Keywords: Seismic assessment, Latin Hypercube sampling, RC bridges, Period estimation

Abstract. *The nodes of a road transportation network of a certain region can represent a population of bridges. In view of a sound characterization of corresponding fragility or vulnerability functions, the knowledge of real data, such as geometrical and material properties available from a national bridge inventory database, is a crucial element. In fact, the outcome of damage seismic assessment can be strongly affected by the variability of such information. When only limited information for each node is known and the relevant structural behaviour needs to be assessed for e.g. loss estimation studies at macro-scale level, the use of statistical tools is of extreme importance. Accordingly, the present paper furnishes a double-fold contribution: (1) provide the systematic statistical characterization of geometrical and material properties of typical Italian reinforced concrete (RC) bridges and (2) simplified formulae for the quick evaluation of the fundamental elastic period of vibration of RC bridges. This allows the development of typological fragility curves for RC bridge classes, which might be chosen according to their fundamental period of vibration. As such, the bridges can be identified with a specific bridge class, characterized by a representative fragility curve, used for expedite large-scale seismic assessment.*

1 INTRODUCTION

Severe past earthquakes had a significant impact on road network systems as well as considerable catastrophic effects on human life, buildings and economy. Examples of such disastrous events are the San Fernando earthquake in 1971, Loma Prieta in 1989, Northridge in 1994 and more recent events such as Italian and New Zealand earthquakes in 2009 and 2011, respectively. It is due to such consequences that the management of the emergency phase in the immediate aftermath of an earthquake is significant. One way to efficiently tackle such an issue is to rapidly assess the status of the main network components, which may exhibit weak seismic response, which, in turn, may cause infrastructure or cascading system disruptions. The main components of a network can be point-site or distributed components [1]. Bridges belong to the former category and they play an important role to ensure the efficiency of the network system itself and the interconnection between cities' strategic facilities or of its surrounding area [2]. A number of past studies have addressed the seismic assessment of individual bridge structures through nonlinear static or dynamic analysis [3-7]. However, such research was built upon the knowledge and the applications initially developed for building structures [8-12] and it resulted in the proposal of fragility curves for individual structures [13-16].

The derivation of fragility curves from a number of relevant geometrical or structural parameters taken from real case studies is of utmost importance for the accuracy of loss assessment investigations as part of decision-making strategies [17-18]. In such way, civil protection or other expert bodies can rely on them during the management of post-extreme event emergency phases. Yet, especially when dealing with broad areas, the development of fragility curves for each individual bridge can be unfeasible, mainly for the computational onus that such approach requires. Therefore, a parametric statistical approach may be particularly advantageous to characterize the parameters that affect the existing RC bridges response [19]. Given such characterization, one can simulate reliable data to represent additional structural configurations to fully characterize a wide range of bridges.

With the above in mind, the present study uses statistical tools to characterize populations of Italian bridges, targeting a specific typology. The collected data includes construction year, pier heights, total bridge length, span length, number of spans, superstructure area, pier main section sizes, compressive strength, tensile strength, shear strength, Young modulus and shear modulus of materials. In particular, geometrical and material properties associated to a real bridge stock are presented in a statistically usable form. Specifically, in the initial phase, they are summarized in terms of average (mean values) and corresponding dispersion (standard deviation and coefficient of variation). Successively, statistical distributions are assigned to each parameter by means of goodness-of-fit tests for small and larger samples. Such summary statistics are then used as input for the generation of a population of a specific bridge typology, representing a typical class of Italian bridges, through standard or Latin Hypercube-based Monte Carlo sampling schemes [20] in order to obtain a wide variety of bridge configurations. Finally, the configurations are analysed in order to define a simplified relationship between the period of vibration and the bridge geometrical properties that can be easily obtained or estimated through field survey or other equivalent methods. This relationship is intended for use in risk and loss assessment models and constitutes a first step towards the assignment and/or the generation of analytical fragility and vulnerability functions for specific bridge categories. In spite of its drawbacks, the relationship can be used as a potential proxy for seismic structural demand estimate of well-defined bridge typologies. It would also enable the possibility of rapidly sub-dividing bridge populations in classes for the expedite application of recent record selection procedures (e.g. conditional spectrum method) or early loss assessment

approximations, through immediate assignment of a proper fragility curve for the assessment of damage level. Ultimately, this relationship may also be applied to estimate structural properties or damage levels when no detailed information on the bridge is available.

2 SEISMIC ASSESSMENT FRAMEWORK

The global framework involving the present study targets the development of typological fragility and vulnerability functions for specific bridge classes. The framework, illustrated in Figure 1, starts with the random generation of multiple bridge structural configurations, generated through summary statistics of geometrical and material properties, which can be typically drawn from national bridge inventories. The obtained bridge portfolio can then be characterized in terms of eigenvalue analyses output, which will be useful to either identify the fundamental period of vibration or define pushover curve loads for nonlinear seismic demand estimation methods. In fact, in the past, a large number of simplified equations to estimate the fundamental period of vibration have been proposed and are commonly used for buildings (e.g. [21, 22]) whereas the absence of similar equations for bridges is well known. This paper intends to contribute to fill such a gap by proposing simplified equations as function of one or more parameters strongly correlated to the fundamental period. The fundamental period of vibration becomes also handy to e.g. carry out proper selection of records according to recent methodologies, such as the conditional spectrum method [23], also successfully applied to bridges [24]. Such a selection guarantees reliable performance points for any employed nonlinear static procedure or seismic input for nonlinear dynamic analyses.

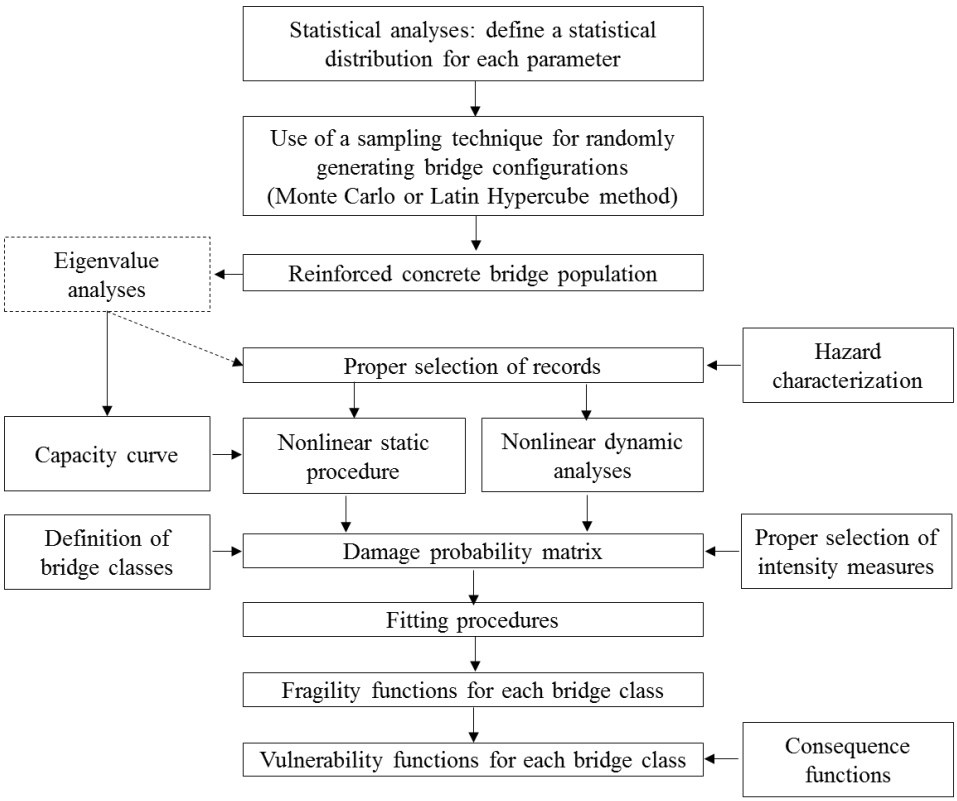

Figure 1. General framework

Once bridge classes are identified, a proper intensity measure and damage limit states are selected so that the damage probability matrix can be derived. This matrix becomes the input of a fitting procedure developed to identify the main fragility function parameters. Therefore,

the framework is very much dependent on randomly simulated bridges, featuring different geometrical configurations. Indeed, the randomness that characterizes the simulated population is exclusively related to the structural layout of the pier heights and deck spans, together with the variability associated to the material properties. With this portfolio it is possible to establish, through regression analysis, empirical equations that relate geometrical properties with corresponding structural response and, afterwards, fragility. Such equations may then find useful application in expedite risk assessment methodologies or national design codes.

3 STATISTICS AROUND BRIDGE PROPERTIES

In order to provide the input for numerical simulation of bridge populations, the available information of the bridge stock under investigation has been statistically characterized. Statistical distributions were assigned to each parameter deemed relevant to the behaviour of reinforced concrete bridges. For the selected geometrical and material properties, the main statistical quantities were evaluated from the sample. Chi-Square and/or Kolmogorov-Smirnov goodness-of-fit (GoF) tests were applied to assign normal, lognormal, gamma, exponential or Weibull distributions, according to typical alpha values (0.05, 0.10 and 0.20). At an initial stage, all the properties available from the source database were statistically characterized through GoF testing. Afterwards, bridge configuration sampling and empirical relationships were carried out only for the properties that were relevant for a common RC bridge configuration, as detailed in Section 4, namely piers height, total length of bridges, span length, section diameter, reinforcing bars' Young modulus, concrete compressive strength.

3.1 Chi-Square Goodness-of-Fit test

This test should be employed under specific conditions: it requires a sufficient sample size, only binned data are allowed and a minimum expected frequency is required. Given that the selection of the number of bins affects the value of the test, some rules (e.g. Sturge's rule, Normal reference rule and Scott's rule) suggest the most appropriate bin widths in order to minimize the squared error in the approximation of the Chi-Square test. The minimum expected frequency is unanimously established by literature equal to five, and if this minimum requirement is not reached, the combination of adjacent bins in the tails is applied. The subsequent overlapping of the theoretical probability density function of the assumed distribution on each histogram shows if there is probabilistic agreement; if there is not, the null hypothesis, which asserts that the data follows the pre-specified distribution, is most likely incorrect.

3.2 Kolmogorov-Smirnov Goodness-of-Fit test

The Kolmogorov-Smirnov GoF test belongs to the class of distance tests and is among the best distance tests for small samples, yet it is still reliable for large ones. The test is developed starting from the assumption of an empirical distribution, characterized by parameters estimated from the data set or from expert judgment. The comparison between theoretical and empirical CDFs follows. If the two CDF curves agree from the probabilistic point of view, the assumed distribution is accepted. Such comparison consists of defining the maximum vertical distance between the two curves and the p-value based on the maximum distance. The Kolmogorov-Smirnov test is widely used in practice and it works properly even if the sample size is small; hence it becomes particularly useful for the statistical characterization of geometrical and material properties of existing structures, such as the ones herein investigated.

3.3 Goodness-of-Fit testing with data truncation

A non negligible percentage of the data for the different variables was located at the tails of the corresponding distribution functions. The identification of outliers was therefore necessary. One way to recognize outliers is by using box plots, which synthetically represent all the data and group it in quartiles. The variability outside the upper and lower quartiles (respectively q3 and q1 in Figure 2) was assumed as 1.5 times the interquartile range (IQR) and is represented by whiskers. The data outside the whiskers length is identified as outliers. The range of data that excludes outliers is the so-called inner fence and it was used as input for the statistical tests [25].

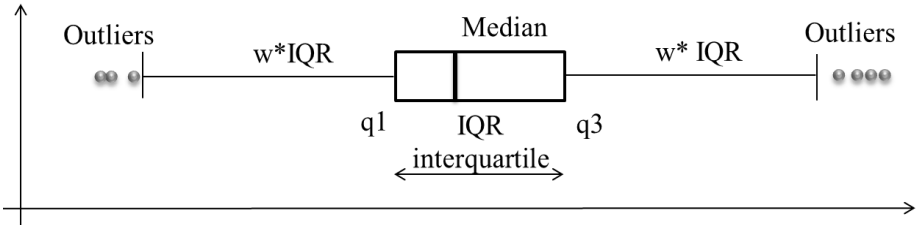

Figure 2. Typical box plot for identifying outliers

In the present work, the variables that did not satisfy goodness of fit tests were analysed through box plots and in some cases, to better fit the theoretical statistical distribution, a whisker length of 3.0 was allowed. All the distribution parameters were accordingly derived.

4 DEFINITION OF A TYPICAL BRIDGE STOCK

The statistical treatment of geometrical and material properties was conducted by selecting, among the available data, the most relevant parameters from the structural seismic response viewpoint. The main bridge typology considered corresponds to Italian reinforced concrete bridges built between the 1970s and 1990s, when the major development of the highway network took place. In most cases, such bridges are characterized by simply supported deck or monolithic connections (Figure 3). About 30% of the structures exhibit circular or rectangular pier cross sections, whereas 35% include several section shapes such as octagonal or composite sections. The pier-to-deck connection is typically of the concrete-concrete or elastomeric bearings or other devices type.

Figure 3. Typical Italian highway bridge. [26]

A case study made up of nearly five hundred Italian bridges (the exact number is 458), illustrated in Figure 4, was built up with a view to the simplified seismic vulnerability estimates for RC bridges by using parameterized structural behaviour relationships and future fragility curves.

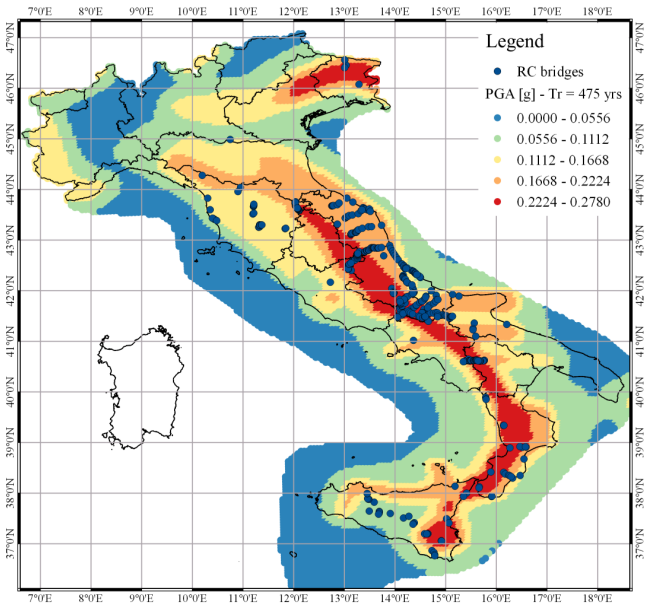

Figure 4. Case study: Italian reinforced concrete bridge population

Ideally, within a seismic risk assessment context, the definition of fragility curves of each bridge should be carried out. However, to avoid the considerable time demand of such an approach, the definition of bridge classes for a certain country would be reasonable if one assumes that the characteristics of bridges in a certain region are typically similar. Furthermore, the approach followed in the present section is based on general geometric and material information provided by a database, which is not enough to define an exhaustive characterization of different bridge classes.

At this point, the portfolio characterization in terms of random simulation of bridge properties can follow two macro strategies. The first is to consider specific geometric configurations with a specific layout (predefined number of piers, spans and regularity level) and then establish a distribution for every variable of the layout to perform simulations. The second, that is adopted here, considers the number of piers, spans and regularity level (pier heights) as random variables, defined statistically.

As such, the Italian bridges represented in Figure 4 were gathered in a single macro bridge category, corresponding to straight multi-span continuous reinforced concrete bridges. These bridges were modelled using the same deck and pier cross section type and featured no isolation at the pier-to-deck connection level. Abutments were considered as of very high stiffness hence nearly fully fixed. Furthermore, curved bridges were assumed as straight and were grouped in that same class, whilst arch bridges were considered as part of a different configuration type hence not included in the present study. The available geometrical parameters for each bridge, schematically depicted in Figure 5, were individually analysed and general inference on bridge class was made when the full set of bridge properties was not available.

Construction type, column height, span length, number of spans, superstructure area, radius of curvature in plan, main geometrical dimension of the column section, steel bars tensile strength, steel bars Young Modulus were the available parameters that provide insight to-

wards the typical geometric configuration and material properties of the selected bridges. No specific information related to the seismic design was available. A possible indicator to determine whether the bridges were seismically designed or not could be the year of construction. With respect to the bridges for which the construction year is known, 65% were built before 1970; 25% between 1970 and 1980, and 10% after 1980. Therefore, all the bridges were conservatively assumed as non seismically designed.

