumed for mortar allow for a total displacement formulation of the model, where the only variables entering into the homogenization problem are represented by displacements.

The model is benchmarked at a structural level both in the non-linear static and dynamic range on a masonry deep-beam [20][21] in-plane loaded up to collapse and on a masonry church façade [22][23] loaded by a real accelerogram and collapsed during the 1976 Friuli (Italy) seismic sequence [24].

2 THE HOMOGENIZATION MODEL

2.1 The simplified compatible homogenization model

Homogenization relies in the determination of averaged quantities representing the macroscopic strain and stress tensors [1][6] on a REV (Y), i.e. $\mathbf{E} = <\boldsymbol{\varepsilon}> = \frac{1}{A}\int_Y \boldsymbol{\varepsilon}(\mathbf{u})dY$ and $\boldsymbol{\Sigma} = <\boldsymbol{\sigma}> = \frac{1}{A}\int_Y \boldsymbol{\sigma} dY$, where A stands for the area of the elementary cell, $\boldsymbol{\varepsilon}$ and $\boldsymbol{\sigma}$ stand for the local quantities (strains and stresses respectively) and <*> is the averaging operator.

Anti-periodicity conditions are imposed on the stress field and periodicity on the displacement field **u**, given by:

$$\begin{cases} \mathbf{u} = \mathbf{E}\mathbf{y} + \mathbf{u}^{\text{per}} & \mathbf{u}^{\text{per}} \text{ on } \partial Y \\ \boldsymbol{\sigma}\mathbf{n} & \text{anti-periodic on } \partial Y \end{cases} \tag{1}$$

Where **u** is the total displacement field, $\mathbf{u}^{\text{per}}$ stands for a periodic displacement field, $\widetilde{x} = \{x \quad y \quad z\}$ is the local frame of reference (see Figure 2), **E** is the homogenized strain tensor and **n** is the outward versor of the ∂Y surface.

In this work, a simple compatible homogenization model suitable for the analyses of masonry in and out of plane loaded is proposed. The method herein discussed allows to use a coarse discretization, where only ¼ of the REV is meshed with 6 constant stress triangles (see Figure 1). Bricks are supposed to behave elastically while mortar joints are reduced to non-linear zero thickness interfaces. Two interface relationships are considered: a piece-wise linear law and an improved version of the Xu-Needleman exponential law, accounting for, respectively, a decoupled and fully coupled approach.

The homogenization procedure is subdivided in two steps: in the first one the homogenization model is implemented in a Matlab environment, while in the second one a series of non-linear analyses on masonry panels are discussed.

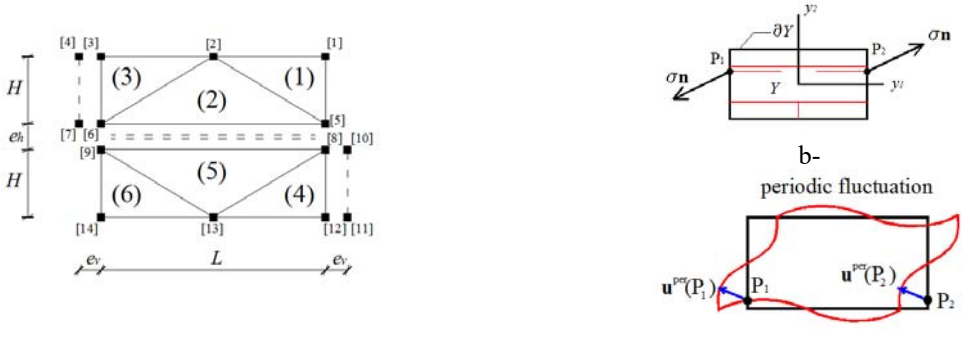

Figure 1. Micro-mechanical model proposed: a- Geometric properties of the elementary cell, b- Anti-periodicity of the micro-stress field and c- periodic displacement field.

Indicating with $\circ^{(n)}$ a stress component belonging to the n-th element, the plane stress Cauchy stress tensor inside the n-th CST element $\boldsymbol{\sigma}^{(n)}$ is constituted by the components $\sigma_{xx}^{(n)}$ (horizontal stress), $\sigma_{yy}^{(n)}$ (vertical stress) and $\tau^{(n)}$ (shear stress). When dealing with static quantities, equilibrium inside each element is a-priori satisfied, $div\boldsymbol{\sigma}=0$, whereas two equality constraints involving Cauchy stress tensor components of triangles have to be imposed for each internal interface between adjoining elements.
Assuming that the triangular elements are linear elastic, the following relationship between strains and stresses can be written:

$$\begin{bmatrix}\varepsilon_{xx}\\ \varepsilon_{yy}\\ \gamma_{xy}\end{bmatrix}=\begin{bmatrix}\dfrac{\sigma_{xx}}{E_b}-\dfrac{\nu_b\sigma_{yy}}{E_b}\\ -\dfrac{\nu_b\sigma_{xx}}{E_b}+\dfrac{\sigma_{yy}}{E_b}\\ \dfrac{\tau}{G_b}\end{bmatrix} \qquad (2)$$

Where E_b, ν_b and G_b are the brick elastic modulus, Poisson's ratio and shear modulus, respectively. The simplified compatible identification procedure allows separating the analyses of the biaxial macroscopic strain state from the pure shear deformation one. In the following sections both deformation states are discussed and the results obtained using both the non-linear interface laws are critically compared.

2.2 Elastic case, biaxial strain state

Let us consider a biaxial macroscopic strain state characterized by the following independent displacement variables: $\xi=\bar{U}_x^0-U_x^9$ and $\eta=U_y^{[5]}+U_y^{[6]}$. The evaluation of the aforementioned variables allows the determination of the kinematic and static unknowns governing the problem. The solution, fully explained in [9], can be obtained graphically plotting the two following curves:

$$\eta=\bar{U}_y^0+\frac{2H}{\nu_b L}\left[\bar{U}_x^0-\xi-L\frac{1-\nu_b^2}{E_b}f_n^I(\xi)-\frac{L^2}{2H}\frac{1-\nu_b^2}{E_b}f_t^{II}(\xi)\right] \qquad (3)$$

$$\xi = \bar{U}_x^0 + \frac{L}{2\nu_b H}\left[\bar{U}_y^0 - \eta - 2\frac{1-\nu_b^2}{E_b} H f_n^{II}(\eta)\right] \tag{4}$$

Where f_n^I and f_t^{II} are the non-linear laws of the interfaces I and II under normal (n) and shear (t) stresses. $\overline{U}_{x,y}^0$ are the applied displacements on the boundary of the REV mimicking a macroscopic homogeneous biaxial strain state, in agreement with the compatible identification procedure proposed.

2.3 Shear deformation

In case of a pure shear deformation, the deformation independent variables are ξ^t, η^t and κ, where:

$$\xi^t = 2\bar{U}_x^t - \frac{H}{G_b}\left[-\frac{\bar{U}_y^t - \eta^t}{L/2} G_b + 2 f_t^I\left(\eta^t\right) - \frac{4H}{L} f_n^{II}\left(\eta^t - \kappa\right) + 2\frac{\kappa}{L} G_b\right] \tag{5}$$

$$\eta^t = \bar{U}_y^t - \frac{L}{2G_b}\left[2 f_t^{II}\left(\xi^t - \bar{U}_x^t\right) - \frac{2\bar{U}_x^t - \xi^t}{H} G_b + 2\frac{\kappa}{L} G_b\right] \tag{6}$$

$$\kappa = \frac{e_v}{G_b}\left[2 f_t^{II}\left(\xi^t - \bar{U}_x^t\right) - f_t^I\left(\eta^t\right)\right] \tag{7}$$

$\overline{U}_{x,y}^t$ are the applied displacements on the boundary of the REV mimicking a macroscopic shear, in agreement with the compatible identification procedure proposed. The numerical approach used to solve the previous problem is discussed in [9], where the reader is referred for further details.

2.4 Holonomic relationship for non-linear interfaces

In the present work, mortar joint interfaces are assumed to behave in agreement with two interface relationships: (a) a multi-linear relationship, hereafter labeled as "PL", with normal and tangential decoupled responses, i.e. $\sigma(\Delta_n)$ and $\tau(\Delta_t)$; an improved version of the Xu–Needleman exponential law, hereafter labeled as "XN". In the latter case, the stress vector **T** at the interface is given by the following closed-form expression:

$$\begin{aligned}\sigma &= \frac{\phi_n}{\delta_n}\left(\frac{\Delta_n}{\delta_n}\right) e^{-\left(\frac{\Delta_t}{\delta_t}\right)^2} e^{-\frac{\Delta_n}{\delta_n}} \\ \tau &= 2\frac{\phi_t}{\delta_t}\left(\frac{\Delta_t}{\delta_t}\right)\left(1+\frac{\Delta_n}{\delta_n}\right) e^{-\left(\frac{\Delta_t}{\delta_t}\right)^2} e^{-\frac{\Delta_n}{\delta_n}}\end{aligned} \tag{8}$$

Symbols ϕ_n and ϕ_t denote the work of separation under pure Mode I and Mode II, respectively, while δ_n and δ_t indicate the relevant characteristic lengths [17][19].

2.5 Non-linear behavior

In the present section the results obtained with the proposed model are discussed with reference to two masonry patterns commonly used.
Two different textures are studied: the first one (Type A) is a running bond masonry with bricks having dimensions equal to 122x37x54 mm^3 and mortar joints of thickness 5 mm (see

Figure 2). The second one (Type B) is a header bond with blocks of dimensions 250x55x120 mm^3 and mortar joints 10 mm thick.

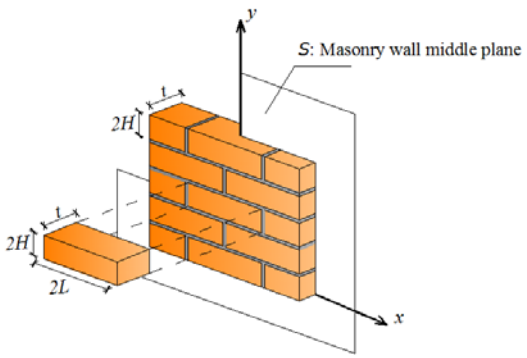

Figure 2. Running bond texture.

The elastic and inelastic mechanical properties of the considered masonry patterns are summarized in Table 1-Table 2.

Table 1. Mechanical properties assumed for the running bond texture.

Stretcher bond	*Mortar joints*	*Bricks*
Young Modulus	E_m=1250 MPa	E_m=7000 MPa
Poisson's ratio	-	ν=0.2
Shear Modulus	G_m=0.4* E MPa	G_b
Peak tensile stress	f_t= 0.29 MPa	-
Cohesion	c=1.4* f_t MPa	-

Table 2. Mechanical properties assumed for the running bond texture.

Stretcher bond	*Mortar joints*	*Bricks*
Young Modulus	E_m=1500 MPa	E_m=8000 MPa
Poisson's ratio	-	ν=0.2
Shear Modulus	G_m=0.4* E MPa	G_b
Peak tensile stress	f_t= 0.1 MPa	-
Cohesion	c= 0.1 MPa	-

Both a PL and XN holonomic law (for the sake of brevity only Type A masonry interfaces are depicted in Figure 3) has been adopted for mortar joints.

3 INELASTIC CASE, BIAXIAL AND SHEAR DEFORMATIONS

3.1 Biaxial strain state

The homogenization approach discussed in the previous sections is herein adopted to perform a series of analyses at a cell level taking into account the non-linear behaviour of the mortar joint interfaces. Let us consider the strain E_{nn} defined as $E_{nn} = \sqrt{E_{xx}^2 + E_{yy}^2}$. In Figure 4, the homogenized stress-strain relationship obtained using the proposed model and assuming an $E_{xx} \neq 0$ and $E_{yy} = 0$ strain state applied up to failure of the REV is depicted. In Figure 4 the deformed shapes of the elementary cell at three different steps of the analysis (A elastic, B peak and C failure) are also represented (Type A and Type B).

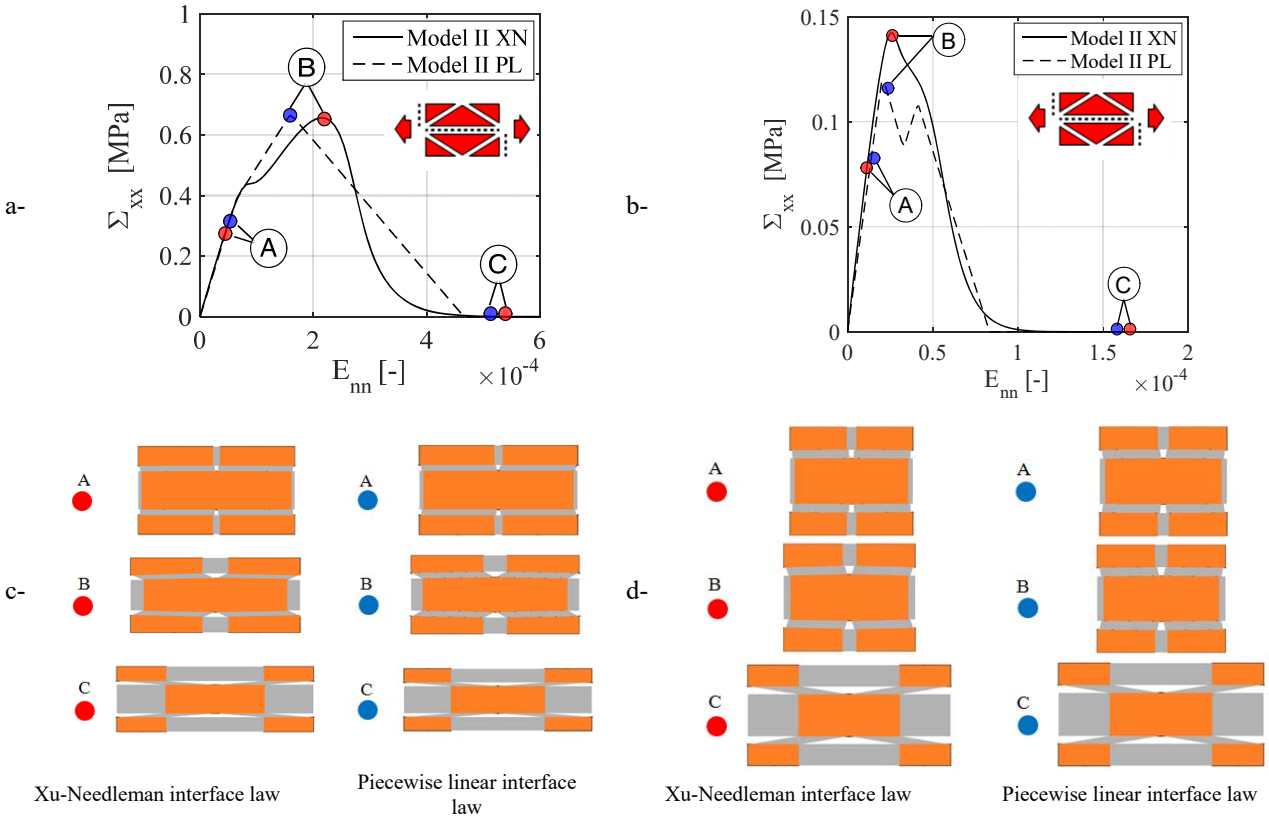

Figure 4. Homogenized stress-strain curves (Type A texture) (a-) and (Type B texture) (b-), deformed shapes of the homogenized cell at different steps for horizontal stretching, Type A texture c- and Type B texture d-.

The same results in case of application of $E_{yy} \neq 0$ and $E_{xx} = 0$ are summarized in Figure 5 (Type A) and (Type B). The reader is referred to [16] for further details.

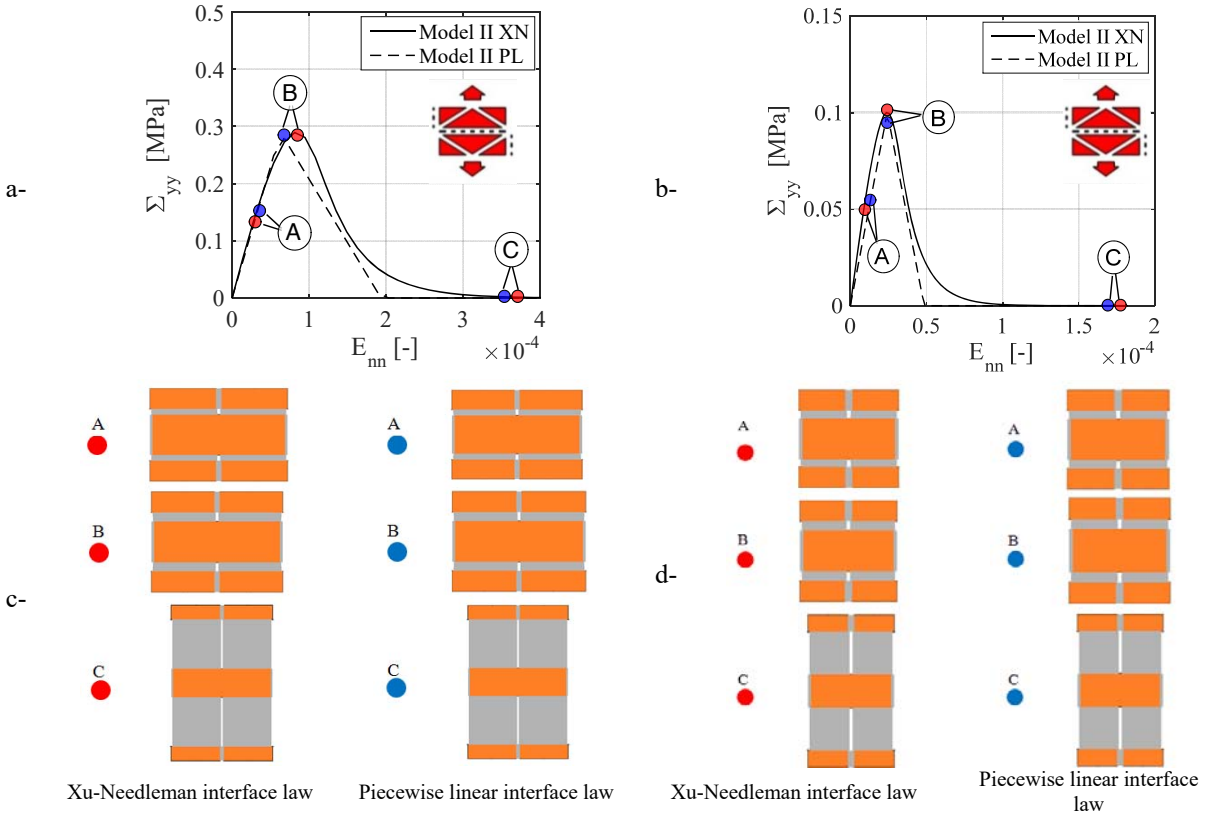

Figure 5. Homogenized stress-strain curves (Type A texture) (a-) and (Type B texture) (b-), deformed shapes of the homogenized cell at different steps for vertical stretching, Type A texture c- and Type B texture d-.

From an analysis of the results, the following considerations can be done:
- When dealing with a biaxial strain state both interface models furnish comparable outputs. Some differences can be found due to the coupling between normal and transversal response in the XN law.
- Under horizontal stretching (see Figure 4), a not-negligible shear stress is detected. The failure mechanism of the REV is characterized by bed joint cracking under tangential stresses while head joints fail under normal tensile stresses.
-For vertical stretching (see Figure 5) the failure experienced is always on the bed joint and strongly influenced by the value of the ultimate tensile strength adopted for mortar.

3.2 Shear deformation state

The results obtained applying a pure shear deformation state on the elementary cell are depicted in Figure 6 for Type A and Type B masonries. As expected in both cases both head and bed joint exhibit inelastic deformation that contributes to the overall strength and post peak behavior of the elementary cell.