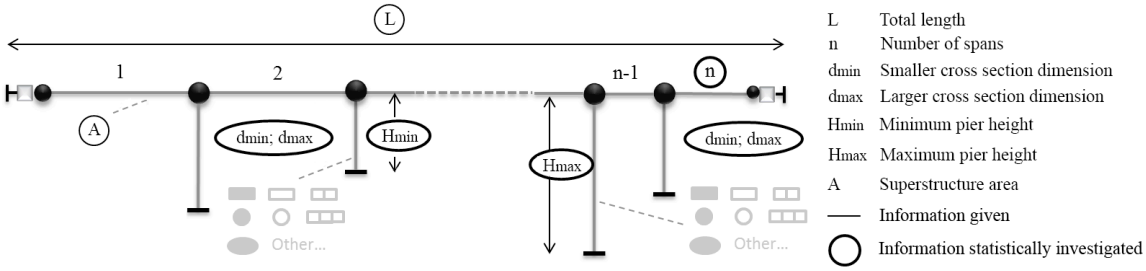

Figure 5. Available information on the case study bridges

For most of the properties, statistical details were investigated using the conventional statistical tools for distribution testing, described in Section 3, to define input for numerical simulation. Specific attention was paid to discrete data, for which different statistical treatment was required, particularly for the number of spans variable, which only admits integer values. In fact, even though the use of Poisson regression would be required, the resulting inappropriate short spans obtained with such an approach led the authors to consider instead the relationship between number of spans and total length, as given in Table 1.

Variable	**Distribution**	**Distr. parameters**	**Statistical tests**
Pier height [m]	Lognormal	Mean (log): 1.95 std: 0.8275	Chi-sq. not sat. K-S: **10%, sat.**
Total length [m]	Lognormal	Mean (log): 5.10 std: 1.145	Chi-sq. not sat. K-S not sat
Span length [m]	Normal	Mean: 31.18 std: 11.527	Chi-sq. not sat. K-S not sat.
Average span length [m]	Normal	Mean: 29.936 std: 12.174	Chi-sq. not sat. K-S not sat.
Number of spans	Regression	# spans=1.483+0.0273*Total length R^2=0.89	
Superstructure area [m^2]	Lognormal	Mean (log): 7.88 std: 0.9087	Chi-sq.: **5 %, sat.** K-S: **10%, sat.**

Table 1. Statistical distributions – geometrical layout properties

The superstructure width, required for structural modelling and not included in the set of available variables, was derived from the superstructure area, considering a trapezoidal widespread Italian deck cross section with the assumption of a solid cross section. The depth of the section was defined in line with real bridges, taking into account the average span length. In particular, for an average span length of 20m, a reasonable value of deck depth was registered to be 1.30m; whilst in the case of 40m, the deck depth assumed was 2.20m. In order to randomly generate superstructure widths, a linear trend was assumed and inference of data was then applied. The 458 observations for superstructure width were then derived from the corresponding superstructure area and total bridge length, whose fitting to the most common statis-

tical distributions were tested through Chi-squared and Kolmogorov-Smirnov GoF tests. Although the test was not satisfied at either 99%, at 90% or at 95% confidence levels, the best fit was observed to be obtained with a lognormal distribution, without truncation of data. The random data was generated between 4.7m and 34.7m, with a mean value of 12.5m and coefficient of variation of 29.1%.

The pier cross section characterization was carried out in terms of solid sections, particularly circular cross sections, which were used for the random simulation in Section 5. As for material properties, elevation compressive strength, bar tensile strength and reinforcing bars Young Modulus statistical distributions were available.

Finally, it is worth noting that when carrying out data truncation of the geometrical properties that exhibited a number of outliers, the distribution parameters sometimes significantly changed.

5 RANDOM SAMPLING: GENERATION OF BRIDGE POPULATIONS

Following the statistical characterization of the geometrical and material properties, the random generation of bridge populations can be carried out by simulating possible values from the probability distribution functions, adjusted to the different variables described in Section 4. To accomplish this, two random simulation schemes, sharing the same underlying concepts, were selected: standard and Latin Hypercube-based Monte Carlo. A sufficient number of iteration steps was ensured to guarantee that sampled parameters approximate the initially assumed probability distribution functions. Accurate results for output distributions depend on how complete the sampling from the input distributions is, thus more efficient methods are those that reach this objective with the lower number of iterations. The most popular sampling algorithm in engineering applications is standard Monte Carlo (MC), which generally requires a large number of iteration steps, whereas a more recent sampling strategy proposed is the Latin Hypercube Sampling-based Monte Carlo (LHS) that converges faster on the statistics of the input distribution. Needless to say, the selection of a proper sampling method is a crucial phase of nonlinear engineering data analysis applications, as it affects both computational onus and accurateness of results.

5.1 Sampling with standard Monte Carlo scheme

Monte Carlo is a widely spread technique applied to many problems that require the extraction of random or pseudo-random numbers to sample from a probability distribution. In its crude or standard version, the Monte Carlo sampling technique assumes that any given sample may fall anywhere within the range of the input distribution. Its main drawback is that when probability distributions are noticeably skewed, it can present outcomes of low probability, together with clustering. These limitations have incited researchers to develop new sampling schemes, such as the Latin Hypercube-based Monte Carlo, discussed ahead. In the study presented herein, Monte Carlo sampling was tested for the generation of a population set of 1000 bridges, assuming as variables the pier height (lognormal distribution), span length (normal distribution), total bridge length (lognormal distribution), section diameter (normal distribution), longitudinal reinforcement yield strength (normal distribution), transverse reinforcement yield strength (normal distribution) and steel Young Modulus (normal distribution).

5.2 Sampling with Latin Hypercube scheme

The Latin Hypercube sampling scheme is a particular case of the Monte Carlo method and consists of the stratification of the input cumulative distribution function (CDF). This CDF is

subdivided into equal intervals from which the samples are randomly drawn without replacement, retracing the input probability distribution [27]. The input parameters of each simulation constitute the rows of an NxK matrix (N is the number of the numerical simulations and K is the number of parameters), obtained according to the inverse target distribution of the parameter associated with the column involved [28].

Even though the LHS-based method exhibits the advantage of reducing computational time demand, it does not allow the specification of parameter lower and upper bounds nor generating a new single bridge configuration. To be consistent with the bounds specified in the standard Monte Carlo method, for each parameter, such a drawback was overcome by imposing a greater number of simulations and by eliminating the entire input rows associated to those out of range values. Moreover, in order to avoid unrealistic negative parameter values, the possible entire input rows of the aforementioned N by K matrix with negative values were removed. Very few simulations did not respect the imposed restrictions therefore the described assumptions were considered acceptable.

According to the aforementioned rationale, assumptions, steps, and available information (Figure 5), a sample of 100 bridge configurations was generated. This sampling size is in agreement with recent studies in the field [29], which focused on the employment of LH sampling to the probabilistic seismic assessment of RC bridges. The distributions of the fundamental period in the transverse direction of the bridge populations generated with standard and LH-based Monte Carlo sampling are shown in Figure 6.

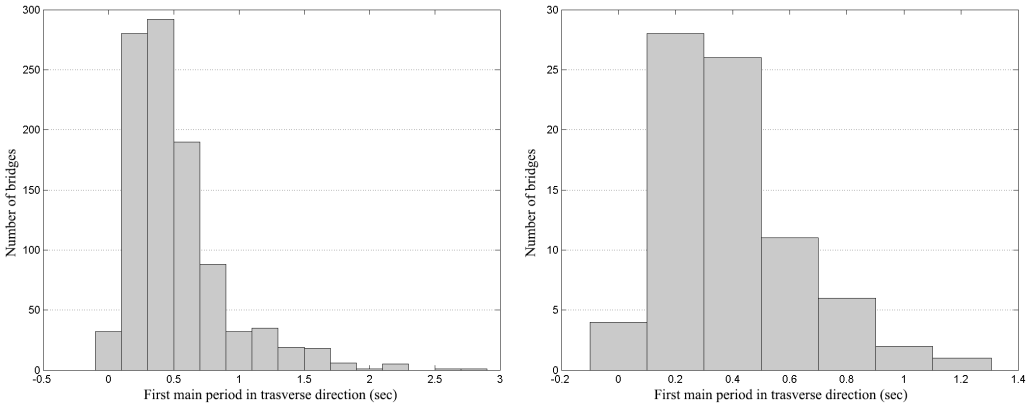

Figure 6. Fundamental transverse period of bridges randomly generated with (left) standard and (right) Latin Hypercube–based Monte Carlo sampling schemes.

6 PERIOD ESTIMATION – REGRESSION ANALYSIS

In seismic analysis, the knowledge related to the fundamental period of vibration is very important as it represents a parameter capable of providing relevant information related to the global demand on a structure under a given ground motion. Structural mass, stiffness and strength are the variables that primarily affect such a dynamic behaviour parameter. However, their knowledge is not always immediate, which renders many times useful a relationship between the period and easily obtainable properties, such as geometrical information. This relationship will in turn be useful to get an accurate estimate whenever detailed data for a certain bridge is missing. The lack of this sort of studies for bridges, as opposed to buildings, led to the identification of one or more parameters strongly correlated to the fundamental period of vibration, through an analytical procedure based on the numerical simulation of bridge portfolios. Single variable and multivariate regression analyses were carried out on the randomly generated bridge populations for the development of the period estimation relationship.

6.1 Existing bridge period relationships

Eurocode 8 proposes different formulae for the structural period of vibration based on stiffness and displacements, differentiated for the cases of rigid and flexible decks. A recent methodology [30] produced simplified capacity curves to be used for seismic loss assessment of bridges. A bridge population of twenty-one assets was considered as case study. It was characterized by two deck lengths (200m and 400m), three different types of abutments and different geometrical layouts, corresponding to different regularity classes: regular, semi-regular, and irregular. The initial period in the transverse direction, corresponding to the equivalent single-degree-of-freedom system's yielding point, resulted as a relevant parameter for characterizing simplified capacity curves, thus a preliminary trend line was drawn for defining its relationship with deck length. The number of bridges used was very limited hence the need for an improved relationship of that sort is evident. When detailed information of existing bridges is not readily available, the properties that can be easily obtained are of geometric nature. For such reason, at this initial stage, only their correlation with the fundamental period is considered.

6.2 Bridge modelling

Each case-study bridge was modelled in [31], which enabled the creation of an automatized procedure controlled by an external script [32], capable of generating and updating model files for each run. The deck was modelled as a continuous elastic element, located right at the pier top, with lumped masses and with geometrical properties referred to its centre of mass, connected through rigid link elements. Considered the bridge stock characteristics, circular solid sections were assigned to each pier. With respect to material modelling, Kent-Scott-Park model with zero tensile strength was assigned to represent concrete behaviour, accounting for confinement factor in case of concrete cores. The confinement level was evaluated for each bridge component through equations proposed by Mander, since neither Kent-Park's model nor its modified version provided information about the confining effects of spiral hoops. A bilinear model was assumed for steel, with no isotropic hardening. On the other hand, kinematic hardening was considered through the ratio between post-yield tangent and initial elastic tangent, i.e. strain-hardening ratio equal to 0.002. The connection between the piers and the deck was assured by shear keys that were modelled with rigid zero length elements and equal-degree-of-freedom connections. As far as abutments were concerned, a simplified model made up of very high stiffness springs with bilinear response along horizontal directions and fully restrained at the ground was employed.

6.3 Parametric study

Trying to fill the identified gap in the current state-of-the-art, a relationship between the fundamental period of the defined bridge class and relevant geometrical parameters was sought using eigenvalue analysis. Such approach made use of the randomly generated bridges, guaranteeing the consideration of a large breadth of different structural configurations. The representation of the fundamental period versus various geometrical parameters (tallest pier height, shortest pier height, average pier height, bridge length, average pier height) for 1000 bridges generated with standard Monte Carlo simulation was carried out in accordance with the statistical distributions proposed in Section 4. This did not evidence a clear nor satisfactory trend between fundamental period and each parameter considered individually. This is certainly due to the fact that several variables are being randomly considered and, as such, multivariate regression is envisaged with a view to an improvement in the strength of such a relationship. Nevertheless, pier height and average pier height parameters seemed to yield a

stronger correlation with the fundamental period, which preliminary indicates a possible influence by factors as regularity and bridge length.

With respect to the set of 100 bridges generated with LH–based Monte Carlo sampling, a screening of the different configurations was carried out to eliminate those including characteristics without physical meaning (e.g. negative pier heights). After such filtering, the remaining number of configurations was 78.

Considering multivariate regression, the analyses were carried out using the standard (1000) and LH–based Monte Carlo (78) sampling generated bridges. The corresponding equations and plots are presented, respectively, in Tables 2 and 3. The results denote a trend very similar to the standard Monte Carlo based results. Indeed, the comparison between the results obtained from multivariate regression analyses applied to the bridge populations associated with the two sampling procedures are summarized in Table 4. Such results demonstrate that the LH–based sampling scheme provides very close results, even slightly better, to those obtained with the standard Monte Carlo algorithm.

Table 2. Multivariate regression for 1000 bridges using standard Monte Carlo simulation

The final set of regression analysis tests considered the ratio between the two best performing variables (average pier height and section diameter), H_{av}/D_{sec}, which better fitted the results obtained with numerical simulation. Further improvement of the quality of the fitting was obtained by:

- carrying out robust regression, which assigns a different weight to each point while performing the regression;
- considering the semi-studentized residuals in order to identify the presence of outliers. According to a rough rule of thumb, suggested in [25], semi-studentized residuals with

absolute value of four or more are to be considered outliers hence they were not included when deriving regression equations.

Table 4. Comparison between multivariate regression results for the two sampling schemes

The plots and equations representing the improved relationship, associated with both Latin Hypercube and Monte Carlo sampling schemes, are illustrated in Table 5. When considering the ratio between average pier height and section diameter, the improvement in the period of vibration parametric characterization is notorious, whether standard or LH–based Monte Carlo sampling is employed. The quality and strength of the identified correlation is now at a level able to provide enough confidence in the use of the corresponding formulae. Indeed, a very quick estimate of the period of vibration of bridges with the characteristics used in this study can be taken as one tenth of the ratio between the average pier height and the pier cross section diameter.

Standard Monte Carlo sampling	**LH-based Monte Carlo sampling**
	$T = \text{-}0.088 + 0.117\frac{H_{av}}{D_{sec}}$	$T = -0.048 + 0.101\frac{H_{av}}{D_{sec}}$
$R^2 = 0.830$	$R^2 = 0.805$

7 CONCLUSIONS

The study presented in this paper shows, as main contribution, a relationship to estimate the period of vibration of a typical class of Italian reinforced concrete bridges, based on easily measurable geometrical parameters. with a view to seismic assessment studies. Such bridge typology features simply supported continuous deck, nearly fixed abutments and piers with circular cross section. The geometrical variability was defined in terms of pier and span layout (number and, respectively, height or length) and material properties. The parametric characterization is useful to e.g. rapid loss assessment studies of bridge portfolios. In such a context, expedite estimates of structural characteristics are useful, especially when limited information is available. In specific, the period of vibration is intended to provide simplified seismic structural demand information, enabling also future development of fragility curves by classes.

The geometrical and material properties characterization related to existing bridges was successfully carried out through a thorough assignment of statistical distributions based on goodness-of-fit tests and outlier elimination techniques. Using such distributions, the random generation of a large number of bridges was then performed by applying two different sampling schemes: standard Monte Carlo, characterized by fully randomness, and Latin Hypercube–based Monte Carlo, based on stratified randomness. Both procedures proved to be effective in sampling bridge populations to obtain the desired parametric relationships through robust nonlinear regression analysis. For both sets of generated bridges, corresponding to the

different simulation techniques, the determination coefficients were similar and higher than 0.8, a fair result from an engineering viewpoint. Taking into account the reduced computational onus without loss of accuracy, the Latin Hypercube–based Monte Carlo sampling scheme revealed itself more advantageous and is therefore proposed as the preferable solution for numerical simulation in engineering applications of this sort.

For what concerns the specific relationship between the period of vibration and the geometrical parameters of the bridges, a simplified equation has been successfully proposed. From the authors perspective, it can be employed as a starting step for the expedite assessment of existing bridges of predefined bridge classes (with corresponding e.g. fragility curves). For the considered class, the period of vibration is seen as typically related to the ratio between the average pier height and the pier cross section diameter, properties that can be easily obtained through visual inspection or even remote techniques (e.g. GIS tools). It is believed that the work herein presented overcomes its inherent limitations when considering that current risk assessment studies, carried out in academic and industry, are based on fragility and exposure models built upon proxies with less technical content (e.g. census data). Future developments of the present work will indeed investigate the possibility to extend the proposed period equation to other branches of bridge taxonomy i.e. structural bridge classes. Important developments will also concern the consideration of code-prescribed levels of seismic design in terms of strength and ductility in the classification of bridges.

Keywords: Finite element method, Kalman filter theory, Estimation of flow field

Abstract. *The Kalman filter developed by R. E. Kalman and R. S. Bucy is states estimation theory in the target domain and has been employed in various field of engineering. In general, observation data in any system include observation noise and the computational model includes system noise. The finite element equation is applied to derive the state transition matrix in the system equation of the Kalman filter. We can estimate state values after the time progress of spatial models. On the other hand, tidal power generation has the potential to contribute significantly as one of the clean energy. In tidal power generation, propellers of generator are rotated by tidal current and tidal power is converted to electric energy. Therefore, the generator should be placed in the fast point of tidal current to produce more electric energy. Thus, we focused on the flow field estimation using the observation data at limited observation points to find out the fast point of tidal current. As the fundamental study, the estimation of the flow field in open channel is carried out based on the finite element method and the Kalman filter theory. As the governing equation, the shallow water equations are employed, and the finite element and the selective lumping methods are applied to discretize the governing equations in space and time, respectively. The estimation of the distribution of the velocity vector and the water elevation is carried out by using the discretized equation. The open channel model is employed in the numerical experiment, and some examinations are carried out by changing the observation variables, number and position of observation points. In addition, numerical experiments using practical observed values are carried out.*

1 INTRODUCTION

In this study, the estimation of the flow field is carried out based on the finite element method and the Kalman filter theory in open channel. Figure 1 shows an example of open channel. As the governing equation, the shallow water equation is employed, and the finite element and the selective lumping methods are applied to discretize the governing equation in space and time, respectively. The estimation of the distribution of the velocity vector and the water elevation is carried out by using the discretized equation obtained by the Kalman filter theory. In the numerical experiments, the open channel flow is treated, and some examinations are carried out by changing the observation variables, number and position of observation points.

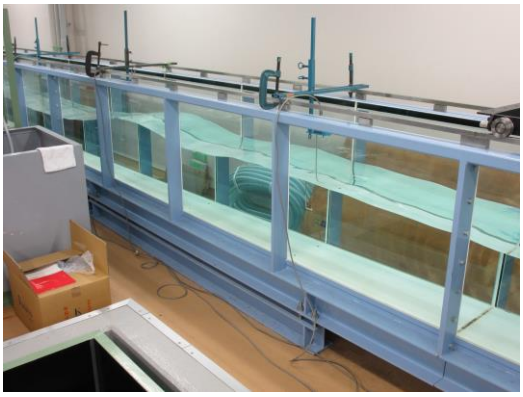

Figure 1: Open channel.

2 DISCRETIZATION OF GOVERNING EQUATIONS

The shallow water equations are used as a governing equations, which is represented as equation (1) and (2) in the two-dimensional plane.

$$\dot{u}_i + g\eta_{,i} = 0 \tag{1}$$

$$\dot{\eta} + hu_{,i} = 0 \tag{2}$$

where u, η, g, and h are flow velocity, water elevation, the gravitational acceleration and water depth. The Galerkin method and the selective lumping method are applied to discretize the governing equations in space and time, respectively. Consequently, the finite element equation can be written as equation (3). Equation (3) is represented by equation (4).

$$\begin{Bmatrix} \{u^{n+1}\} \\ \{v^{n+1}\} \\ \{\eta^{n+1}\} \end{Bmatrix} = \begin{bmatrix} [\overline{M}] & [0] & [0] \\ [0] & [\overline{M}] & [0] \\ [0] & [0] & [\overline{M}] \end{bmatrix}^{-1} \begin{bmatrix} [\tilde{M}] & [0] & -g\Delta t[S_x] \\ [0] & [\tilde{M}] & -g\Delta t[S_y] \\ -\overline{h}\Delta t[S_x] & -\overline{h}\Delta t[S_y] & [\tilde{M}] \end{bmatrix} \begin{Bmatrix} \{u^n\} \\ \{v^n\} \\ \{\eta^n\} \end{Bmatrix} \tag{3}$$

$$\{\hat{\phi}^{n+1}\} = [A]\{\hat{\phi}^n\} \tag{4}$$

where, Δt, $\overline{h}$, $[S_i]$, $[M]$ and $[\overline{M}]$ are time increment, mean water depth in the element, the matrix for the pressure, consistent mass matrix and diagonal mass matrix. $[\tilde{M}]$ is represented as equation (5) by ramping parameter $e(0 \le e \le 1)$. $\{\hat{\phi}\}$ indicates the true value.

$$\left[\tilde{M}\right] = (1-e)\left[\overline{M}\right] + e[M] \tag{5}$$

The system equation in the Kalman filter is obtained by adding the vector represented by the multiplication of the driving matrix $[\Gamma]$ and the system noise vector $\{q\}$, and is shown as Equation (6). Here, the vector $\{\phi\}$ indicates the estimation value in computation by the Kalman filter. In addition, the observation equation shown in Equation (7) is introduced. The vectors $\{z\}$ and $\{r\}$ and the matrix $[H]$ denote the observation value and the observation noise vectors and the observation matrix.

$$\left\{\phi^{n+1}\right\} = [A]\left\{\phi^{n}\right\} + [\Gamma]\left\{q^{n}\right\} \tag{6}$$

$$\left\{z^{n+1}\right\} = [H]\left\{\phi^{n+1}\right\} + \left\{r^{n+1}\right\} \tag{7}$$

3 COMPUTATIONAL ALGORITHM

It shows the numerical calculation algorithm by Kalman filter below.

1. Set input data : $[A]$, $\left[P_{(+)}^{0}\right]$, $\left\{\hat{\phi}_{(+)}^{0}\right\}$, $[\Gamma]$, $[Q]$, $[R]$, ε, $\left\{z^{n+1}\right\}$*(n = 0~imax)*
2. Calculation of estimated error covariance matrix: $\left[P_{(-)}\right] = [A]\left[P_{(+)}\right][A]^{T} + [\Gamma][Q][\Gamma]^{T}$
3. Calculation of Kalman gain matrix: $[K_1] = \left[P_{(-)}\right][H]^{T}\left([H]\left[P_{(+)}\right][H]^{T} + [R]\right)^{-1}$
4. Calculation of predicted error covariance matrix: $\left[P_{(+)}\right] = \left[P_{(-)}\right] - [K_1][H]\left[P_{(-)}\right]$
5. Check of convergence: if $\sqrt{tr\left(\left(\left[P_{(+)}^{k+1}\right] - \left[P_{(+)}^{k}\right]\right)\left(\left[P_{(+)}^{k+1}\right] - \left[P_{(+)}^{k}\right]\right)^{T}\right)} \le \varepsilon$ then go to 6, else go to 2.
6. Calculation of estimated value: $\left\{\hat{\phi}_{(-)}^{n+1}\right\} = [A]\left\{\hat{\phi}_{(+)}^{n}\right\}$
7. Calculation of optimal estimated value: $\left\{\hat{\phi}_{(+)}^{n+1}\right\} = \left\{\hat{\phi}_{(-)}^{n+1}\right\} + [K_1]\left(\left\{z^{n+1}\right\} - [H]\left\{\hat{\phi}_{(-)}^{n+1}\right\}\right)$

4 EXMINATION BY NUMERICAL EXPERIMENT

This examination is carried out by changing the observation variables, number and location of observation points. The computational conditions in this study is shown in Table 1. Computational model is shown in Figure 2.

Time increment Δt, s	0.001
Time steps	2000
Number of nodes	153
Number of elements	200
Gravitational acceleration g, m/s^2	9.8
Lumping parameter *e*	0.8
Initial of estimated error covariance $P_{(+)}^{0}$	1.0
Initial of estimated value $\hat{\phi}_{(+)}^{0}$	0
Convergence determination constant ε	0.01

Table 1: Computational conditions.

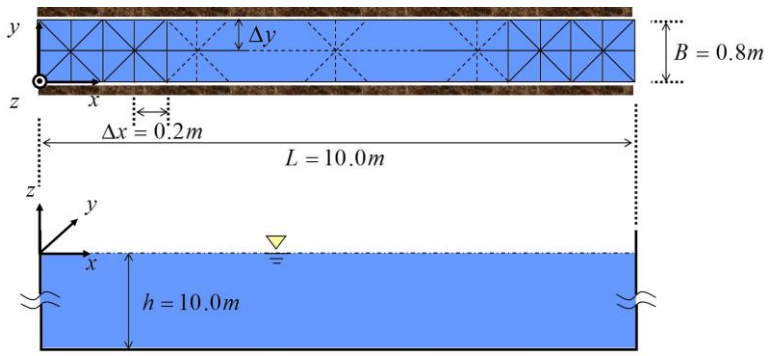

Figure 2: Computational model.

When the water elevation in amplitude 1.0m and period 2.0π s are given for the equation (5), the shallow water flow analysis is carried out. The results by this analysis are used as the artificial observation values. In this computation, the covariance for the system noise and observation noise is set 0.0001 and 0.1, respectively. The system noise covariance matrix $[Q]$ and observation noise covariance matrix $[R]$ are the diagonal matrix that diagonal component are 0.0001 and 0.100. In addition, case 'a' represents that observation variables are flow velocity for *x*-*y* direction u, v and water η and case 'b' of setting that observation variable is η only. These cases are distinguished by subscript 'a' or 'b', number of observation points and position of observation points are shown in Figure 3. Numerical results are shown in Figure 4 - 7.

	Observation variable	Position and number of observation points
Case1	Case 1a : x-y velocities and water elevation		Case 1b : only water elevation	
Case2	Case 2a : x-y velocities and water elevation		Case 2b : only water elevation	
Case3	Case 3a : x-y velocities and water elevation		Case 3b : only water elevation	
Case4	Case 4a : x-y velocities and water elevation		Case 4b : only water elevation	
Case5	Case 5a : x-y velocities and water elevation		Case 5b : only water elevation	

Figure 3: Numerical test conditions.

In Cases 1-4, the observation points are set on center line of the channel, and number and position of the observation points are changed. In Case 5, the observation points are set on one side of the wall boundary.

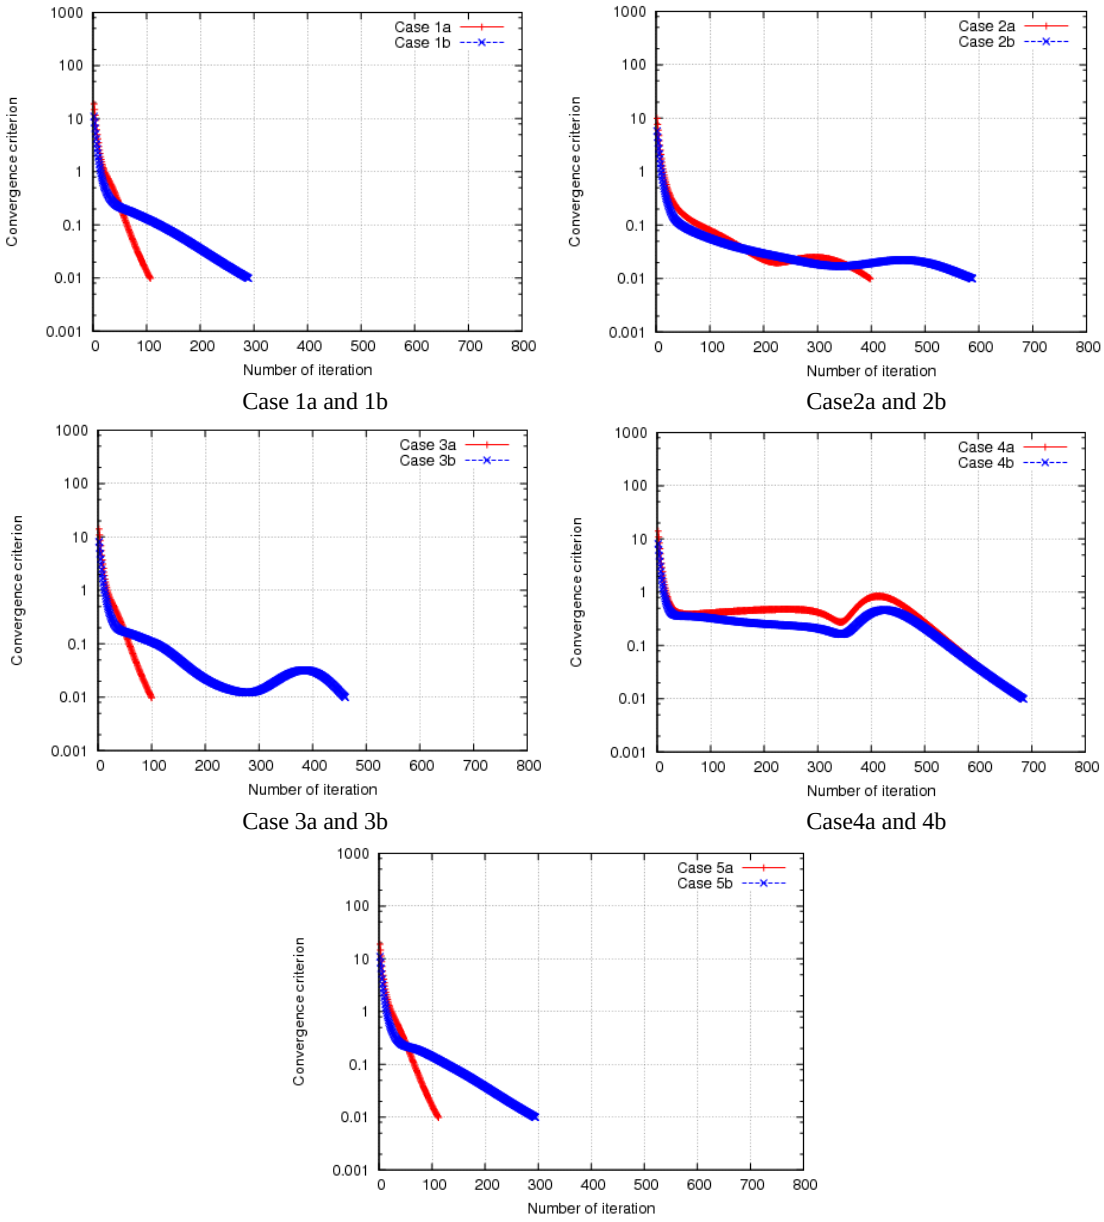

Figure 4: Comparison of variation of convergence criterion.

Figure 4 shows comparison of variation of convergence criterion expressed by the Frobenius norm. The equation of the Frobenius norm is shown in the flow chart of section 3.The convergence criterion ε is set 0.01. This convergence criterion follows to the reference by Heemink [3]. From this result, it was found that convergence rate in Case 'a' is faster than that in Case "b" in the iterative computation of the predicted error covariance matrix.

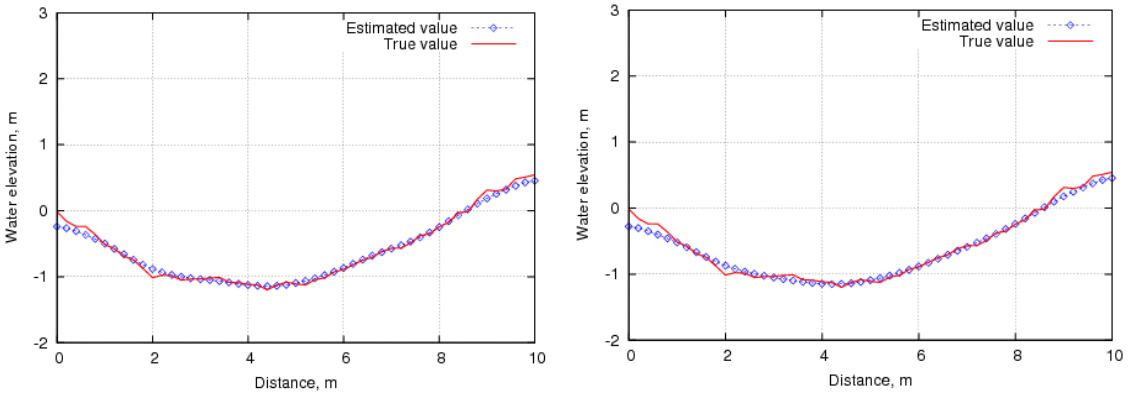
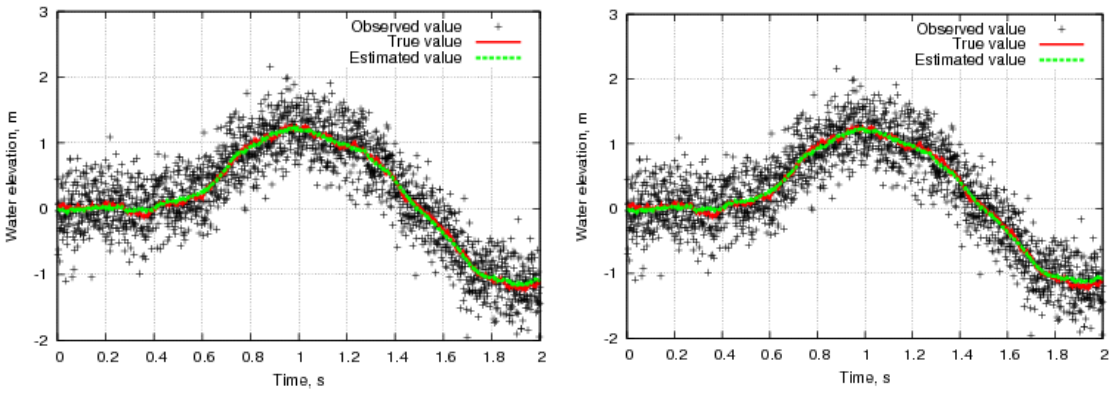
Case 4b



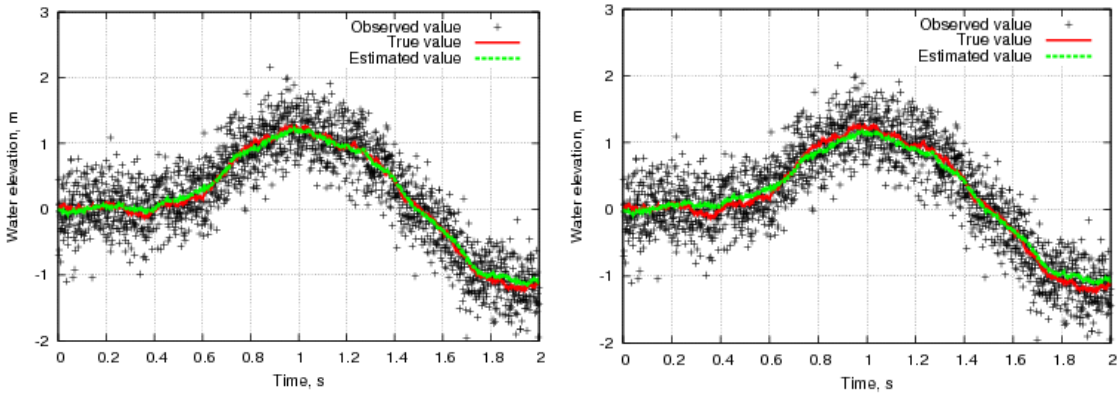
Case 5a Case 5b

Figure 5: Comparison of distribution of estimated water elevation at T =2.0s.