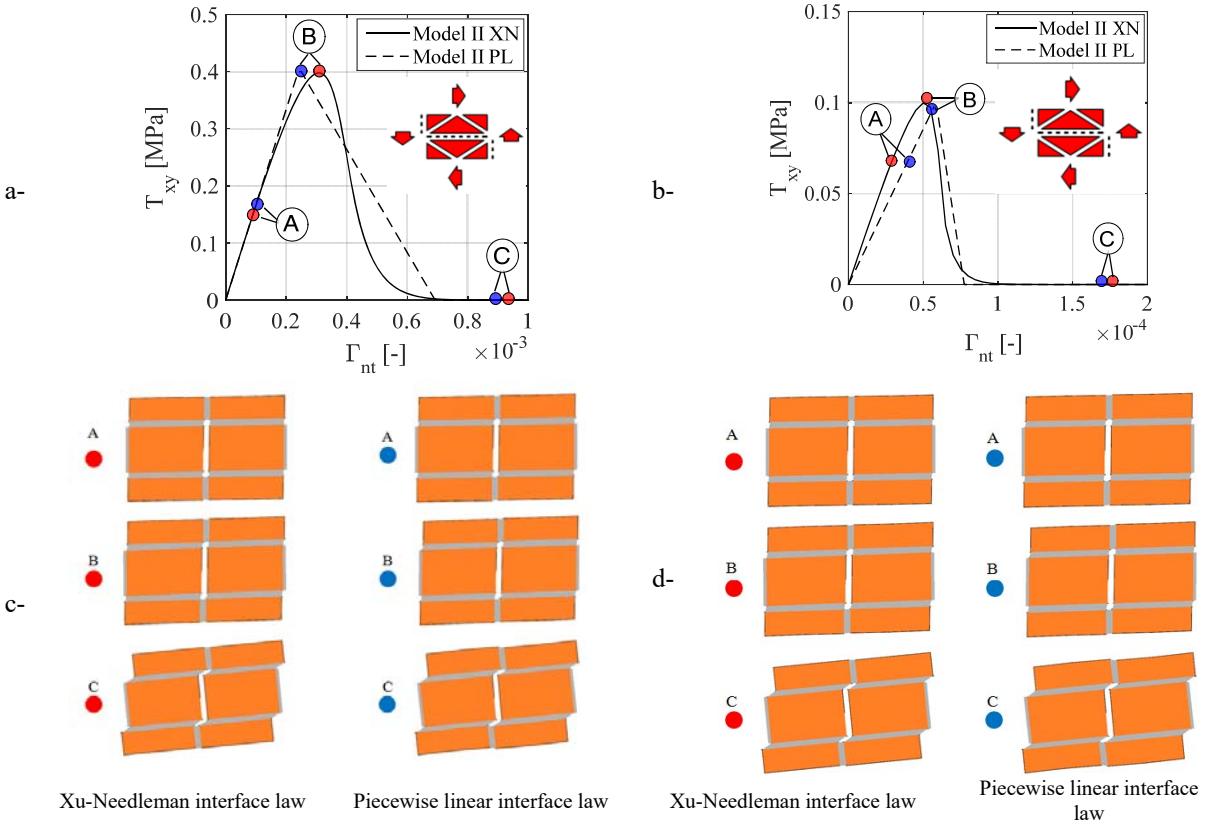

Figure 6. Shear deformation state (Type A texture) (a- c-) and (Type B texture) (b- d-).

4 STRUCTURAL IMPLEMENTATION

4.1 Rigid body and spring model

The present section is devoted to the discussion of a series of non-linear analyses performed in order to show the capability of the proposed model for the simulation of large scale panels subjected to different load conditions. All the analyses performed are conducted through the commercial software Abaqus, were the homogenized mechanical properties are implemented. The panels simulated are discretized by means of rigid quadrilateral elements connected with non-linear interfaces exhibiting an orthotropic behaviour. The interfaces are assumed to obey stress-strain curves with softening directly deduced by an energy equivalence criterion with the homogenized material. The method adopted for the spring identification will be briefly recalled in the following, but the reader is referred to [16] for further details.
In order to perform the identification of the springs two adjoining rigid elements connected through non-linear interfaces with dimensions showed in Figure 7 were considered.

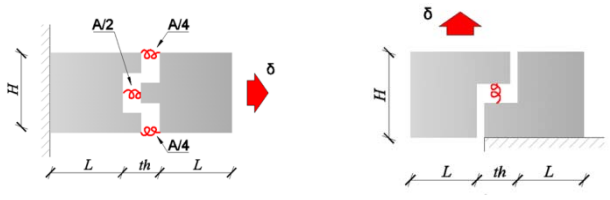

Figure 7. Spring model: a- Axial spring, b- Shear spring.

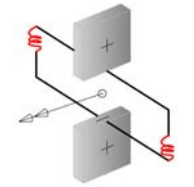
Equating the volumetric strain energy of the rigid-spring model and the one related with the continuum, the following expressions can be deduced for the identified elastic moduli:

$$E_{nxx} = \frac{th/2 \cdot E_{xx}}{2L + th} \tag{8}$$

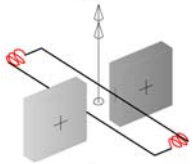
$$E_{nyy} = \frac{th/2 \cdot E_{yy}}{H + th} \tag{9}$$

$$G_{nxy} = G_{xy} \cdot \frac{H^2/4}{th \cdot (2L + th)} \tag{10}$$

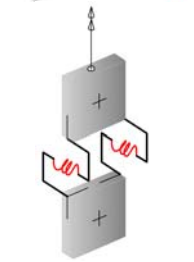
Where H and L are respectively the height and the length of the rigid elements and "t" is the out of plane thickness. The non-linear interfaces have thickness equal to "th". E_{xx}, E_{yy} and G_{xy} are the elastic properties of the homogenized orthotropic continuum model.
The procedure previously recalled is adopted even for the definition of the elastic properties of out of plane interfaces. The extension of the model to the out-of-plane mechanisms has been achieved adopting suitable interfaces, whose behaviors have been formulated in order to describe flexural and torsional failures. To this aim the following expressions can be obtained. Where "t" refers to the thickness of the rigid quadrilateral elements, while "E_{bxx}", "E_{byy}" and "G_{bxy}" refer respectively to the elastic properties of the flexural and torsional interfaces.



$$E_{bxx} = \frac{E_{xx}}{(1-\upsilon^2)} \cdot \frac{t \cdot th \cdot L}{12 \cdot 2 \cdot A_b \cdot (H + th)} \tag{11}$$



$$E_{byy} = \frac{E_{yy}}{(1-\upsilon^2)} \cdot \frac{t \cdot th \cdot L}{12 \cdot 2 \cdot A_b \cdot (H + th)} \tag{12}$$



$$G_{bxy} = \frac{2G_{xy} \cdot t^4}{3th \cdot L^3} \tag{13}$$

4.2 Deep beam test

The previously discussed procedure is used to simulate a deep beam panel tested up to failure by Page [20]. The wall, with dimensions of 757x457 mm^2, was subjected to a uniform pressure applied by a stiff steel beam placed on the central upper part of the panel.
A running bond texture (Type A) was adopted to build the panel, using half scale bricks with dimensions equal to 122x37x54 mm^3 and 5 mm thick mortar joints.
The springs identification discussed in the previous section, led to use the following moduli for the springs: E_{nxx}= 360 MPa, E_{nyy}= 280 MPa and G_{nxy}= 2840 MPa.

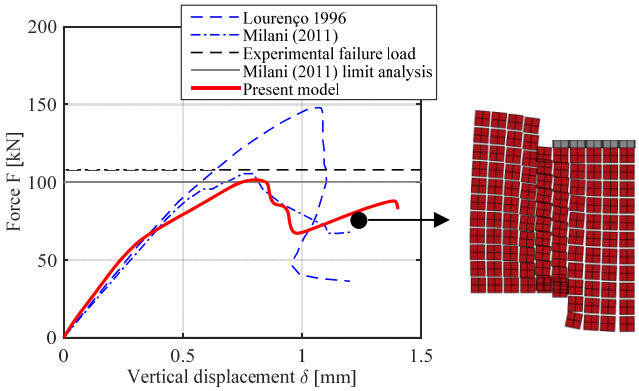


Figure 8. Deep beam. Numerical and experimental results.

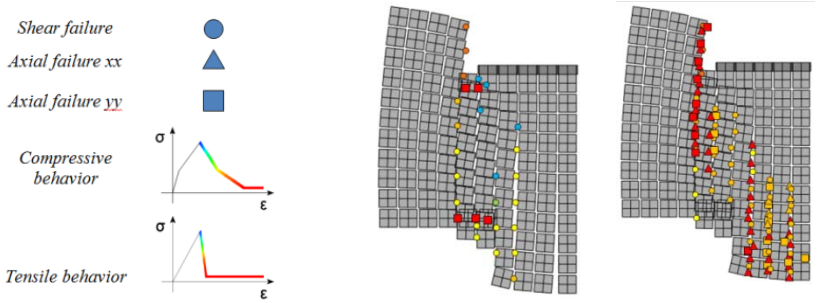

a- b-

Figure 9. Deep beam. Damage maps in compression (-a) and in tension (-b).

Despite the exiguous number of information reported by Page, in the recent past several researchers have tried to simulate the aforementioned deep beam test using different numerical approaches. A comparison between the results (force displacement curves) obtained using the present model and those found numerically by Lourenço [21] and Milani [13] is shown in Figure 8.

As can be noted, a satisfactory agreement is found, in terms of both elastic and post peak phase. The collapse load obtained numerically is very close to the value found experimentally by Page. In Figure 9 the damage maps obtained numerically at the end of the simulation are shown, in compression, tension and shear.

As can be noted, the collapse mechanism is clearly formed by a compressive strut departing from the steel beam and ending on the support, with shear cracks appearing on a vertical line (orange circles, Figure 9-a) and compressive damages near the toe (red squares, Figure 9-a). Tensile damages are mainly concentrated in the central part of the panel along vertical interfaces and near the steel beam. This latter finding can be explained with the high level of stress concentrations reached in that zone.

4.3 Transfiguration church non-linear static and dynamic analyses

A second series of simulations is performed with reference to 3D masonry structures subjected to both static and dynamic excitations, under in- and out-of-plane loads. As confirmed in the literature, some classes of buildings are particularly prone to experience severe damages during seismic events, among them masonry churches can be mentioned. In order to show how accurate results can be obtained using the proposed model even in presence of out of plane failure mechanisms, the authors chose to analyze the façade of the Transfiguration Church, collapsed during the 1976 Friuli, Italy seismic sequence. The church under considera-

tion was located in Moggio Udinese, in the North-East of Italy, in a region (called Friuli) characterized by a high seismicity level. On Thursday, 6 May 1976, a devastating 6.4 Richter magnitude earthquake took place there, killing 989 people. The church reported severe damage after the first main shock, and later collapsed as a consequence of the second seismic sequence that occurred during September of the same year. After the first main earthquake, a survey of the geometry and masonry walls was conducted by Doglioni et al. in [24], which is our main source of information for the problem at hand. The geometry of the façade, along with the discretization adopted for the present structural analyses are sketched in Figure 10. It is interesting to notice that a small portion of the unique nave perpendicular walls is modeled in order (a) to properly account for the actual lateral interlocking of the vertical edges and (b) to favor the reproduction of the 3D behavior, which includes a predominant two-way flexural deformation and a possible detachment for overturning in case of insufficient interlocking between façade and nave walls.