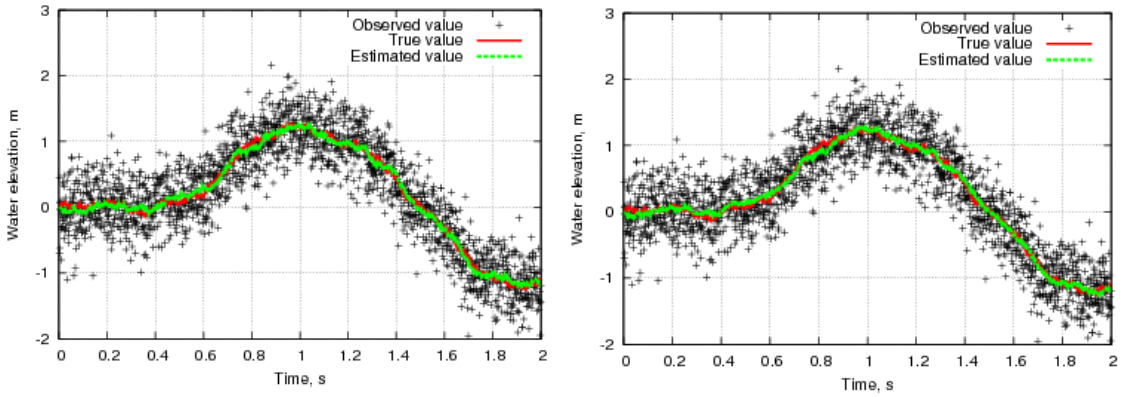
Figure 6 shows the distribution of estimated water elevation of the channel center line at T =2.0s. In Case 1 and Case 2, estimated values are good agreement with the true value. In Case 3, when the observation points are set on the inflow boundary side, the estimated value is good agreement with the true value in the outflow boundary side region, but, In Case 4, when the observation points are set on the outflow boundary side, it was found that it is difficult to estimate the distribution of the water elevation in inflow boundary side region. In Case 5, when the observation points are set on one side of the wall boundary, it was confirmed that the distribution of the water elevation is similar to that in Case 1.



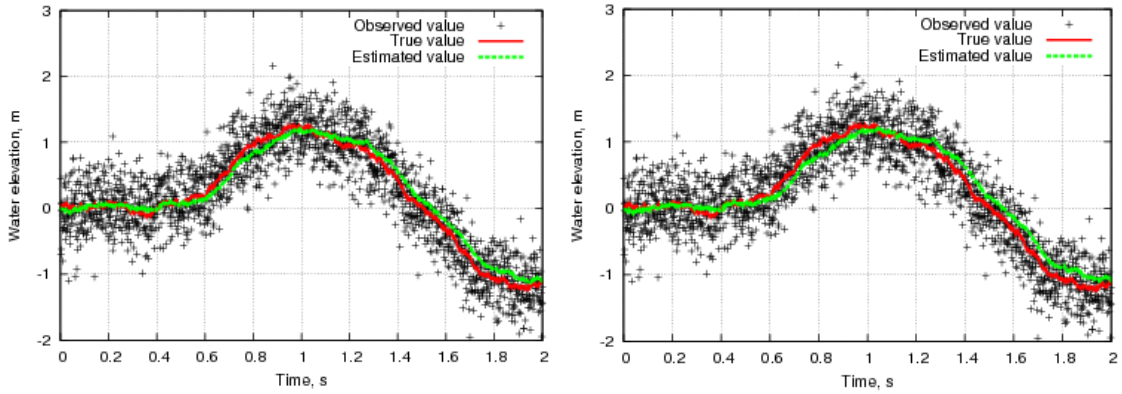
Case 1a Case 1b



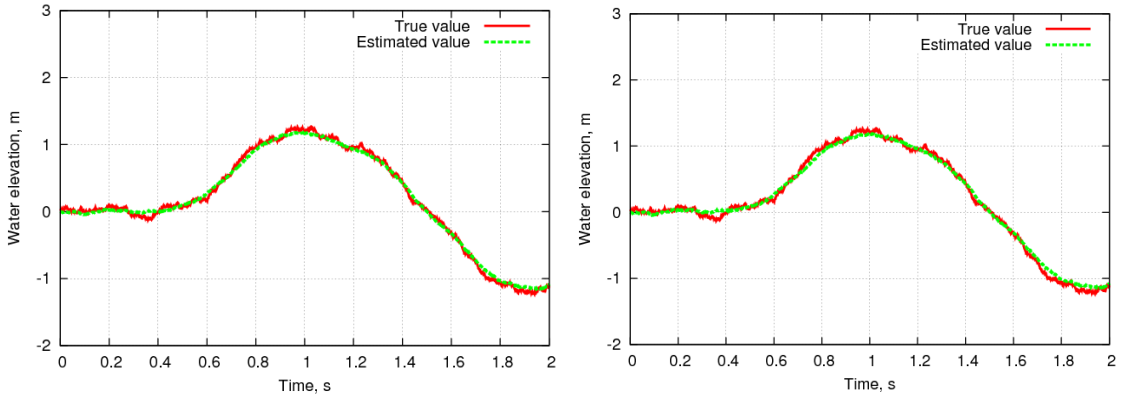
Case 2a Case 2b



Case 3a Case 3b



Case 4a Case 4b



Case 5a Case 5b

Figure 7: Comparison of time history of estimated water elevation at center point of channel (x =5.0m, y =0.4m).

Figure 7 shows time history of estimated water elevation at center point of channel (x =5.0m, y =0.4m). In all cases, observation noise is removed from observed value, and estimated values are good agreement with the true value. Table 2 shows L^2 norm for difference of true and estimated values in Figure 7. In Case 3a and Case 3b, L^2 norm is approximately equivalent. In other cases, the value of L^2 norm in Case 'a' (the flow velocity for x and y directions and the water elevation are set as the observation variable) is less than that in Case 'b' (the water elevation is only set as the observation variable.). Therefore, it can be said that estimated values in Case 'a' are better agreement with the true value than estimated values in Case 'b'.

Case	L^2 norm for difference of true and estimated values
1a	1.899
1b	1.984
2a	2.339
2b	4.050
3a	2.531
3b	2.524
4a	4.161
4b	4.988
5a	2.126
5b	2.206

Table 2: Comparison of L^2 norm for difference of true and estimated values.

5 CONCLUSIONS

In this study, flow field estimation analysis in open channel was carried out based on the Kalman filter FEM. The linear shallow water equation is employed as the governing equation, the Galarkin and the selective lumping methods are used to discretize the governing equation in space and time, respectively. The conclusions in this study is shown as follows.

- It was seen that high accurate flow field estimation result is obtained in case that the observation points are set to the downstream side in the open channel in comparison with the case that the observation points are set to the upstream side in the open channel.
- It was found that if the flow velocities for x and y directions and the water elevation are set as the observation variable in the computation of the flow field estimation, high accurate estimation result is obtained comparing to the case that the water elevation is only set as the observation variable.

APPENDIX

An example of flow field estimation using the practical measurement water elevation is shown in the appendix. The position of observation points and the size of the channel is shown in Figure 8, and the finite element mesh is shown in Figure 9. In addition, Table 3 shows the computational conditions in the flow field estimation. The flow field estimation analysis is carried out using the observed data at only points No.1 and No.2. The comparison of the time history of water elevation in case of the observed and the estimated values at points No.1 – No.3 is shown in Figures 10-12. From this result, it is found that though the flow field estimation can be carried out, there is difference between the observed and the estimated water elevation at point No.3. Therefore, it can be said that there is a possibility that flow distribution can't be appropriately obtained, if a lot of observation points are not employed, and the period of the inflow wave is short. We suppose that this is one of the future work of this study.

Keywords: Stochastic analysis, PDE solutions, Random walk, Itô's theorem.

Abstract. *This paper describes a family of stochastic methods based on Itô's theorem for the numerical solution of Dirichlet, Neumann and mixed boundary value problems. The major advantages of these techniques are:*

- *No mesh is needed. Only the geometry of the domain and the boundary conditions should be defined.*
- *The solution can be obtained at any point or at any part of the integration domain. It is not necessary to solve the whole domain, which can be of special interest in 3D applications.*
- *The error threshold can be controlled mainly with the step width of the random walk generation*
- *The algorithms can be easily parallelized.*
- *The same approach could be used to the numerical solution of stochastic partial differential equations.*

The theoretical approach is described, the corresponding algorithms are presented, and the general technique is applied to well-known engineering PDE equations of the elliptic and parabolic type.

1 INTRODUCTION

From the origin of calculus in the 17th century by Isaac Newton and Gottfried Leibniz partial differential equations have been used to generate mathematical models of natural, economic and social phenomena. In general, these equations cannot be solved by analytical methods and, from the beginning of the 20th century, different approaches generating several discretization approximations have been developed (i.e. Ritz methods [1]). Since then a number of numerical methods, as Finite Differences, Finite Element Method, Boundary Element Method, Finite Calculus Techniques and many others have proved to give accurate results for quite difficult problems, both linear and nonlinear, in one, two and three dimensions.

In general, all these techniques imply some type of domain decomposition or discretization, and the solution of the problem must be obtained in the whole integration domain. As a consequence of the discretization, a set of algebraic equations (linear or nonlinear) must be solved.

A different approach to the solution of PDE's is presented in this paper. Probabilistic methods that have been developed from 1940 [2] may be used to solve both deterministic and stochastic differential equation by means of simulation techniques.

One of these possible techniques, based in Brownian motion particle simulation will be shown to be applied to elliptic and parabolic partial differential equations.

The advantages of this technique are:

- No mesh is needed. Only the geometry of the domain and the boundary conditions should be defined. This implies that the time-consuming discretization process in unnecessary.
- As it is not necessary to get the solution at every point of the domain, no system of equations must be solved.
- The solution can be obtained at any point or at any part of the integration domain. It is not necessary to determine the solution at the whole domain, and therefore there is not system of equations to solve, which can be of special interest in 3D and nonlinear problems.
- The error threshold can be controlled mainly with the step width of the random walk generation
- The algorithms can be easily parallelized.
- The same approach could be used to the numerical solution of stochastic partial differential equations [3].

In this paper the general technique for elliptic and parabolic differential equations will be presented, and will be applied to benchmark problems whose analytical solution is known.

2 PREVIOUS DEFINITIONS

2.1 Wiener processes.

A real stochastic process $\{W_t, t \geq 0\}$ is called a Wiener process if all the following requirements are accomplished:

- $W_0 = 0$
- $W_t - W_s$ is a random normal variable $N(0, t-s)$ for every t and s such that $t > s \geq 0$
- For every set of arguments $0 < t_1 < t_2 < \cdots < t_n$, the set of random variables $W_{t_1}, W_{t_{12}} - W_{t_1}, \ldots . W_{t_n} - W_{t_{-1}}$ are independent.
- W_t has continuous paths for every t > 0.

2.2 Martigales

Consider a sequences of random variables $Z_1, Z_2 \ldots\ldots Z_n$ and the conditional expected value $E[Z_{n+1}|Z_1, Z_2 \ldots\ldots Z_n]$ for each n. The conditional expected value is the mean of Z_{n+1} if all values $Z_1, Z_2 \ldots\ldots Z_n$ are known. If $E[Z_{n+1}|Z_1, Z_2 \ldots\ldots Z_n] = Z_n$ the sequence, $Z_2 \ldots\ldots Z_n$ is a martingale.

The Wiener process is a Markov process as well as a martingale.

2.3 Itô's process

The stochastic process

$$dX = b(X(t), t)dt + \sigma(X(t), t)dB \tag{1}$$

in which dB is a standard Brownian motion (BM), is called an Itô's process and $b(X(t), t)$ and $\sigma(X(t), t)$ are functions both of time and the stochastic process $X(t)$. [4, 5]

2.4 Standard Brownian motion

A standard Brownian motion $B(t)$ is a Wiener process such that:

- $E[B(t)] = 0$
- $\Delta B = B(t + \Delta t) - B(t)$ has a probability distribution $N(0, s^2)$

Therefore $Var(\Delta B) = \Delta t = E(\Delta B^2) - \big(E(\Delta B)\big)^2 = E(\Delta B^2)$ and as the variance of ΔB is small it can be assumed that $\Delta t \approx \Delta B^2$. [6, 7]

2.5 Stochastic ordinary differential equations

An ordinary differential equation is only a rule which determines the change of a dependent variable which is a function of an independent variable expressed in terms of the function and its derivatives.

$$\boldsymbol{\frac{dX}{dt} = a(t, X)} \tag{2}$$

If non deterministic parameters appear in the differential system, the equation becomes a stochastic differential equation

$$\frac{dX}{dt} = a(t, X, Y) \tag{3}$$

where $Y(t)$ represents a stochastic process. It is obvious that in this case $X(t)$ is also a stochastic process and the solution will be the given by the probability distribution of $X(t)$.

2.6 Itô's integral

If one cannot integrate $a(t, X, Y)$ the stochastic ordinary differential equation can be rewritten as

$$\frac{dX}{dt} = b(X, t) + \sigma(X, t)\frac{dB(t)}{dt} \tag{4}$$

where $dB(t)$ is a standard brownian motion. The integral of the above equation is

$$X(t) = X_0 + \int_{t_0}^{t} b\big(s, X(s)\big)\, ds + \int_{t_0}^{t} \sigma\big(s, X(s)\big) dB(t) \tag{5}$$

This second integral $\int_{t_0}^{t} b\big(s, X(s)\big) dB(t)$ cannot be univocally defined, because W(s) variations are unbounded, given that $\sup \sum_{k=1}^{n-1} \left|B_{t_{k+1}} - B_{t_k}\right| = \infty$. The most correct definition

from a mathematical point of view was established by Itô in the forties and was the origin of the so called stochastic analysis [4, 5, 8, 9].

The most important property of Itô's integral is $E\left(\int_0^T GdB\right) = 0$ [10, 11].