The façade of the Church is modeled using 354 rigid quadrilateral elements, which appears a fair compromise between numerical efficiency paramount for non-linear dynamic computations and refinement needed to properly reproduce actual crack patterns.

The church can be considered an example of Romanesque architecture quite frequent in the small towns of Italy, like those located in Friuli, and therefore it appears an interesting benchmark for the proposed models at the macro-scale. Approximately, the façade has a width of 16.30 meters, with a maximum height (tympanum top) of 18.05 meters and small openings in correspondence of the symmetry axis, see Figure 10. The façade has therefore global dimensions equal to 16.30x18.05 m, with walls 55 cm thick. Mechanical properties of the constituent materials are assumed in agreement with those available in the literature [22][23] and are not reported here for the sake of conciseness. Homogenized moment-curvature diagrams obtained with the model proposed and used at a structural level are depicted in Figure 11, under three levels of vertical pre-compression roughly indicating what occurs on the tympanum (almost zero vertical in-plane load), middle height and base of the façade. The utilization of different moment-curvature relationships as a function of vertical membrane load is paramount for masonry buildings, since it has been proved that vertical compression plays a key role in the increase of both ductility and out-of-plane strength.

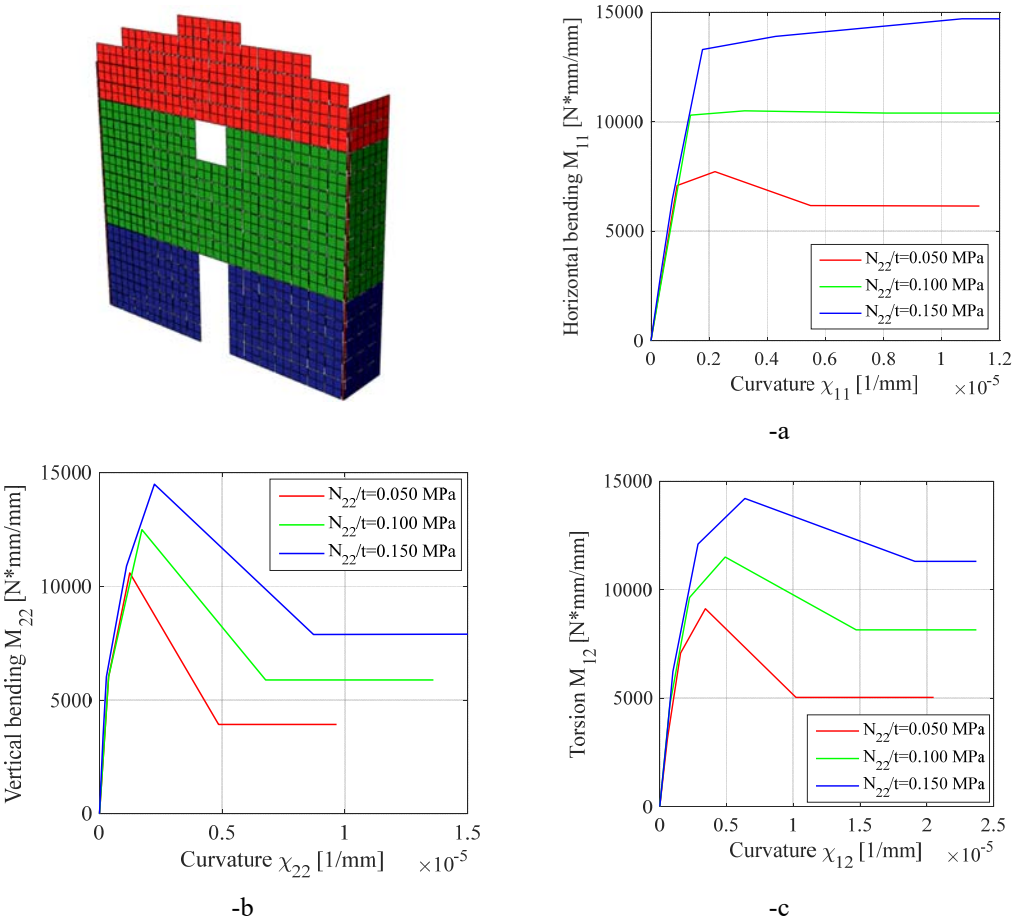

Figure 11. Moment curvature diagrams used at a structural level, Transfiguration Church. Diagrams are plotted at different levels of vertical pre-compression.

Two sets of simulations are performed in order to show the reliability of the proposed model for the seismic analyses of 3D masonry structures. First of all, the façade is analyzed using a non-linear static (pushover) approach and taking into account two distributions of forces in agreement with Italian code, one constant and the other reverse-linear along the height of the façade. Hereafter such distributions are called Mode 0 and Mode I respectively, but it is worth mentioning that in the Italian code they are labeled as G2 and G1 distributions. The results obtained using the proposed model are compared to those provided by Casolo and co-workers [22][23] in Figure 12. The control point for the displacement evaluation is placed in the upper part of the façade (tympanum center). As can be noted, there is satisfactory agreement with previously presented results, meaning that the proposed homogenization approach is able to accurately describe the elastic and inelastic behavior of real scale structures starting exclusively from the knowledge of the constituent materials mechanical properties.

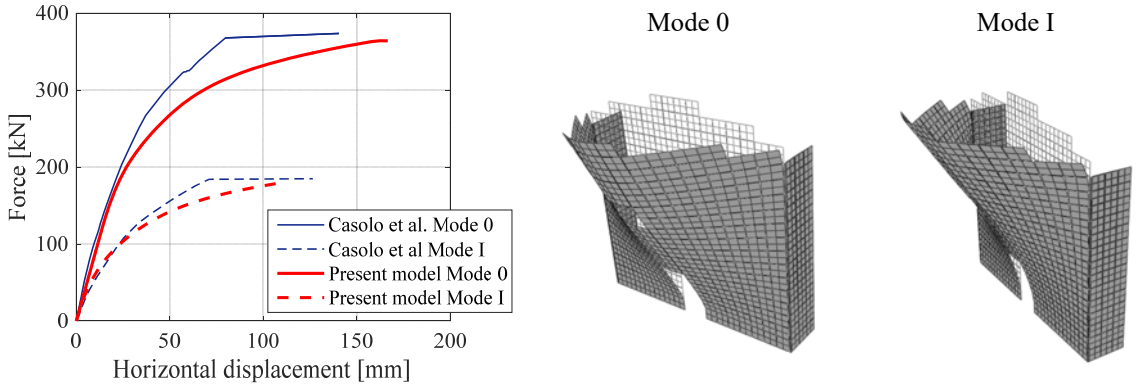

Figure 12. Pushover curves obtained (left) and corresponding deformed shapes (right)

A non-linear dynamic analysis is then performed in order to deepen the seismic behavior of the facade when subjected to natural accelerograms. The results obtained applying to the structure the Fogaria (Friuli 1976) accelerogram are summarized in Figure 13 and Figure 14.
In particular, in Figure 13 a comparison between a previous model [22][23] and present numerical results at different heights of the control point is provided, whereas Figure 14 shows the façade deformed shape and crack patterns numerically obtained at the end of the simulations(A: deformed shape. B1: vertical bending. B2: horizontal bending. B3: torsion).
As can be noted, good agreement is found between the results obtained using the proposed approach and those achieved by Casolo and co-workers [22][23], in terms of both time-displacements history and damage patterns found at the end of the simulations.
As highlighted by the residual displacement found at the end of the application of the accelerogram (Figure 13-b), the façade exhibits a collapse mechanism that mainly involves the upper part, with the resultant overturning of the tympanum. This finding suggests the activation of a slightly different failure mechanism with respect to that found in [22][23] where again the upper part is the most vulnerable, but with the formation of two inclined yield lines spreading from the upper corners down to the central rose window. Present results appear more in agreement with the expected behavior of masonry church façades. Damage patterns at the end of the simulation are depicted in Figure 14, separately for flexion and torsion as it usually occurs in RBSM models. As confirmed by the deformed shape of the façade in Figure 14-a, which clearly shows the overturning of the tympanum, high levels of damage are reached in correspondence of the horizontal line where the out-of-plane mechanism of the tympanum takes place. It is worth noting that severe damages are visible also in correspondence of the vertical edges and near the central opening, in quite reasonable agreement with the results found by Casolo and co-workers [22][23].

5 CONCLUSIONS

A simple compatible homogenization model for the non-linear static and dynamic analysis of masonry structures in- and out-of-plane loaded has been presented. The approach consists in a two-step procedure suitable for the analysis of masonry panels subjected to a variety of loads. First of all, the REV is discretized by means of triangular elastic FEs and joints are reduced to non-linear holonomic interfaces. In order to obtain quickly homogenized properties of the continuum, a pseudo analytical approach has been proposed. A series of structural analyses have been finally performed on two cases of technical relevance, namely a deep beam loaded in-plane up to collapse and a church façade subjected to equivalent static (push-over) and non-linear dynamic out-of-plane analyses. The structures have been discretized using a rigid body and spring model RBSM strategy. The springs identification has been carried

out using an energy equivalence on the stress-strain homogenized relationships deduced at the meso scale. The homogenized RBSM have been implemented into the commercial software Abaqus, where all the discussed analyses have been performed. The procedure is efficient and reliable because: (1) the homogenized mechanical properties can be directly implemented at structural level with a very limited computational effort; (2) it is not necessary to discretize with refined meshes the elementary cell; and (3) the holonomic laws assumed for mortar joints allow for a total displacement formulation of the model, where the only variables entering into the homogenization problem are represented by displacements.

Keywords: masonry structures, equivalent frame model, construction phases analysis, construction stages.

Abstract. *Structural analysis of masonry buildings is affected by many uncertainties and characterized by issues related to the very nature of the material. In this scenario, refined analysis methodologies are confined to the research environment, while professional applications need simpler methodologies, which allow for a better understanding of the analysis results: the equivalent frame model is one of these methodologies. However, the method is affected by some issues, which, if not adequately addressed, may lead to unrealistic stress distributions. In this work, we propose a procedure that increases the reliability of the analysis results. It consists in the modification of the model depending on the nature of the acting loads in relation to the different construction phases of the structure. In addition, an extension of the method for the analysis of buildings constructed in different periods is introduced. Finally, the results of the analysis performed for a case study are presented in order to validate the proposed methods.*

1 INTRODUCTION

Among the various methods available for structural analysis of masonry buildings, the "equivalent frame model" is the most widely used in the professional field, thanks to the simplicity of one-dimensional finite elements and the good capacity to assess the real behavior of the structure.

More accurate finite element models, which make use of shell or solid elements, are mainly employed in the research field. They require a rather high computational effort for being used in engineering practice and are still affected by uncertainties related to various parameters (in particular, the constitutive laws of the materials).

Furthermore, dealing with existing buildings it should be pointed out that the fundamental method of analysis is the kinematic analysis of the collapse mechanisms, which assesses the stability of the structure.

Static and dynamic, linear and nonlinear analyses performed on elastic models are meaningful only if the local collapse mechanisms have been prevented. They assess the resistance of the building, which is generally secondary to its stability. Therefore, elastic modelling should be kept simple avoiding excessive complexity. This is the reason why many national and international Standards [1] including Eurocodes [2] indicate the equivalent frame model as the reference methodology.

On the other hand, modelling of a spatial structure through one-dimensional finite elements implies some critical issues, most of them related to the fact that one single model is used for the analysis under different load actions with the same mechanical parameters, internal and external constraints. Adjacent walls significantly different in dimensions correspond to a local inhomogeneity in the stiffness distribution. In fact, the stresses migrate towards the most stiff elements, with consequent unrealistic stress distribution even if the sole self-weight of the walls is applied. Moreover, under the action of vertical loads, significant shear and bending moment acting on masonry piers and spandrels appear quite unrealistic, as well as tensile stress, which may occur in masonry piers usually due to big stiffness discrepancy at the various stories or differential displacements in the foundations.

These issues are not caused by the equivalent frame method, but by the way it is normally applied. In compliance with this modelling technique, a methodology that allows a more realistic stress distribution can be applied.

The methodology illustrated in the following paragraphs stems from the will to overcome the difficulties described above through a generalized algorithm valid for any masonry structure and automatically executable by software. This procedure is based on the diversification of the characteristics of the model (mechanical parameters of the materials, internal and external constraints) depending on the type of load action. Although the methodology is calibrated on the equivalent frame model, it introduces concepts related to the construction phases, which are valid regardless of the modelling technique applied.

2 CONSTRUCTION PHASES ANALYSIS

Analysis of the construction phases has long been used in structural engineering for specific structural typologies, such as bridges. In general, before a construction is completed, the static scheme of the structure evolves. The mechanical characteristics and the restraint conditions can be considered variable during the different construction phases, which are characterized by loads of different nature.

Normally, dealing with buildings, all the loads, whether they are vertical or horizontal, permanent or variable (including wind, seismic action) are applied to the same structural model,

and the results of the analyses performed for the different load actions are then combined together. In frame structures, sufficiently regular in terms of geometry and stiffness, such as steel or reinforced concrete frame structures, this methodology leads to acceptable approximations. In masonry structures, instead, issues related to the stress distribution among the resistant elements may arise.

The proposed approach differentiates the structural scheme depending on the different load actions, which occur at different times during the life of the structure. While the structure is being built, it cannot be assumed that it behaves as a frame under the action of the self-weight; the frame will appear only once the construction is complete. The structure shows a frame behavior only under the actions that occur at the end of the construction: variable loads, wind and earthquake. Therefore, three construction phases have been defined and referred to as Phase 0, Phase 1 and Phase 2.

In Phase 0, the permanent loads, both structural (G1) and non-structural (G2), are applied on a static scheme, which leads to a stress distribution consistent with the influence area of each element. In Phase 1, the vertical variable loads (Q) are applied on a static scheme, which allows occurrence of in-plane and out-of-the plane stresses in masonry piers, while spandrels remain unstressed. Finally, in Phase 2 horizontal variable loads, wind and seismic action, are applied to the structure: in this last phase, the equivalent frame is considered totally reacting.

2.1 Phase 0

While the structure is being built, it settles under its own weight; this leads each pier to be mainly subjected to axial force with a value close to the one calculated with the classic method of the influence areas. Bending or shear stress may occur in the elements in case of walls which are offset at the different stories or in case of vaults and arches, whose thrust stresses the adjacent piers in-plane and out-of-plane.

In Phase 0, only permanent loads, both structural and non-structural, are applied. In order to achieve the previously described behaviour, the piers are assumed fixed at the base and with an in-plane hinge at the top, while the spandrels are considered hinged in their plane, taking into account the arch-behaviour, that is, the presence of an ideal arch which transform the distributed load acting on the spandrel as point loads at its two ends. Therefore, the spandrels are unstressed under vertical actions, since they develop an “arch behaviour” instead of a “beam behaviour”.

However, these hypotheses alone are not enough to ensure the desired behaviour. In fact, there remains the issue of stress migration due to large stiffness variation between adjacent elements. In addition, unrealistic moments may occur within irregular frames where piers are not continuous form foundations to top and lability may arise in the wall plane due to the applied releases.

The following modifications have been introduced in order to overcome these issues:

- Migration of stress due to sharp stiffness variation. Besides the pier restraints mentioned above (fixed end at the base and in-plane hinge at the top), the values of modulus of elasticity E and shear modulus G are amplified in order to obtain very stiff elements. In this way, the effects of stress redistribution due to different pier sections vanish, since the stresses are distributed within a rigid system. Furthermore, vertical translation is released in the rigid links between orthogonal walls, in this way a more realistic distribution of the slab loads is achieved, avoiding stress migration among transversal walls.
- Occurrence of local lability due to the applied releases. The figure below highlights the mechanism that may occur in the wall plane: the hinges introduced at the top of the piers and

at the two ends of the spandrels are aligned, thus the system is labile. To overcome this issue the joint X and Y rotations are restrained at the top of the piers and, as a result, the system assumes a "shear-type" behaviour.

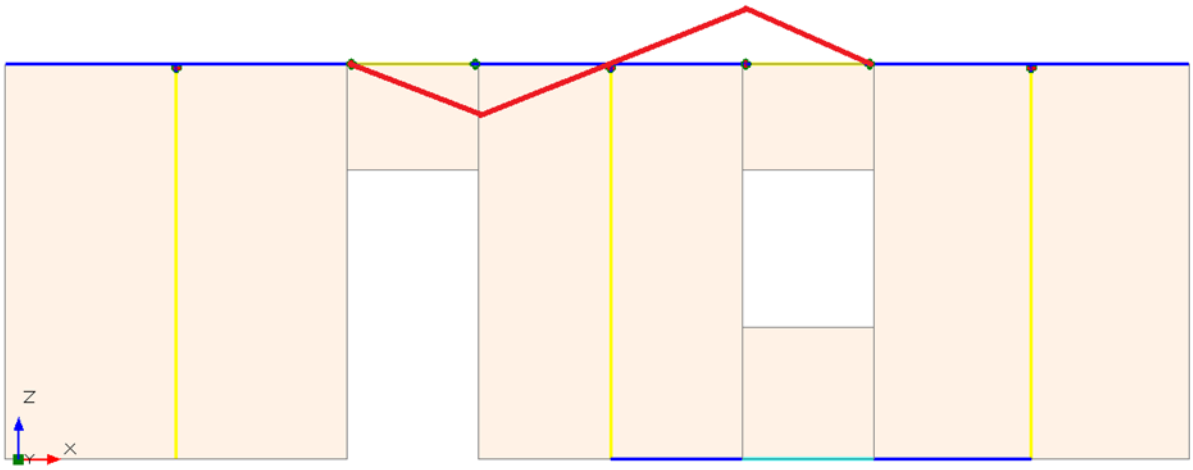

Figure 1. Possible lability in the wall plane.

In order not to create rigid relations among the joints, which may affect the distribution of the vertical loads, the hypothesis of rigid level and rigid slabs are ignored.

As regards the foundations, it should be pointed out that in masonry structures they are usually very stiff, they do not deflect and during the construction they settle under the weight of the structure. Therefore, in this phase it can be assumed that the stress are transferred to the ground through a rigid body and that differential settings capable to create stress states in the superstructure will occur in a later phase when the structure behaves as a spatial frame. In order to achieve the goal, first, the foundation joints at the base of the walls are fixed allowing evaluating the resultant of the action in terms of vertical load and bending moment. Then, the stress in the ground is determined using the formula for compression and flexure applied to the section defined by the foundation plan:

$$\sigma(\xi,\eta) = N/A + N \cdot \eta_N \cdot \eta/J_\xi + N \cdot \xi_N \cdot \xi/J_\eta$$

where: ξ and η are the coordinates of the vertex of each foundation frame in the global reference, N is the resultant vertical force, ξ_N and η_N are the eccentricity of N with respect to centroid of the section, A is the total area of the foundation plan, J_ξ and J_η are the second moment of inertia about the axes ξ and η.

To sum up, the hypothesis introduced in Phase 0 are the following:

- Piers fixed at the base and with in-plane hinge at the top.
- Spandrels hinged in their plane at the two ends with arch-behavior.
- Amplified modulus of elasticity for masonry elements.
- Shear-type behavior for joints at the top of masonry piers.
- Vertical translation released for rigid links between orthogonal walls.
- Rigid levels (master-slave relations) and slab stiffness are ignored.

- Rigid foundations and determination of soil stresses through the formula of compression and flexure applied to the section defined by the foundation plan.

2.2 Phase 1

In Phase 1, the vertical variable loads are applied to the equivalent frame. These loads occur once the structure is completely built, so it cannot be assumed that the structure settles under their action. Therefore, moments and shear force in masonry piers are considered plausible. However, since the vertical load acting in this phase are still static, the spandrels are modelled so as not to be subjected to bending moment and shear.

As regards the foundations, in this phase they can be modelled as beams on elastic soil according to Winkler theory, allowing for the occurrence of differential settlements.

To sum up, the described behavior is achieved through the following modification of the standard frame: spandrels are hinged in their plane with arch-behavior; rigid levels and slab stiffness are ignored.

2.3 Phase 2

In Phase 2, the horizontal loads (wind and seismic action) are applied to the completely reacting frame. Bending moments and shear forces are accepted in all the elements including spandrels. This is the last phase where the equivalent frames method is applied with the original formulation without modification of the elements.