2.7 Itô's formula

Let $u = u(t, \bar{x})$ be a continuous function defined over $[t_0, T] \times \mathbb{R}^d$ taking values in $\mathbb{R}^d$ and with continuous partial derivatives. We will use the following notation:

$$\begin{aligned} \frac{\partial}{\partial t}u(t,\bar{x}) &= u_t(t,\bar{x}) \\ \frac{\partial}{\partial x}u(t,\bar{x}) &= u_x(t,\bar{x}) \\ \frac{\partial^2}{\partial x^2}u(t,\bar{x}) &= u_{x^2}(t,\bar{x}) \end{aligned} \tag{6}$$

For $i, j = 1 \ldots . d$ let $\{X, t_0 \leq t \leq \mathrm{T}\}$ be a stochastic process in $\mathbb{R}^d$. This process is defined by the following stochastic differential (Itô's process)

$$dX = b(X(t), t)dt + \sigma(X(t), t)dB \tag{7}$$

where dB is a standard Brownian motion. Then, the process defined by

$$Y(t) = u\big(t, X(t)\big), \forall t \in [t_0, \mathrm{T}] \tag{8}$$

can be differentiated with respect the same Brownian motion

$$\begin{aligned} dY &= u_t(t, X_t)dt + u_x(t, X_t)dX + \frac{1}{2}u_{x^2}(t, X_t)\sigma^2 dt = \\ &= \left(u_t(t, X_t) + u_x(t, X_t)b(X(t), t) + \frac{1}{2}u_{x^2}(t, X_t)\sigma^2\right)dt + u_x(t, X_t)\,\sigma(X(t), t)dB \end{aligned} \tag{9}$$

To prove this result we apply Taylor's expansion to *u*,

$$du = \frac{\partial u}{\partial X}\Delta X + \frac{\partial u}{\partial t}\Delta t + \frac{1}{2}\frac{\partial^2 u}{\partial X^2}\Delta X^2 + \cdots \tag{10}$$

Itô's process can be rewritten as:

$$\begin{aligned} dX &= b(X(t), t)dt + \sigma(X(t), t)\sqrt{dt} \\ (dX)^2 &= (b(X(t), t))^2 dt^2 + (\sigma(X(t), t))^2 dt + 2b(X(t), t)dt\sigma(X(t), t)\sqrt{dt} \\ (dX)^2 &= (\sigma(X(t), t))^2 dt \end{aligned} \tag{11}$$

By replacing dX y $(dX)^2$ in the above Taylor expansion expression

$$\begin{aligned} du &= \frac{\partial u}{\partial X}(b(X(t), t)dt + \sigma(X(t), t)dB) + \frac{\partial u}{\partial t}\Delta t + \frac{1}{2}\frac{\partial^2 u}{\partial X^2}(\sigma(X(t), t))^2 dt \\ du &= \frac{\partial u}{\partial X}\sigma(X(t), t)dB + dt\left(b(X(t), t)\frac{\partial u}{\partial X} + \frac{\partial u}{\partial t} + \frac{1}{2}\frac{\partial^2 u}{\partial X^2}(\sigma(X(t), t))^2\right) \end{aligned} \tag{12}$$

Which is known as Itô's formula.

3 ELLIPTIC PROBLEM GENERAL APPROACH

Let be the following elliptic partial differential equation in one spatial dimension

$$\mathrm{L}u = -f(x) \tag{13}$$

with Dirichlet boundary condition

$$u(x) = g(x)\ si\ x \in \partial D \tag{14}$$

being ∂D the boundary of the integration domain D and L(.)

$$\mathrm{L}(.) = \sum b_i \frac{\partial(.)}{\partial x_i} + \frac{1}{2}\sum\sum \sigma_{ij} \frac{\partial^2}{\partial x_i \partial x_j} \tag{15}$$

that will be applied to a function $u(t, X(t))$. The *du* differential can be written as

$$du = \frac{\partial u}{\partial X}\sigma(X(t), t)dB + dt\left(b(X(t), t)\frac{\partial u}{\partial X} + \frac{\partial u}{\partial t} + \frac{1}{2}\frac{\partial^2 u}{\partial X^2}\big(\sigma(X(t), t)\big)^2\right) \tag{16}$$

As the problem is steady state by definition

$$\frac{\partial u}{\partial t} = 0 \tag{17}$$

and therefore

$$du = \frac{\partial u}{\partial X}\sigma(X(t), t)dB + dt(L(u)) \tag{18}$$

or

$$du = \frac{\partial u}{\partial X}\sigma(X(t), t)dB - \big(f(x)\big)dt \tag{19}$$

This equation can be integrated as

$$\int_0^{\tau_x} du = \int_0^{\tau_x} \frac{\partial u}{\partial X}\sigma(X(t), t)dB - \int_0^{\tau_x} \big(f(x)\big)dt \tag{20}$$

being τ_x the so called stopping time, which is defined as the shortest time in which the stochastic process X reaches the boundary ∂D,

$$\tau_x = \inf\left(\frac{t}{X} \in \partial D\right) \tag{21}$$

and consequently

$$u(X^{\tau_x}) - u(X^0) = \int_0^{\tau_x} \frac{\partial u}{\partial X}\sigma(X(t), t)dB - \int_0^{\tau_x} \big(f(x)\big)dt \tag{22}$$

The expected value of these expressions is

$$E\big(u(X^{\tau_x})\big) - E\big(u(X^0)\big) = E\left(\int_0^{\tau_x} \frac{\partial u}{\partial X}\sigma(X(t), t)dB\right) - E\left(\int_0^{\tau_x} \big(f(x)\big)dt\right) \tag{23}$$

As we have defined the stopping time τ_x as the shortest time in which the stochastic process X reaches the boundary ∂D, if $u(X^0)$ is the value of $u(x)$ to obtain inside the integration domain,

$$E\big(g(X^{\tau_x})\big) - u(x) = E\left(\int_0^{\tau_x} \frac{\partial u}{\partial X}\sigma(X(t), t)dB\right) - E\left(\int_0^{\tau_x} \big(f(x)\big)dt\right) \tag{24}$$

where $g(X^{\tau_x})$ is the boundary condition at the point in which the stochastic process X reaches the boundary ∂D. Remember that dB is a martingale and one of its properties is $E\left(\int_0^T GdB\right) = 0$.

Therefore

$$E\big(g(X^{\tau_x})\big) - u(x) = 0 - E\left(\int_0^{\tau_x} \big(f(x)\big)dt\right) \tag{25}$$

and the Itô's formula becomes

$$u(x) = E\big(g(X^{\tau_x})\big) + E\left(\int_0^{\tau_x} (f(x))dt\right) \tag{26}$$

3.1 Problem solution in several variables

In the case of more than one variable the elliptic problem can be stated as

$$\begin{gathered} \mathrm{L}u = -f(\bar{x}) \\ u(\bar{x}) = g(\bar{x})\ si\ \bar{x} \in \partial D \\ \mathrm{L}(.) = \sum b_i \frac{\partial(.)}{\partial x_i} + \frac{1}{2}\sum\sum \sigma_{ij} \frac{\partial^2}{\partial x_i \partial x_j} \end{gathered} \tag{27}$$

The corresponding stochastic process could be written as

$$d\bar{X} = \bar{b}(\bar{x}))dt + \bar{\bar{Z}}(\bar{x}))d\bar{B} \tag{28}$$

where b_i are the components of vector $\bar{b}(\bar{x}))$.

The matrix $\bar{\bar{Z}}(x)$ is defined as follows [12]

$$\bar{\bar{C}} = \bar{\bar{Z}} * \bar{\bar{Z}}^T \tag{29}$$

where σ_{ij} are the components of the $\bar{\bar{C}}$ matrix. This matrix $\bar{\bar{Z}}$ can be easily determined if $\bar{\bar{C}}$ is symmetric, by using, for example, the Cholesky factorization technique.

The b_i and σ_{ij} components are the parameters of the differential operator $\mathrm{L}(.)$.

3.2 Problems with Neumann boundary conditions

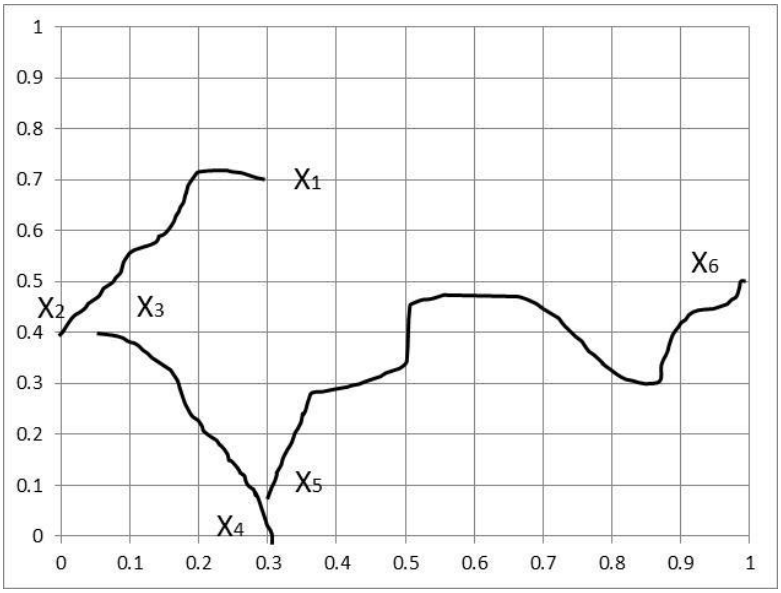

Figure 1 Particle random walk

It must be noted that every particle follows a random walk determined by the Itô's stochastic process (Figure 1).

But in this case there are some Neumann boundary conditions. We describe now the procedure to take into account these boundaries. [13].

In a general case with Neumann boundary conditions and at least a Dirichlet boundary condition the procedure will be as follows:

$$\begin{gathered} \mathrm{L}u = -f(\bar{x}) \\ u(\bar{x}) = g(\bar{x})\ si\ \bar{x} \in \partial D_d \\ \frac{\partial\big(u(\bar{x})\big)}{\partial n} = c(\bar{x})\ si\ \bar{x} \in \partial D_n \end{gathered} \tag{30}$$

where ∂D_d are the boundaries in which Dirichlet conditions hold and $\partial \mathrm{D_n}$ the boundaries in which Neumann conditions are defined.

One should determine X_1 when the particle reaches a Neumann boundary before getting to a Dirichlet boundary.

$$u(X_5) = E\big(g(X^{\tau_x})\big) + E\left(\int_0^{\tau_x}(f(x))dt\right) = E\big(g(X_6)\big) + E\left(\int_{\tau_{X_5}}^{\tau_{X_6}}(f(x))dt\right) \tag{31}$$

The integration limits $[\tau_{X_5}, \tau_{X_6}]$ correspond to the time the particle takes to move from X_5 to X_6

If the coordinates X_4 correspond to a point located in a boundary with Neumann condition, the value $u(X_4)$ may be determined by Taylor expansion as

$$u(X_4) = u(X_5) - \frac{\partial u}{\partial y}(X_4)h_y = u\ (X_5) - c(X_4)h_y \tag{32}$$

In this way, the Neumann condition in X_4 is transformed to a Dirichlet condition and therefore:

$$\begin{gathered} u(X_3) = E\big(g(X^{\tau_x})\big) + E\left(\int_0^{\tau_x}\big(f(x)\big)dt\right) = E\big(u(X_4)\big) + E\left(\int_{\tau_{X_4}}^{\tau_{X_5}}\big(f(x)\big)dt\right) = \\ = E\big(u(X_5)\big) - E\big(c(X_4)h_y\big) + E\left(\int_{\tau_{X_4}}^{\tau_{X_5}}\big(f(x)\big)dt\right) = \\ = E\big(g(X_6)\big) + E\left(\int_{\tau_{X_3}}^{\tau_{X_4}}\big(f(x)\big)dt\right) + E\left(\int_{\tau_{X_5}}^{\tau_{X_6}}(f(x))dt\right) - E\big(c(X_4)h_y\big) \end{gathered} \tag{33}$$

If this procedure is repeated with X_2 the solution at point X_1can be written

$$\begin{gathered} u(X_1) = E\big(g(X^{\tau_x})\big) + E\left(\int_0^{\tau_x}(f(x))dt\right) = E\big(u(X_2)\big) + E\left(\int_{\tau_{X_1}}^{\tau_{X_2}}(f(x))dt\right) = \\ = E\big(u(X_3)\big) - E(c(X_3)h_x) + E\left(\int_{\tau_{X_1}}^{\tau_{X_2}}(f(x))dt\right) = \\ = E\big(g(X_6)\big) + E\left(\int_{\tau_{X_1}}^{\tau_{X_2}}(f(x))dt\right) + E\left(\int_{\tau_{X_3}}^{\tau_{X_4}}\big(f(x)\big)dt\right) \\ +E\left(\int_{\tau_{X_5}}^{\tau_{X_6}}(f(x))dt\right) - E\big(c(X_4)h_y\big)\ - E(c(X_3)h_x) \end{gathered} \tag{34}$$

In a general case Itô's formula can be written as

$$u(\bar{x}) = E\big(g(X^{\tau_x})\big) + E\left(\int_0^{\tau_x}(f(x))dt\right) + E\left(-\sum_i \frac{\partial u}{\partial n}(X_i)h_n\right) \tag{35}$$

where

$E\big(g(X^{\tau_x})\big)$ is the contribution of Dirichlet boundary conditions

$E\big(\int_0^{\tau_x}(f(x))dt\big)$ is the contribution of the input function

$E\left(-\sum_i \frac{\partial u}{\partial n}(X_i)h_n\right)$ is the contribution of Neumann boundary conditions

In these expressions X_i are the points where the particle reaches a Dirichlet boundary and h_n is a small value such that Taylor's expansions are accurate enough.

It is clear that for a unique simulation Neumann boundaries can be reached several times.

To explain more clearly the general technique we propose the following academic example.

$$\frac{\partial^2 u}{\partial x^2} + 3\frac{\partial^2 u}{\partial y^2} = -16 \tag{36}$$

with a rectangular boundary $D = (0,1)x(0,1)$ and mixed boundary conditions.

$$\begin{aligned} &\frac{\partial u}{\partial x} = \beta(y) \quad x = 0 \\ &u = 0 \qquad\quad x = 1 \\ &\\ &\frac{\partial u}{\partial y} = \alpha(x) \quad y = 0 \\ &u = \gamma(x) \qquad y = 1 \end{aligned} \tag{37}$$

Itô's process is in this case:

$$d\bar{X} = \bar{b}(x)dt + \bar{\bar{Z}}(x)d\bar{B} \tag{38}$$

with $b_i = 0,\ \sigma_{11} = 2,\ \sigma_{12} = 0,\ \sigma_{21} = 0,\ \sigma_{22} = 6.$:

To determine the $\bar{\bar{Z}}$ matrix we use $\bar{\bar{C}} = \bar{\bar{Z}} * \bar{\bar{Z}}^T$, this is to say

$$\begin{pmatrix} 2 & 0 \\ 0 & 6 \end{pmatrix} = \begin{pmatrix} z_{11} & z_{12} \\ z_{21} & z_{22} \end{pmatrix}\begin{pmatrix} z_{11} & z_{12} \\ z_{21} & z_{22} \end{pmatrix}^T \tag{39}$$

and therefore

$$\bar{\bar{Z}} = \begin{pmatrix} \sqrt{2} & 0 \\ 0 & \sqrt{6} \end{pmatrix} \tag{40}$$

If we apply now Itô`s formula, the solution at point (x, y) is

$$u(\bar{x}) = E\big(g(X^{\tau_x})\big) + E\left(\int_0^{\tau_x}(f(x))dt\right) \tag{41}$$

In this example:

$$\begin{aligned} u(\bar{x}) = E\big(g(X^{\tau_x})\big) + E\left(\int_0^{\tau_x} 16\, dt\right) = E\big(g(X^{\tau_x})\big) + 16E\left(\int_0^{\tau_x} dt\right) = \\ = E\big(g(X^{\tau_x})\big) + 16E\,(T_x) \end{aligned} \tag{42}$$

where:

- $E\left(g(X^{\tau_x})\right)$ is the expected value of the particles positions when they reach for the first time a Dirichlet boundary condition.
- $E\ (T_x)$ is the expected value of the time the particles take to reach for the first time a Dirichlet boundary condition. In other words, the expected value of the particles stopping times.

Let a particle initially at position X_1 (see Figure 1). After a random walk as previously described the particle reaches the boundary at X_2 where a Neumann condition holds. Then the particle is reflected to X_3, and the process will be restarted at point $X_3 = X_2 + (h_x, 0)$. After the corresponding walk, the particle reaches the boundary at X_4 where again a Neumann condition holds. The particle is then reflected to $X_5 = X_4 + (0, h_y)$ and the process continues until the particle reaches a point in which a Dirichlet boundary condition holds (X_6). Then the process stops.

Let:

T_1 the time it takes the particle to go from X_1 to X_2
T_2 the time it takes the particle to go from X_3 to X_4
T_3 the time it takes the particle to go from X_5 to X_6

By using Itô's formula, the contribution of this particle to the solution is

$$u(X_1) = g(X_2) + 16(T_1) = u(X_2) + 16(T_1) \tag{43}$$

In this expression $u(X_2)$ can be expanded as $u(X_2) = u(X_3) - \frac{\partial u}{\partial x}(X_2)h_x$ and therefore

$$u = u(X_2) + 16(T_1) = u(X_3) - \frac{\partial u}{\partial x}(X_2)h_x + 16(T_1) \tag{44}$$

but

$$u(X_3) = g(X_4) + 16(T_2) = u(X_4) + 16(T_2) \tag{45}$$

and again

$$u(X_4) = u(X_5) - \frac{\partial u}{\partial y}(X_4)h_y \tag{46}$$

and the above expression (44) becomes

$$u = u(X_3) - \frac{\partial u}{\partial x}(X_2)h_x + 16(T_1) = u(X_5) - \frac{\partial u}{\partial y}(X_4)h_y - \frac{\partial u}{\partial x}(X_2)h_x + 16(T_1 + T_2) \tag{47}$$

Finally, as X_6 is a point in which a Dirichlet condition is stablished

$$u(X_5) = g(X_6) + 16(T_3) = 0 + 16(T_3) \tag{48}$$

and the contribution of this particles to the final solution is

$$u = 0 - \frac{\partial u}{\partial y}(X_4)h_y - \frac{\partial u}{\partial x}(X_2)h_x + 16(T_1 + T_2 + T_3) \tag{49}$$

3.3 Simulation procedures

The partial differential equation to solve is:

$$\mathrm{L}u = -f(x) \tag{50}$$

with the following boundary conditions:

$$u(x) = g(x)\ si\ x \in \partial D_d$$
$$\frac{\partial u(x)}{\partial n} = t(x)\ si\ x \in \partial D_n \tag{51}$$

with $\partial D_d \cup \partial D_n = \partial D$ and $D_d \cap \partial D_n = \emptyset$, being ∂D the boundary of the integration domain D and

$$\mathrm{L}(.) = \sum b_i \frac{\partial(.)}{\partial x_i} + \frac{1}{2}\sum\sum \sigma_{ij} \frac{\partial^2(.)}{\partial x_i \partial x_j} \tag{52}$$

As previously stated the solution is

$$u(\bar{x}) = E\big(g(X^{\tau_x})\big) + E\Big(\int_0^{\tau_x}(f(x))dt\Big) + E\left(-\sum_i \frac{\partial u}{\partial n}(X_i)h_n\right) \tag{53}$$

Then the simulation procedure is as follows:

3.3.1 Determine the Ito's process b_i y σ_{ij} coefficients:

$$d\bar{X} = \bar{b}(x)dt + \bar{\bar{Z}}(x)d\bar{B}$$
$$\begin{pmatrix} dx_1 \\ \vdots \\ dx_n \end{pmatrix} = \begin{pmatrix} b_1 \\ \vdots \\ b_n \end{pmatrix} dt + \begin{pmatrix} Z_{11} & \dots & Z_{1n} \\ \vdots & \ddots & \vdots \\ Z_{n1} & \dots & Z_{nn} \end{pmatrix} \begin{pmatrix} dB_1 \\ \vdots \\ dB_n \end{pmatrix} \tag{54}$$

$\bar{\bar{Z}}(x)$ is defined as the matrix calculated from the equation

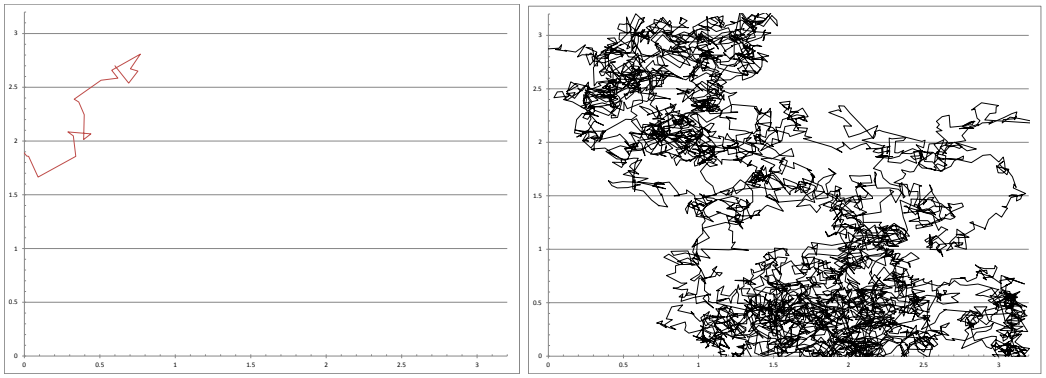
$$\bar{\bar{C}} = \bar{\bar{Z}} * \bar{\bar{Z}}^T \tag{55}$$

where the parameters σ_{ij} are the elements of the $\bar{\bar{C}}$ matrix and the parameters b_i are the elements of the $\bar{b}(x)$ vector.

3.3.2 Set the s and h values, where s^2 is the variance of the Brownian motion process and h the increment to use in the Taylor series expansions.

The Brownian motion variance will determine the length of every leap of a particle for every time step.

The following figures show some examples of a Brownian motion process going on from the same point (x=0.6, y=2.7) with Dirichlet boundary condition at x=0 and Neumann condition at the reflecting border (Figures 2 and 3).



Standard deviation 0.1 Standard deviation 0.05

Figure 2. Examples of paths for different values of the BM standard deviation

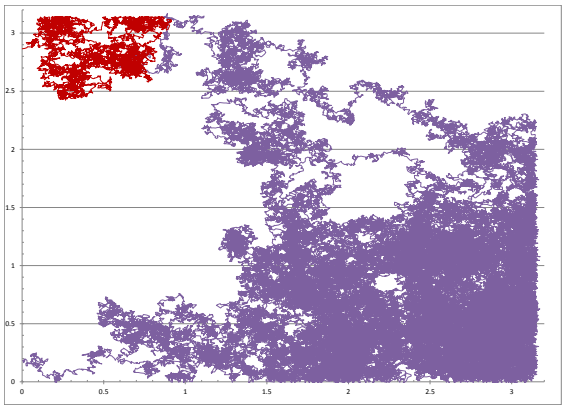


Figure 3. Two BM examples starting from the same point with the same standard deviation 0,01

A high value of the variance s^2 means a faster simulation process but it is generally less exact if the boundaries lie near the particle.

The h value has to be small enough to fulfill the Taylor expansion conditions but large enough to guarantee that the particle is always inside the domain of integration. In this paper a value of h five times the standard deviation of the Brownian motion process has been used, this is to say

$$h = 5\sqrt{\Delta t} = 5s$$

3.3.3 Obtain the solution in $\bar{x}$.

To obtain the problem solution we must calculate

$$u(\bar{x}) = E\big(g(X^{\tau_x})\big) + E\left(\int_0^{\tau_x}(f(x))dt\right) + E\left(-\sum_i \frac{\partial u}{\partial n}(X_i)h_n\right) \tag{56}$$

A possibility is to use Montecarlo method: we select a large number of particles for each point in which the solution must be evaluated.

From $\bar{x}$, every one of these particles performs, for each Δt, a random step defined by Itô's process, namely

$$d\bar{X} = \bar{b}(x)dt + \bar{\bar{Z}}(x)d\bar{B} \tag{57}$$

where dB is a standard Brownian motion with Gaussian distribution $N(0, s^2)$

Remember that the time spent for each particle to reach a boundary in which a Dirichlet condition holds, τ_x, is called stopping time.

The contribution of a particle to the solution is

$$u_j = \frac{\big(g(X^{\tau_x})\big) + \left(\int_0^{\tau_x}(f(x))dt\right) + \left(-\sum_i \frac{\partial u}{\partial n}(X_i)h_n\right)}{N} \tag{58}$$

where i is the number of times the particle reaches a boundary with Neumann condition, N the number of particles used in the simulation and τ_x the time spent for each particle to reach a boundary in which a Dirichlet condition holds (the so called stopping time). In equation (58):

- $g(X^{\tau_x})$ is the contribution of Dirichlet type boundary conditions. It is evaluated as the value of the boundary condition at the point first reached by the particle.
- $\int_0^{\tau_x}(f(x))dt$ is the contribution of the input function at the solution and must be evaluated until the stopping time.

- $-\sum_i \frac{\partial u}{\partial n}(X_i)h_n$ is the contribution of Neumann type boundary conditions. A particle may reach a Neumann type condition never, once or more times before reaching a point in which a Dirichlet boundary condition holds.

The final solution estimation is:

$$u = \sum_{j=1}^{N} u_j \tag{59}$$

3.4 Two dimensional examples

3.4.1 Let Ω be the unit circle defined as $x^2 + y^2 \leq 1$ in Cartesian coordinates. We state the following differential operator.

$$\Delta U = 0 \tag{60}$$

with boundary conditions

$$\begin{gathered} U(r,0) = U(r,2\pi) = 0 \\ U(1,\theta) = \sin\left(\frac{\theta}{2}\right), \;\; 0 < \theta < 2\pi \end{gathered} \tag{61}$$

The analytical solution of this problem is $U = sin\left(\frac{\theta}{2}\right)\sqrt{r}$ (See Figure 4)

The Itô's process governing the particles motion is

$$d\bar{X} = \bar{b}(x)dt + \bar{\bar{Z}}(x)d\bar{B} \tag{62}$$

In this case $b_i = 0$, $\sigma_{i,j} = 1 \;\; \forall \; i = j$ and $\sigma_{i,j} = 0 \; \forall \;\; i \neq j$. Therefore, as $\bar{\bar{C}} = \bar{\bar{Z}} * \bar{\bar{Z}}^T$ and $\bar{\bar{C}} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$, it results that $\bar{\bar{Z}} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$.

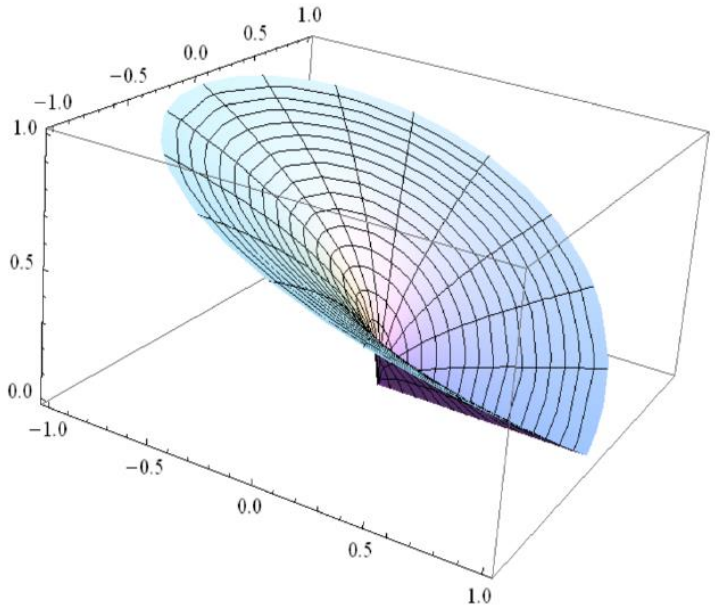

Figure 4. Analytical solution of the problem stated in section 3.4.1

It follows that $dx_1 = dB_1$ and $dx_2 = dB_2$

The numerical solution is:

$$u(\bar{x}) = E\big(g(X^{\tau_x})\big) + E\Big(\int_0^{\tau_x}(f(x))dt\Big) \tag{63}$$

because in this example there are not Neumann boundary conditions. In this case $f(x) = 0$, and therefore

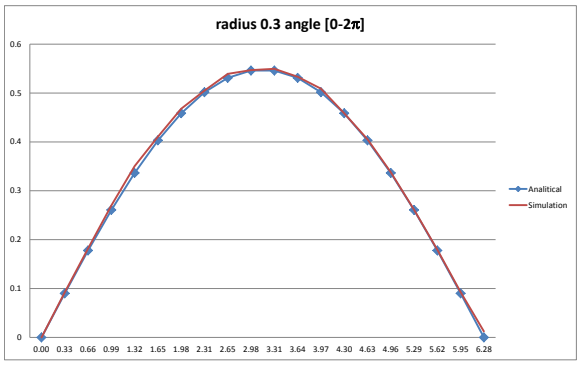
$$u(\bar{x}) = E\big(g(X^{\tau_x})\big) \tag{64}$$

where τ_x is the stopping time of each particle.

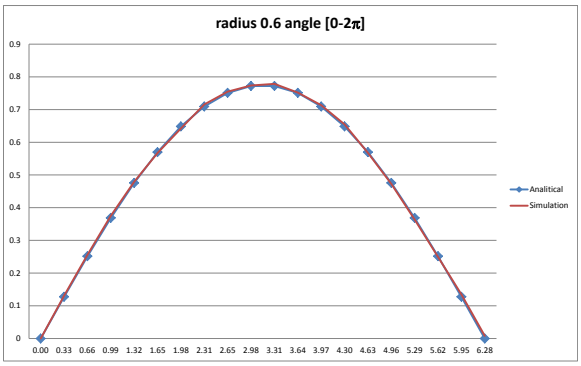
Figure 5 shows the comparison between the exact (analytical) solution and the simulation for different points of the integration domain.

For radii in the [0.3 al 0.9] interval 5.000 particles have been generated with a process standard deviation of 0.01.

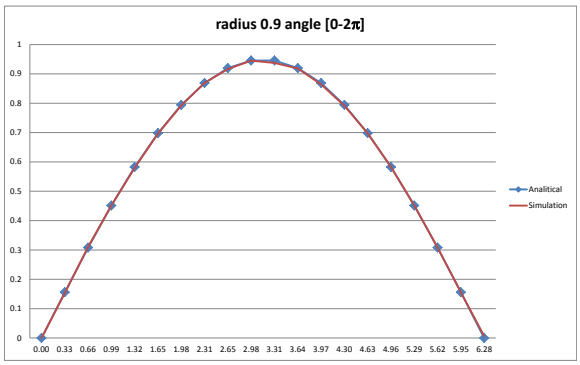
For 0.2 and 0.1 radii 15.000 particles have been generated with a process standard deviation of 0.001.



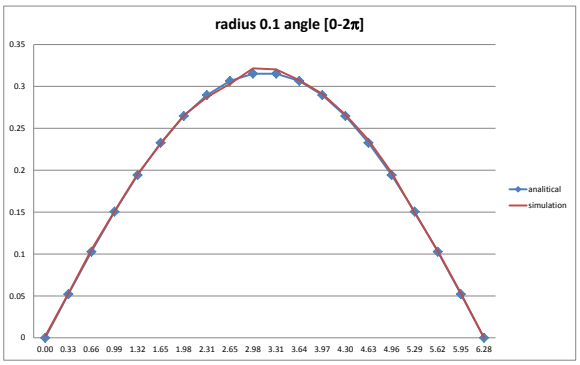
a) r = 0.3, θ in [0,2π]



b) r = 0.6, θ in [0,2π]



a) r = 0.9, θ in [0,2π]



b) r = 0.1, θ in [0,2π]

Figure 5. Simulation vs. analytical solutions of problem 3.4.1 for different domain points

3.4.2 Consider the following problem, in which both Dirichlet and Neumann boundary conditions are defined:

$$\Delta U = 0, \quad 0 \le X \le \pi \quad 0 \le Y \le \pi \tag{65}$$

with boundary conditions

$$u(x=0,y) = -\frac{1}{\tanh(\pi)}[\cosh(y) - \tanh(\pi)\, senh(y)]$$
$$\left.\frac{\partial u}{\partial x}\right|_{(\pi,y)} = 0; \quad 0 \le y \le \pi$$
$$\left.\frac{\partial u}{\partial y}\right|_{(x,0)} = cos(x) \tag{66}$$
$$\left.\frac{\partial u}{\partial y}\right|_{(x,\pi)} = 0 \quad 0 \le x \le \pi$$

The analytical solution, shown in Figure 6, is:

$$\mathrm{u(x,y)} = -\frac{1}{\tanh(\pi)}[\cosh(y) - \tanh(\pi)\, senh(y)]\cos(x) \tag{67}$$

The Itô's process governing the particles motion is

$$d\bar{X} = \bar{b}(x)dt + \bar{\bar{Z}}(x)d\bar{B} \tag{68}$$

Therefore $dx_1 = dB_1$ and $dx_2 = dB_2$

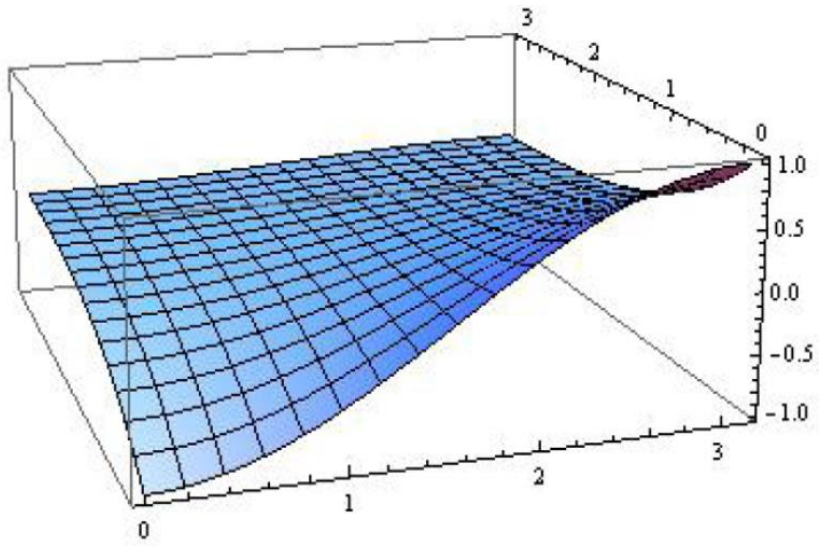


Figure 6. Analytical solution of problem stated in section 3.4.2

The simulation solution is

$$u(\bar{x}) = E\big(g(X^{\tau_x})\big) + E\left(\int_0^{\tau_x}(f(x))dt\right) + E\left(-\sum_i \frac{\partial u}{\partial n}(X_i)h_n\right) \tag{69}$$

because in this case $f(x) = 0$

15.000 particles have been generated for each point, the h value is 0.05 and the standard deviation of the Brownian motion is 0.01.