2.4 Combination of the results

Construction phases analysis is performed by means of three different structural models, one for each phase. The final stress and strain state of each element is given from the combination of the results obtained for each phase, of course taking into account the combination coefficients.

However, modal analysis is carried out on the standard equivalent frame model (Phase 2), since it is representative of the dynamic behavior of the structure. In seismic analysis, the static effects obtained from Phase 0 and Phase 1 are combined with the seismic effects obtained from Phase 2.

3 ANALYSIS OF THE CONSTRUCTION STAGES

The study of the construction phases analysis provided the basis for developing a more accurate analysis procedure when dealing with buildings which have undergone modification in later construction stages. In particular, the study considers buildings that have been enlarged with the integration of new volumes, rather than those which have undergone a demolition. This case occurs frequently in the engineering practice, since interventions aimed to extend or raise an existing building are very common.

Looking at the very nature of the intervention, it is evident that it represent an extension of the construction phases methodology outlined in the previous paragraphs. Even in this case, the building can be analyzed considering three different construction phases, but it should be taken into account that when the enlargement has been built the original part of the structure was already consolidated.

For the purposes of the analysis the original structure is referred to as Structure A while the enlargement is referred to as Structure B. The construction phases analysis is performed through the analysis of the following models:

- *Model 0-A.* This model consists only of the original structure modelled according to the hypothesis of Phase 0. The analysis is performed for the corresponding permanent loads.
- *Model 0-B.* The enlargement is modelled according to Phase 0 while the original structure is modelled according to Phase 1. The analysis is performed for the permanent loads related to the enlargement.
- *Model 1.* Both original structure and enlargement are modelled according to Phase 1. The analysis is performed for vertical variable loads.
- *Model 2.* Both original structure and enlargement are modelled according to hypothesis of Phase 2. The analysis is performed for horizontal variable loads (wind, seismic action).

Once all the analysis have been performed on the four models, the results are combined taking into account the combination coefficients provided by the Standards for each different load action.

4 CASE STUDY

The proposed methodology has been applied to the case of a three-story building located in Fivizzano, Tuscany [5]. The construction dates back to 1918. In 1967, the building has undergone renovations that led to the enlargement of ground floor and first floor. The layout of the structure, although rather simple, shows all the critical aspects related to the equivalent frame modelling and allows focusing the attention on the effects of the construction phases analysis.

Figure 2. View of the building

The different typologies of masonry and slabs confirm that the structure was built in two different periods. The walls of the structure dating back to 1918 are made of irregular stone masonry, while the walls built in the later stage are made of brick masonry with regular pattern. The following figures show an elevation and two floor plan of the building, the different colors highlight the different construction stages.

Figure 3. South-East Elevation

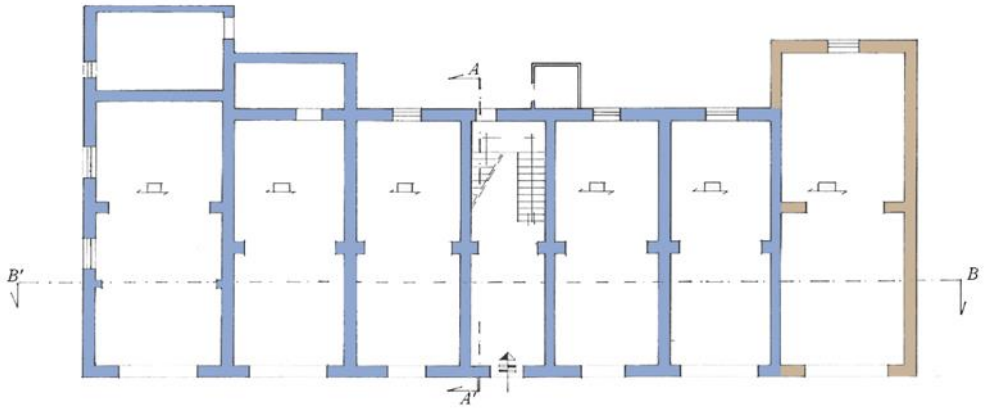

Figure 4. Plan of the Ground Floor.

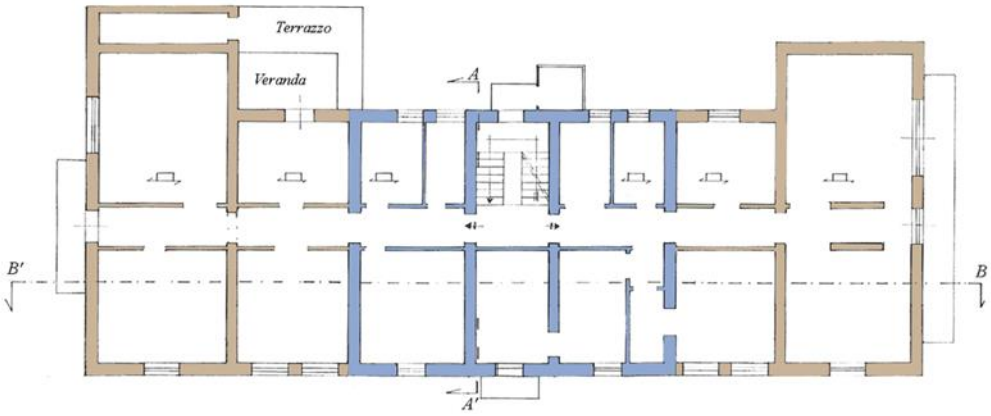

Figure 5. Plan of the First Floor

The analysis of the building was carried out according to three different approaches: (i) standard approach; (ii) construction phases analysis; (iii) analysis of the construction stages. The differences between the three methodologies are highlighted in terms of stress state resulting from linear static analysis.

4.1 Standard approach

The following figures show the modelling of the building through the standard equivalent frame method.

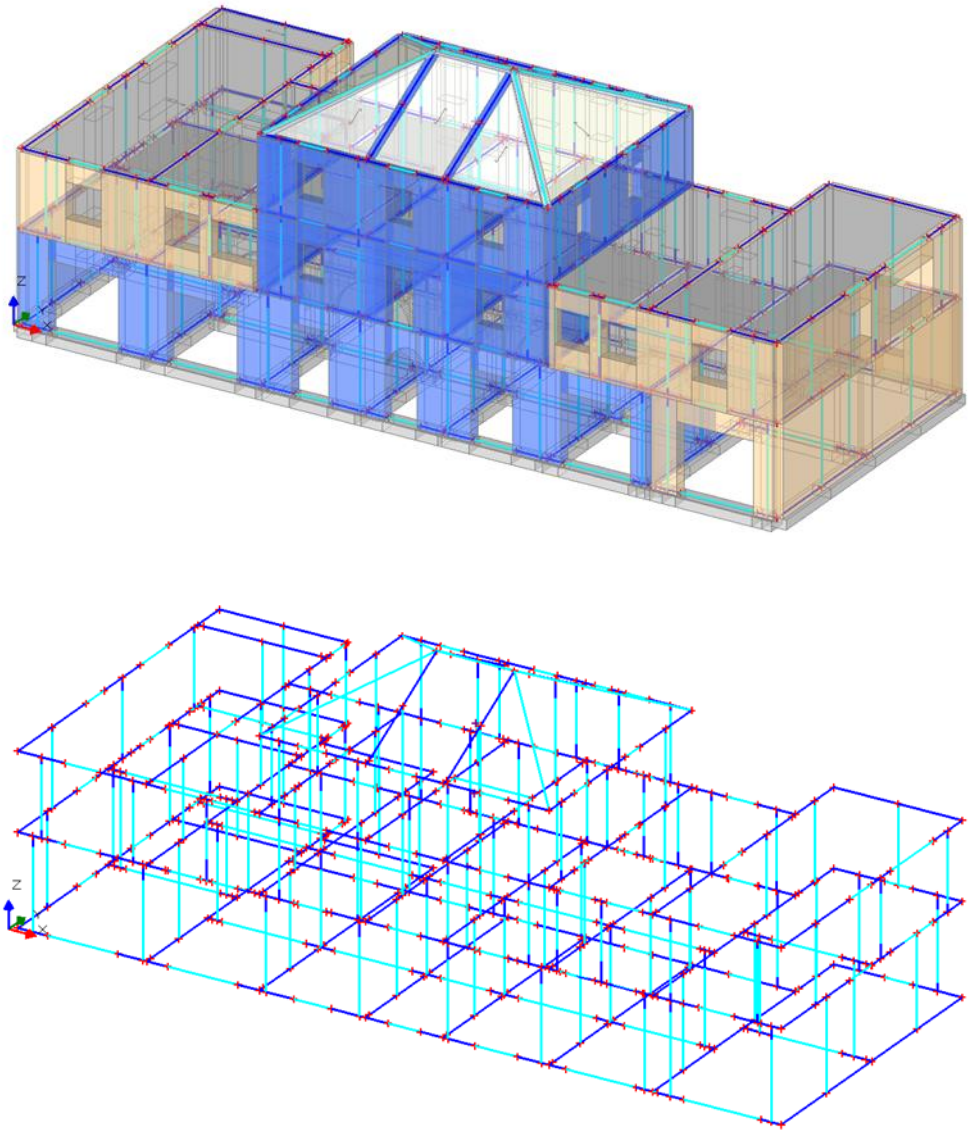

Figure 6. Standard equivalent frame model.

Masonry piers and spandrels are modelled through frame elements. Rigid links connect the spandrels to the adjacent piers and provide the connection between transversal walls. As a result each slab boundary is a closed polyline made of frame elements (spandrels and rigid links). The slabs in the original part of the building are considered deformable, while the ones made of concrete in the enlargement part are considered infinitely rigid. The spandrels are modelled assuming the arch-behavior [6 - 8]. As regards the foundations, they are modelled as beams on elastic soil with Winkler modulus $K = 0.05\ N/mm^3$. The following table gives the mechanical properties of the masonry materials.

		Stone masonry	Brick masonry	
Modulus of elasticity	E	1600	5000	N/mm^2
Shear modulus	G	240	500	N/mm^2
Weight per unit volume	w	23.50	18.00	kN/m^3

Table 1. Mechanical properties of masonry materials

Static linear analysis was performed with the aid of the software Aedes.PCM [9]. The results shown below refer to a load combination that includes only vertical loads with all the combination coefficients equal to 1. Such combination, although not required by the Standards, is useful to simplify the comparison of the results. In fact, the scope of this first analysis is to highlight the critical aspects of the equivalent frame model. The following figure shows the axial force diagram.