Figure 5 shows the comparison between the exact (analytical) solution and the simulation for different points of the integration domain.

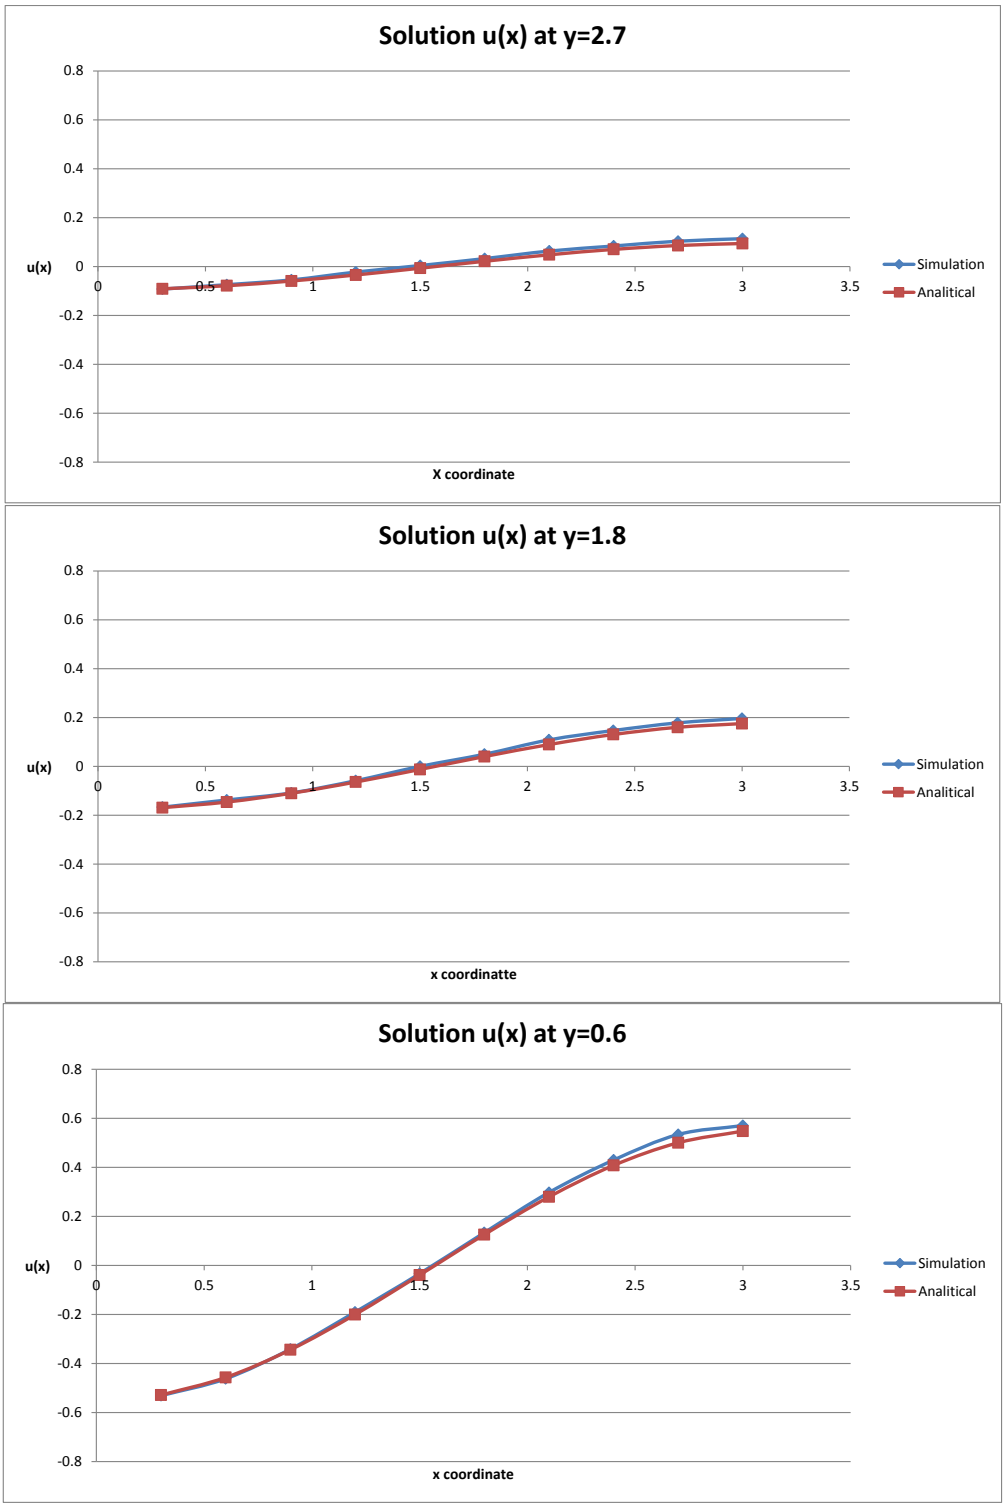

Figure 7. Simulation vs. analytical solutions of problem 3.4.2 for different domain points

4 PARABOLIC PROBLEM GENERAL APPROACH

Consider the following partial differential equation:

$$\mathrm{L}(u) = -f(\bar{x}, t) \tag{70}$$

with boundary and initial conditions:

$$u(\bar{x},t) = g(\bar{x},t)\ si\ \bar{x} \in \partial D_d$$

$$\frac{\partial u(\bar{x},t)}{\partial n} = c(\bar{x},t)\ if\ \bar{x} \in \partial D_n \tag{71}$$

$$u(\bar{x}) = l(\bar{x})\ if\ t = 0$$

with $t > 0$, $\bar{x} \in D$, $\partial D_d \cup \partial D_n = \partial D$ and $D_d \cap \partial D_n = \emptyset$, being ∂D the boundary of the integration domain D. The L(.) operator can be written as

$$\mathrm{L}(.) = -\frac{\partial(.)}{\partial t} + \sum b_i \frac{\partial(.)}{\partial x_i} + \frac{1}{2}\sum\sum \sigma_{ij} \frac{\partial^2}{\partial x_i \partial x_j} \tag{72}$$

where the time *t* may be considered as a new coordinate in the process.

In the n-dimensional case

$$d\bar{X} = \bar{b}(x)dt + \bar{\bar{Z}}(x)d\bar{B} \tag{73}$$

that can also be written as

$$\begin{pmatrix} dx_0 \\ dx_1 \\ \vdots \\ dx_n \end{pmatrix} = \begin{pmatrix} -1 \\ b_1 \\ \vdots \\ b_n \end{pmatrix} dt + \begin{pmatrix} 0 & \cdots & 0 \\ Z_{11} & \cdots & Z_{1n} \\ \vdots & \ddots & \vdots \\ Z_{n1} & \cdots & Z_{nn} \end{pmatrix} \begin{pmatrix} dB_0 \\ dB_1 \\ \vdots \\ dB_n \end{pmatrix} \tag{74}$$

where x_0 is the time coordinate and $x_{i,}$ $i \in (0,n)$ the spatial coordinates.

At every time interval dt, the particle moves randomly in the space (x_i) and goes back a fixed time increment dt.

If the particle reaches a Neumann boundary condition, the particle bounces back and continues the random motion inside the integration domain.

The initial condition $\mathrm{u}(\bar{\mathrm{x}}) = \mathrm{l}(\bar{\mathrm{x}})$ if $\mathrm{t} = 0$ is, in this process, considered as a Dirichlet boundary condition.

The particle random motion may stop because:

- Particle reaches a Dirichlet boundary in the space (x_i)
- Particle reaches time t=0, because, as it was stated before, this initial condition works as a Dirichlet Condition for this simulation process.

4.1 Two dimensional parabolic example

To explain more clearly the general technique we propose the following academic example:

The PDE to solve is:

$$\frac{\partial \mathrm{u}}{\partial \mathrm{t}} = \left(\frac{\partial^2 \mathrm{u}}{\partial \mathrm{x}^2} + \frac{\partial^2 \mathrm{u}}{\partial \mathrm{y}^2}\right) \tag{75}$$

with integration domain $0 \le x \le 2$,$0 \le y \le 4$,$t \ge 0$ (see Figure 8) and boundary conditions

$$\frac{\partial u(x=0,y,t)}{\partial x} = 0, \qquad u(x,y=0,t) = 0$$
$$\frac{\partial u(x=2,y,t)}{\partial x} = 0, \quad u(x,y=4,t) = 0 \tag{76}$$

and the inital condition

$$u(x, y, t = 0) = 7 \tag{77}$$

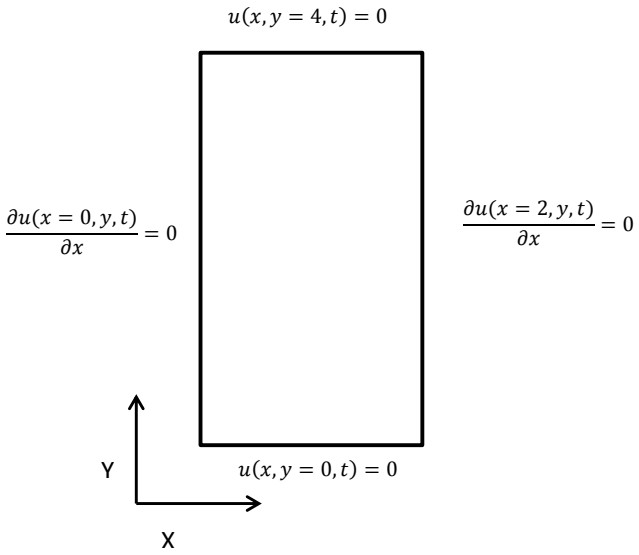

Figure 8. Integration domain for the problem presented in section 4.1

The analytical solution for this problem is:

$$u(x, y, t) = \frac{14}{\pi} \sum_{n=1}^{\infty} (1 - \cos(n\pi)) \left(\frac{1}{n}\right) e^{\left(\frac{-t\pi^2 n^2}{16}\right)} \sin\left(\frac{n\pi y}{4}\right) \tag{78}$$

The stochastic process approach is

$$\begin{gathered} \left(\frac{\partial^2 \mathrm{u}}{\partial \mathrm{x}^2} + \frac{\partial^2 \mathrm{u}}{\partial \mathrm{y}^2}\right) - \frac{\partial \mathrm{u}}{\partial \mathrm{t}} = 0 \\ L(.)u(x)) - f(x) \\ f(x) = 0 \\ L(.) = \sum_i b_i \frac{\partial .}{\partial x_i} + \frac{1}{2} \sum_{ij} \sigma_{ij} \frac{\partial^2}{\partial x_i \partial x_j} \end{gathered} \tag{79}$$

In this case $i = 0, 1, 2$ y $j = 0, 1, 2$.
The Itô process can be written as

$$d\bar{X} = \bar{b}(x)dt + \bar{\bar{Z}}(x)d\bar{B} \tag{80}$$

or

$$\begin{pmatrix} dx_0 \\ dx_1 \\ dx_2 \end{pmatrix} = \begin{pmatrix} -1 \\ 0 \\ 0 \end{pmatrix} dt + \begin{pmatrix} 0 & 0 & 0 \\ 0 & \sqrt{2} & 0 \\ 0 & 0 & \sqrt{2} \end{pmatrix} \begin{pmatrix} dB_0 \\ dB_1 \\ dB_2 \end{pmatrix} \tag{81}$$

with $dB = N(0, dt)$.

The estimate of the solution is

$$u(\bar{x}) = E\big(g(X^{\tau_x})\big) + E\left(\int_0^{\tau_x} (f(x))dt\right) + E\left(-\sum_i \frac{\partial u}{\partial n}(X_i)h_n\right) \tag{82}$$

The second and third addends are null because $f(x) = 0$ and all Neumann boundary conditions are also null.

Then

$$u(\bar{x}) = E\big(g(X^{\tau_x})\big) \tag{83}$$

where τ_x is the already defined stopping time.

Suppose we want to calculate the problem solution at a point with coordinates (x, y, t). As always, the simulation solution is to generate a number of particles at this point and apply the above described technique..

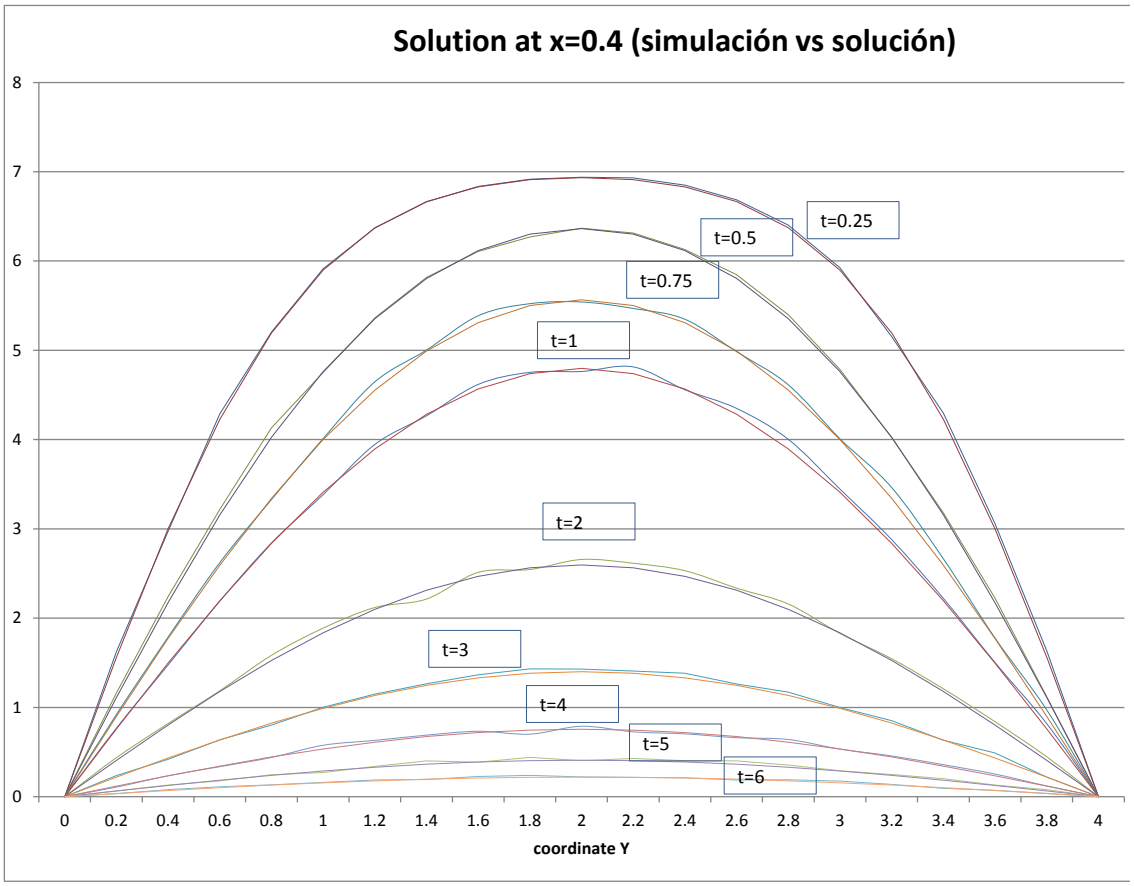

Figure 9. Solution of the problem proposed in section 4.1

5 CONCLUSIONS

A simulation stochastic method to solve partial differential equations (of elliptic and parabolic type) has been presented. The analysis of the specific boundary and (in the parabolic type) initial conditions has been carried out. A number of academic examples, with known analytical solutions, have been used as benchmarks, and the simulation solution has agreed very well with the exact solutions in all cases.

The main advantages of this technique are:

- No domain discretization is necessary.