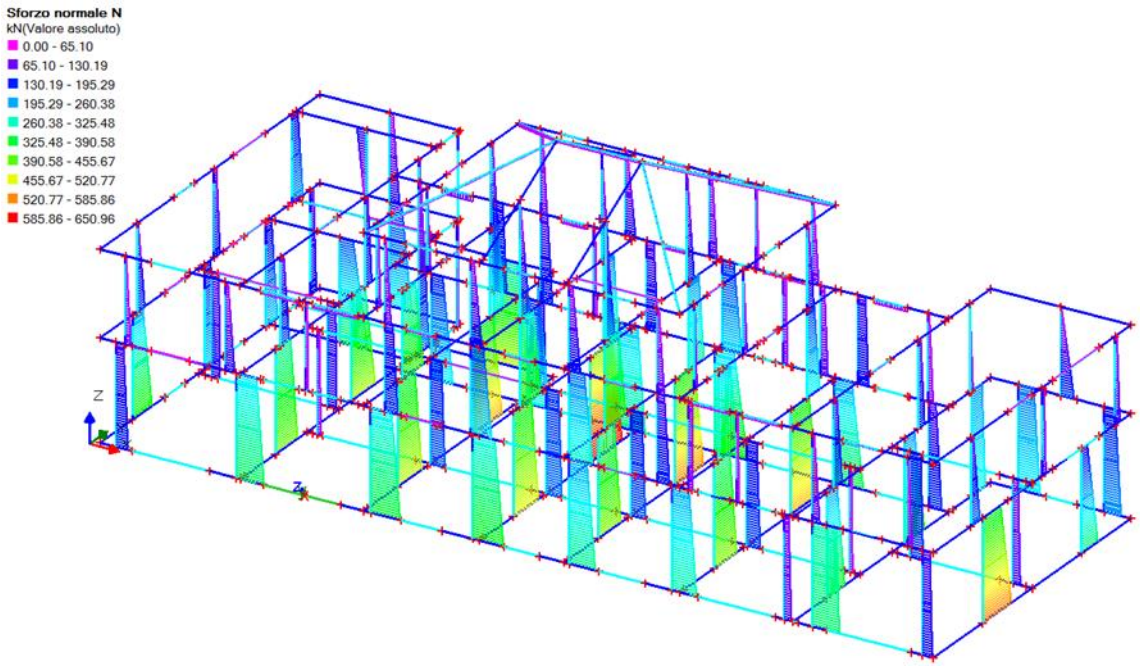

Figure 7. Static analysis. Axial force diagrams

Several issues affect the resulting stress distribution: masonry piers in tension, stress migration among adjacent elements, spandrels subjected to high bending moments and shear force. Let us focus our attention on the frontal alignment (Figure 8), evaluating the differences between the analysis results and a manual calculation of the stress state.

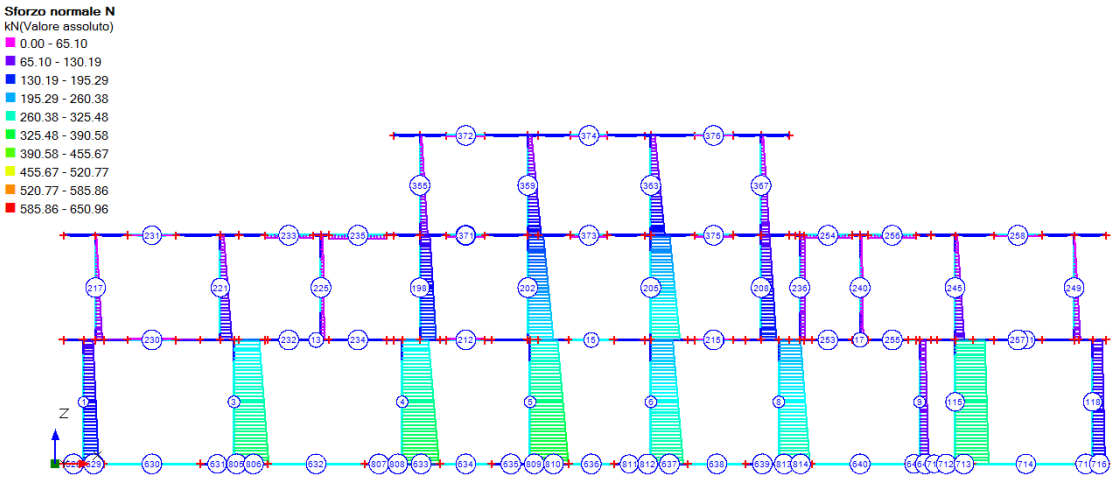

Figure 8. Axial force diagrams. Frontal alignment

Piers 6 and 205 are perfectly aligned and definitely affected by an issue: looking at the axial force diagram we notice an unnatural decrease at the interface between the two elements.

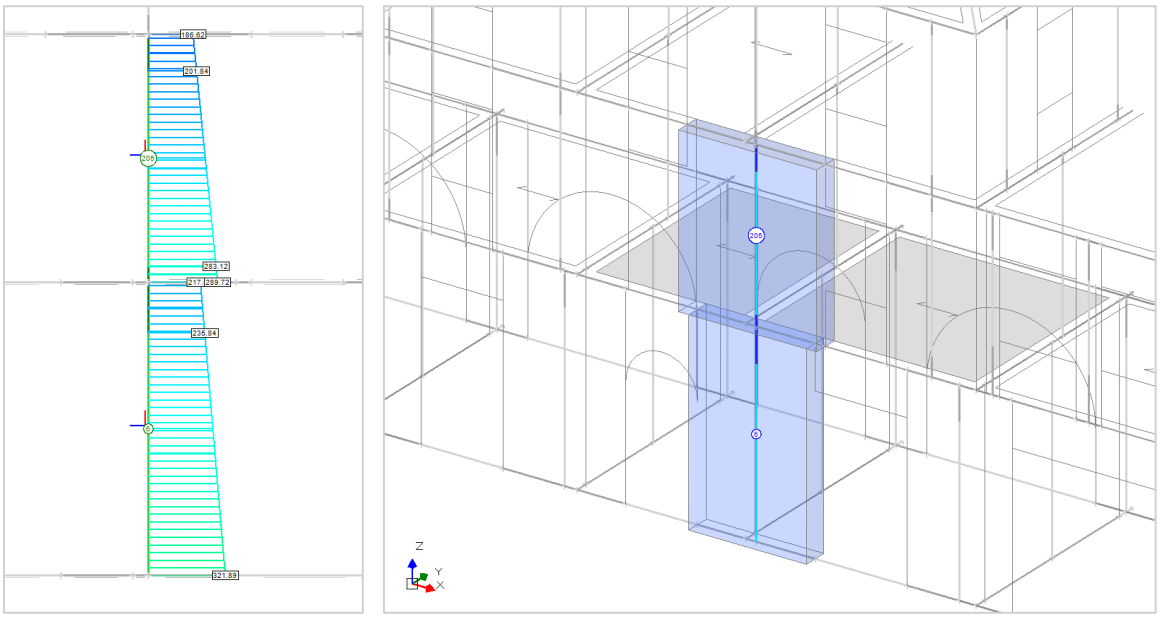

Figure 9. Axial force diagrams. Piers 6 and 205

This issue is caused by stress migration towards other elements. The amount of the decrease in axial force is at least equal to

$$N_{205} - N_6 = 289.72 - 217.84 = 71.88\ kN$$

Considering that the total weight of Pier 205 is equal to 103 kN, the error is rather large. In fact, about 70% of the weight of Pier 205 is not transferred to pier 6 but migrates to other elements.

Another important aspect is the stress state in the spandrels. Despite they were modelled with the arch-behaviour, the spandrels are subject to shear and bending moments under the action of the sole vertical loads. The following table shows the characteristics of the stress state resulting in Spandrel 14.

	Joint i	Joint j	
N	7.47	7.47	kN
V_y	0.78	0.78	kN
V_z	-8.92	8.92	kN
M_x	-0.08	-0.08	kNm
M_y	3.41	-10.85	kNm
M_z	0.65	-0.59	kNm

Table 2. Stress state in Spandrel 14

As highlighted before, these issues are caused by the way the equivalent frame method is applied and construction phases analysis is able to overcome them. The results of the analysis performed with the proposed approaches are given in the following paragraphs.

4.2 Construction Phases Analysis

The building is now analyzed with the construction phases approach described in §2. The following figures show the results of static linear analysis in terms of axial force diagram. Let us focus on the frontal alignment.

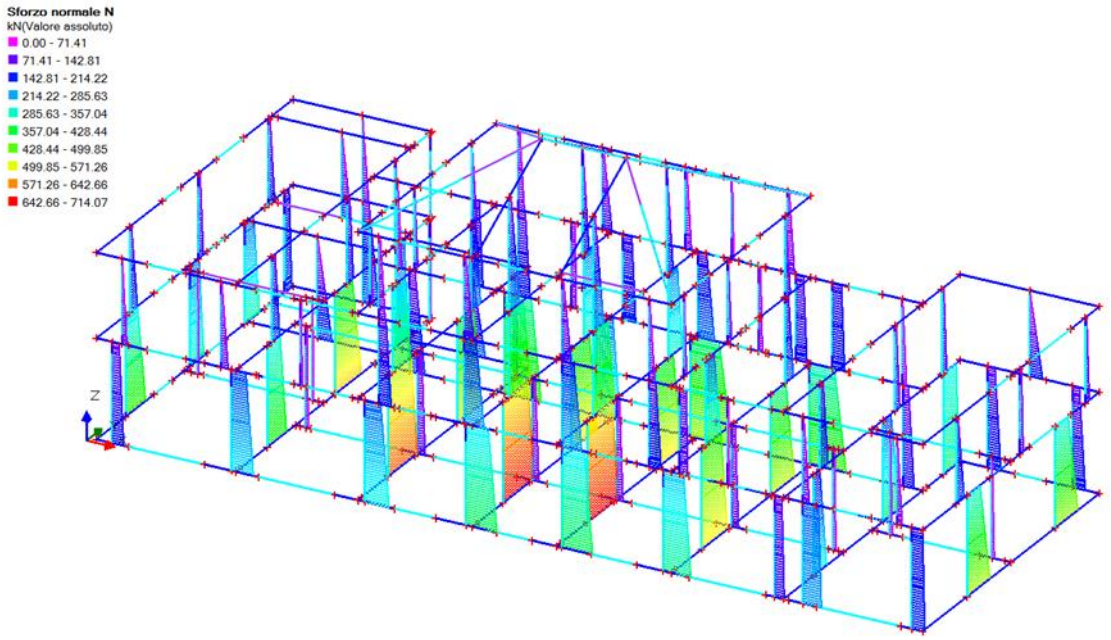

Figure 10. Static analysis results. Axial force diagrams

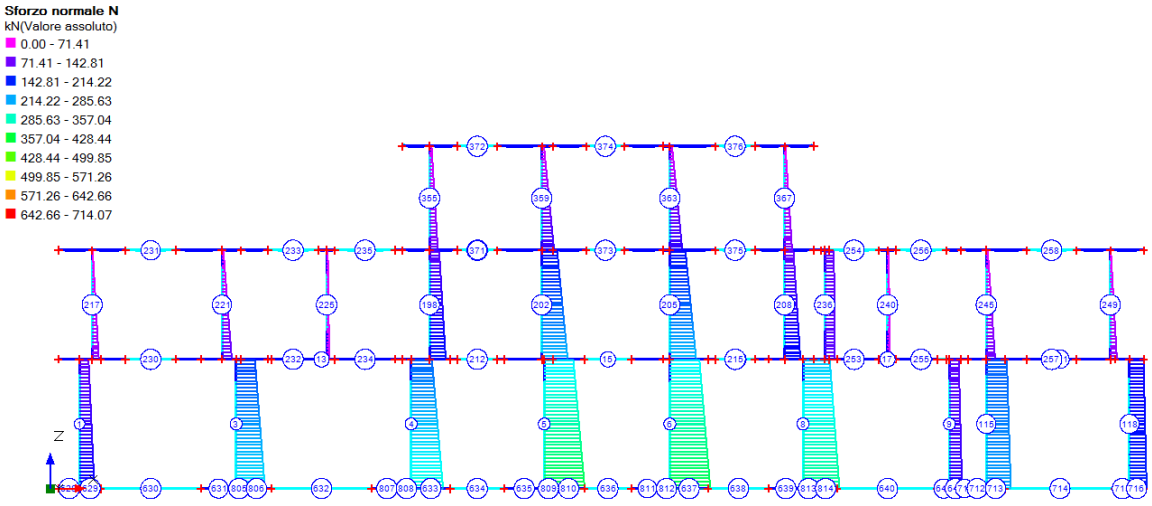

Figure 11. Axial force diagrams. Frontal alignment

The results of the analysis show no elements in tension. Comparing Figure 8 with Figure 11, we can notice in the latter a more rational stress distribution: there are no unnatural variation of axial force in continuous elements. Moreover, in-plane and out-of-plane bending moments are considerably reduced since now they are caused by the sole variable loads acting in Phase 1.

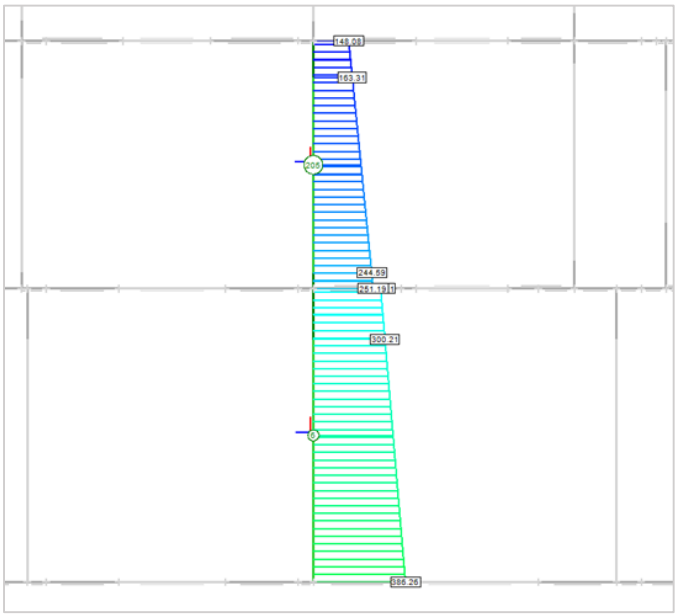

Figure 12. Axial force diagrams. Piers 6 and 205

Looking at Piers 6 and 205, we still notice a step in the axial force diagram, but this time it is the natural increment due to the weight of the spandrels:

$$N_6 - N_{205} = 282.21 - 251.19 = 31.02\ kN$$

The following table show the characteristics of the stress state in Spandrel 14. We notice a significant reduction of the stress, consistent with the hypothesis of arch-behaviour.

	Joint i	Joint j	
N	0.00	0.00	kN
V_y	-0.05	-0.05	kN
V_z	0.00	0.00	kN
M_x	0.00	0.00	kNm
M_y	0.00	0.00	kNm
M_z	-0.04	0.04	kNm

Table 3. Stress state in Spandrel 14

4.3 Analysis of the construction stages

The third approach refers to the analysis of the construction stages described in §3. As shown in Figure 6, part of the structure was built in 1918, while the rest was constructed in 1967 as part of the renovation interventions.

This approach is based on the hypotheses of the construction phases analysis, thus the results are similar to those obtained with the previous approach given in §4.2. The only difference is the influence that the structure built in a later stage exerts on the original structure. This aspect is properly addressed only in the current approach, where the analysis under the action of the permanent loads is carried out by means of two models (0-A and 0-B).

Similarly to the previous approaches, we discuss the results of static linear analysis with a load combination that includes the sole vertical loads, focusing on the frontal alignment of the building (Figure 13, 14). The axial force distribution is regular, without piers in tension or particular stress migration.

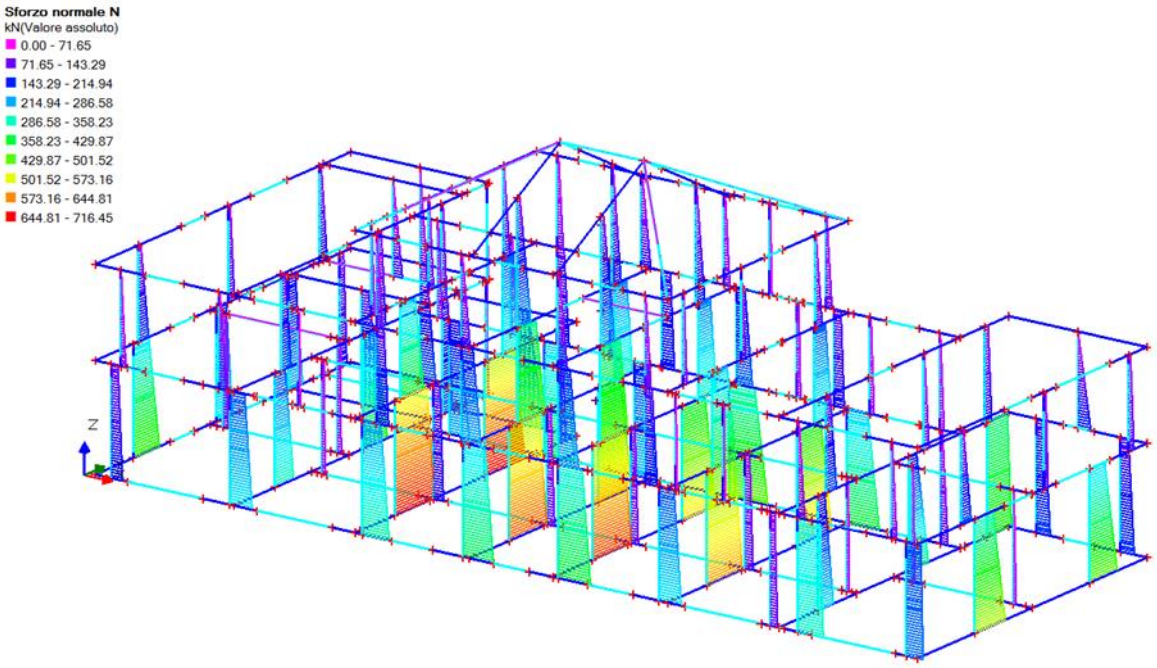

Figure 13. Static analysis results. Axial force diagrams

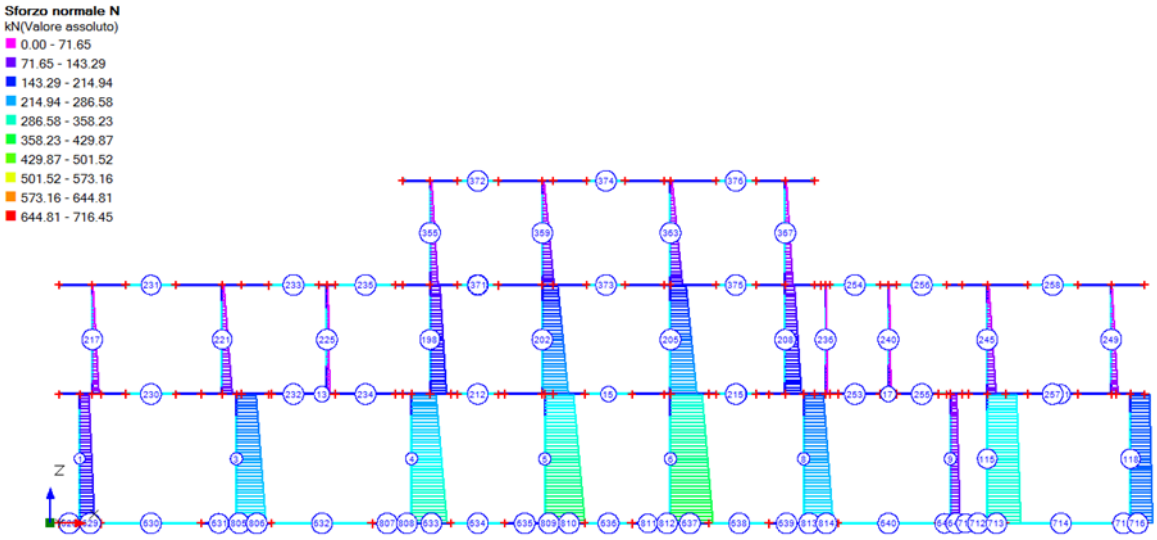

Figure 14. Axial force diagrams. Frontal alignment

As expected, the results are very similar to those obtained with the construction phases approach, although they are obtained through different models. This confirms the feasibility and the accuracy of the proposed methodology.