- No need for a solver, because there are not systems of equations in the solution process
- It is not necessary to solve the PDE in the whole integration domain. The solution can be obtained only where it is needed (a point, several points, a particular area of the domain).
- In parabolic problems, to obtain the solution at time T_f it is not necessary to obtain it at intermediate times $(T_0; T_f)$.
- The approximation error is a function of the number of particles generated in the simulation, and decreases as the number of particles increases. This is so because the solution is an expected value, and because of the central limit theorem the variance will decrease as the number of elements (particles) increases.
- The speed of the process increases as the variance of the stochastic process (Itô's process) increases. However, near the boundaries, the variance should be kept small enough as the walk does not go outside the domain
- As the solution estimate is an expected value, parallel methods may be applied in a very easy way. For instance, the same accuracy will be obtained with a CPU generating a 10.000 particles simulation as with 100 CPU's generating a 100 particles simulation each. As the only process that can be considered time consuming is the particles generation and the corresponding random walk, the process time can be directly divided by the number of CPU's in the cluster.

Keywords: Bootstrap, Statistical Significance, Fixed Effects Model, ANOVA, Materials Science, Surface Layers, Nanoparticles.

Abstract. Since R.A. Fisher introduced the analysis of variance (ANOVA), the classic design of experiments (DoE) utilizes factorial model of fixed effects. The typical procedure assumes the normal distribution of the noise and uses the least square method (LSQ) to identify effects of the model with a priori assumed structure of main effects and some interactions, usually up to the second order. The terms of model are repeatedly eliminated in the specific backward stepwise regression.

Methods of approximation and prediction rapidly evolved in recent years. Apart from this, the classic approach of the fixed effects model is still very useful and popular. In fact, this model is intrinsic to ANOVA however hidden. The significance analytical improvements have appeared in the background of fixed effects models in recent decades: statistics based on widespread strict requirements of the normal distribution have been replaced by so-called robust statistics based on the weak requirement of the continuous distribution or even on the statistics based on numerical simulation like e.g. bootstrap approach. Practically, in the case of small size datasets, the conformity with the normal distribution has very weak reliability and it leads to very uncertain assessment of parameters statistical significance. The bootstrap approach with simulation-based identification of parameters confidence intervals (CI) appears to be better solution than theoretically proved but only asymptotically equal t-distribution based evaluations.

1 INTRODUCTION

The research investigation in a materials science always leads to the datasets. The large (or even huge) datasets should be analyzed to obtain summary results expressed in qualitative or quantitative forms. Such conclusions should be semi-proved by a statistical analysis.

One of the typical methodology is to observe behavior of the phenomenon against different treatments of controlled factors being precisely defined in a matrix known as a design of experiment. The general term 'behavior' is narrowed to a quantitative variable called 'response' or 'output'. The experiment focuses on the 'effect': the difference of the output as a result of the difference of treatments. If only one controlled factor is changed at time, the experiment is named One-Factor-At-Time (OFAT) [1]. On the opposite side, the factorial experiment [2] may be found where all controlled factors are changed simultaneously in a specific manner. The factorial experiment is also known as ALLFAT (All-Factors-At-Time). This name is often used in an industrial environment and quality management procedures.

The sensitivity of the investigated phenomenon to changes of controlled factor decides on the statistical significance of such factor. However this definition is intuitively clear, it requires some quantitative measure and its evaluation. Typical procedure used to assessment of factors significance is the analysis of variance (ANOVA).

ANOVA [2] is a well-known procedure to identify an inequality of means evaluated for subsets selected from the general dataset by a chosen particular classification factor. The null hypothesis H_0 states that all means are mutually equal against the alternative hypothesis H_1 that not all means are equal. The ANOVA workflow leads from the general dataset through its decomposition to subsets. Mathematically, it is described as a decomposition of a variance, which finally leads to comparison of MS_{factor} (variance explained by classification factor) against MS_{error} (remained variance). Technically, it replaces the original null hypothesis to its equivalent: the ratio of MS_{factor} by MS_{error} is equal to zero. As was proved by Fisher, this ratio has F-distribution however it requires some additional assumptions about an independency of observations, a normality of residuals and a homoscedascity in subsets. These assumptions are often questionable, especially when the size of a dataset is small and the statistical inference is weak.

The proposed solution consists of two elements: (a) the replacement of the original null hypothesis with its equivalent related to parameters of an associated fixed effects model and (b) the replacement of the classic test of parameters significance with the bootstrap-based checking of zero existence inside the parameter confidence intervals. This solution is more practical for large datasets with the unknown distribution because it does not require to meet the ANOVA assumptions.

Authors have been tried [3] previously to combine a bootstrap approach with an artificial neural network approximator to analyze materials science data processed by image analysis however they have with many numerical artifacts. Such approach was more successfully for processing non-parametric statistical analysis for surface layer [4].

The bootstrap approach appears to be a promising solution for some aspects of fuzzy statistics which is developed mainly by Buckley [5, 6]. The general workflow for such implementations has been proposed by Grzegorzewski [7]. Some preliminary investigations in the field of a design of experiments (DoE) have been made by Pietraszek [8, 9].

2 COMPUTATIONAL METHODS

Two main methods were used: the fixed effects model [2] and the bootstrap method [10]. The fixed effects model is used to evaluate effects being deviations of particular means from the grand mean. The bootstrap method is used to evaluate confidence intervals for effects. Fi-

nally, the existence of zero inside the intervals is inspected. If any of intervals contains zero, the null hypothesis of ANOVA is rejected.

2.1 Fixed-effects model

The fixed-effects model [2]consist of three terms:

$$y_{ij} = \mu + \alpha_i + \varepsilon_{ij} \tag{1}$$

where:
μ – grand mean (average response),
α_i – an effect at *i*-th treatment,
ε_{ij} – an random error at *i*-th treatment and *j*-th replication,
y_{ij} – the observed response at *i*-th treatment and *j*-th replication.

The grand mean and effects are evaluated using the ordinary least squares (OLS) [2].

2.2 Bootstrap

The bootstrap approach [10] to fixed-effects model (Eq.1) is described by the following workflow. In the beginning, the parameters $\hat{\mu}, \hat{\alpha}_i$ of the model were identified from the dataset using the least squares criterion L

$$\min L(\mu, \alpha_i) = L(\hat{\mu}, \hat{\alpha}_i) \tag{2}$$

then fits $\hat{y}_i$ were evaluated

$$\hat{y}_i = \hat{\mu} + \hat{\alpha}_i \tag{3}$$

and at last residuals r_{ij} of the model

$$r_{ij} = y_{ij} - \hat{y}_i \ . \tag{4}$$

Then, iteratively, (a) the new dataset $\mathbf{R}_\mathrm{B}$ of the same size containing bootstrapped residuals $r_{\mathrm{b}|ij}$ was constructed by drawing with replacement from the set of residuals:

$$\mathbf{R}_B = \left\{ r_{b|ij} : (1 \le i \le n) \wedge (1 \le j \le r) \wedge (\forall i, j \, \exists k, l : r_{b|ij} = r_{kl}) \right\} \tag{5}$$

and (b) new bootstrapped residuals were added to the model fits creating new bootstrapped "observations":

$$y_{B|ij} = \hat{y}_i + r_{B|ij} \ . \tag{6}$$

That new observations were used (c) to identify bootstrapped parameters of the model.

$$\min L(\mu, \alpha_i) = L(\hat{\mu}_B, \hat{\alpha}_B) \tag{7}$$

The parameters were collected until large number of iterations will be reached. Finally, (d) the quantiles were evaluated (typically 2.5% and 97.5%) for datasets of parameters as a range of confidence intervals and at last (e) zero existence inside confidence intervals was checked.

3 MATERIALS AND DATASET

The data were obtained during investigation of the ceramic shell mould of the airfoil blade casting. The description below is a brief, while details can be found in article of Szczotok *et al.* [11].

Nickel-based superalloys are mainly used in aircraft and power-generation turbines. Creep-resistant polycrystalline turbine blades are typically produced by an investment casting process. It is especially useful for making castings of complex and near-net shape geometry, where machining may be impossible or too wasteful. Studies were performed on the IN 713C superalloy. The castings described in the work were produced by the Laboratory for Aerospace Materials at Rzeszow University of Technology in Poland. One casting called GK was selected for the microstructural and statistical analysis. Final castings were cut off. The cross-sections were included and prepared as metallographic samples from nickel-based superalloy. To reveal the microstructure of the investigated material the surfaces of the samples were etched. The microstructural investigations of the cross-sections of the GK casting were carried out by a scanning electron microscope. The recorded microphotographs were next subjected to a computer-aided image analysis program to estimate quantitatively the main parameters describing the (γ+γ') eutectic islands that occurred in the investigated superalloy.

The dataset was created by counting number and size of eutectic island detected at six different traces labelled from T1 to T6 (Table 1). The issue was to check the homogeneity of the eutectic phase i.e. statistical equivalence of observations at any trace.

Trace	No of islands	Mean Area	SE	Median	Quartiles	
					Q1	Q3
T1	31	34.5	7.8	12.0	3.8	53.6

T6	61	24.5	3.5	14.2	8.6	28.4

Table 1: Descriptive statistics of raw data (source [11])

4 ANALYSIS

The typical method for checking the homogeneity of quantitative data is ANOVA. Due to the fact that area measures are positive they need to be transformed by a specific transformation into the whole real space to avoid nonsense negative values [12]. The natural logarithm was selected as transformation mapping i.e.:

$$LnY = \ln(area)\,. \tag{8}$$

Such transformation guarantees that any value has physical sense after retransformation. Descriptive statistics of transformed data are presented in Table 2.

The ANOVA protocol leads to the classic ANOVA table which decomposes the total variation into part assigned to grouping factor and the remain assigned to all other factors grouped under name 'error' which should be treated rather as 'unexplained' than only 'random error'. For the mentioned data, the ANOVA table (Table 3) revealed that critical p-Value is equal to 0.841, much greater than significance level $\alpha = 0.05$, what means that homogeneity of traces was not rejected.

Trace	No of islands	Mean LnY	SE	Median	Quartiles	
					Q1	Q3
T1	31	2.63	0.28	2.49	1.34	3.98

Total	575.338	359	1.603	–	–

Table 3: ANOVA table for transformed data (source [11])

Simultaneously, the general linear model (GLM) (Eq.1) was introduced for 6 levels (T1…T6). The identification of the model resulted in a set of parameters (Table 4). Note that lack of the parameter for T6 is a typical presentation of results by statistical programs (here: StatSoft STATISTICA v12), because all effects from T1 to T6 should sum to 0 and T6 should be deducted from such condition.

Table 5: Model fits and their confidence intervals for transformed data

The model predictions and their confidence intervals are presented in Table 5. It should be noted that such results are still from classic ANOVA for further comparisons.

Now, the approach was switched to the bootstrap. The number of draw iterations was set to 10.000 to easy selection of quantiles from the bootstrapped dataset. After the full bootstrap procedure, the descriptive statistics were evaluated for model parameters (Table 6) and model predictions (Table 7), similarly to Table 4 and Table 5.

The bounds of the confidence intervals were easy identified due to the selected number of bootstrap iterations. They were values found at positions 250 and 9750 in the sorted bootstrapped results. Similarly, the bootstrapped p-Value was evaluated as relative position of sign switching inside the sorted bootstrapped results.

5 CONCLUSIONS

- Bootstrap approach appears to be effective computational method to identify parameters of fixed effects model and their statistical properties.
- Bootstrap approach does not require to make *a priori* inconvenient assumptions.
- Bootstrap approach is very convenient to automatize in computational workflow and further statistical postprocessing.

Keywords: Stochastic Finite Element Method, Fire simulation, Fully coupled thermal-stress analysis.

Abstract. *This work demonstrates an application of the generalized stochastic perturbation technique and the corresponding Stochastic Finite Element Method in numerical analysis of the stresses for the steel structural element subjected to higher temperatures. This approach is based on higher order Taylor expansion of the input random parameters and of the resulting state functions and, independently, on the Least Squares Method determination of the structural responses to the input random parameters. An initial temperature equivalent to the fire exposure of the steel structure is taken as the input Gaussian random variable and uniquely defined by the constant mean value at outer surfaces of this element, where material parameters of the steel as Young modulus, yield strength, heat conductivity, capacity and thermal elongation are all considered as highly temperature-dependent. These functions are adopted according to the experimental evidence provided in the literature. We adopt various degree of polynomial functions to verify an influence of the response function choice upon the resulting probabilistic characteristics. This study is an example of a hybrid usage of the FEM system ABAQUS and the computer algebra system MAPLE in stochastic transient fully coupled thermo-mechanical analysis, where up to the fourth order probabilistic characteristics of the temperatures, displacements and stresses may be directly used in fire reliability analysis of the civil engineering structures with the temperature both independent and dependent material characteristics. The results obtained in this study may serve directly in the stochastic reliability analysis of the steel structures subjected to a fire according to both First and Second Order Reliability Methods (FORM and SORM).*

1 INTRODUCTION

Reliability of engineering structures under fire conditions remains always very challenging and practically important knowledge. It is possible to use it for an efficient prediction of the failure time for the structures to get specific information about their fire resistance and evacuation time. The well-known Monte-Carlo simulation needs huge computer time effort. In this case it is better to use higher order perturbation techniques implemented with the FEM originating from the Second Order Second Moment method [1] relevant to small initial random fluctuations. We compute probabilistic coefficients of up to the fourth order to gain more information about probability density function itself. The basic probabilistic moments as well as skewness and kurtosis are calculated by full symbolic expansion of integral definitions and partial differentiation of the nodal response functions with respect to given random input variable. In this case we consider strength test of elasto-plastic steel cylindrical specimen subjected to high temperatures. All physical and mechanical steel properties like Young modulus, yield strength, conductivity, heat capacity and thermal elongation are temperature-dependent.

2 THEORETICAL BACKGROUND

Let us introduce the random variable b and its probability density function as $p_b(x)$. Then, the first two probabilistic moments of this variable are defined as [2]

$$E[b] \equiv b^0 = \int_{-\infty}^{+\infty} b p_b(x) dx \,, \tag{1}$$

where b^0 means the average value of b itself and

$$Var[b] = \int_{-\infty}^{+\infty} [b - E(b)]^2 \, p_b(x) dx \,. \tag{2}$$

Higher probabilistic moments and related coefficients may be defined according to the classical definitions from the probability theory. The basic idea of the stochastic perturbation approach employed here is to expand all input random variables and all the resulting state functions of the given boundary initial problem via Taylor series about their spatial expectations using the perturbation parameter ε. The random function f with respect to its parameter b around its mean value is given as follows

$$f = f^0 + \sum_{n=10}^{1} \frac{\varepsilon^n}{n!} \frac{\partial^n f}{\partial b^n} \Delta b^n \,, \tag{3}$$

where

$$\varepsilon \Delta b = \varepsilon \left(b - b^0 \right) \tag{4}$$

is the first variation of variable b about its expected value and symbol $(.)^0$ represents the value of a function calculated at its mean. Let us analyse further the expected values of stress state function $\sigma(b)$ defined analogously to the Eqn. 3 by its expansion via Taylor series as follows

$$E[\sigma(b)] = \int_{-\infty}^{+\infty} \sigma(b) p_b(x) dx = \int_{-\infty}^{+\infty} \left(\sigma^0\left(b^0\right) + \sum_{n=10}^{1} \frac{\varepsilon^n}{n!} \frac{\partial^n \sigma(b)}{\partial b^n} \Delta b^n \right) p_b(x) dx \,. \tag{5}$$

We remind that this power expansion is valid only if the state function is analytic in ε and the series converge and, therefore, any criteria of convergence should include the magnitude of the perturbation parameter; perturbation parameter is taken as equal 1 in several practical computations and also here [3, 4]. It yields for the input random variable with symmetric probability density function in the second order perturbation approach

$$E\left[\sigma(b)\right]=\sigma^0\left(b^0\right)+\frac{1}{2!}\frac{\partial^2\sigma(b)}{\partial b^2}\mu_2(b)+\cdots+\frac{1}{10!}\frac{\partial^{10}\sigma(b)}{\partial b^{10}}\mu_{10}(b), \tag{6}$$

where $\mu_n(b)$ denotes nth order central probabilistic moment of the variable b. All the terms with odd orders are equal to 0 for the symmetric random variable and the orders higher than the 10th one are neglected additionally. Similar considerations leads to the expressions, like the variance, for instance

$$Var\left[\sigma(b)\right]=\mu_2(\sigma(b))=\int_{-\infty}^{+\infty}(\sigma(b)-E\left[\sigma(b)\right])^2\,p(b)db\,. \tag{7}$$

Quite similarly, it is possible to derive 3rd central probabilistic moments using also the 10th order approach as

$$\mu_3(\sigma(b))=\int_{-\infty}^{+\infty}(\sigma(b)-E\left[\sigma(b)\right])^3\,p(b)db\,, \tag{8}$$

and also the 4th order probabilistic moment may be recovered from this scheme as

$$\mu_4(\sigma(b))=\int_{-\infty}^{+\infty}(\sigma(b)-E\left[\sigma(b)\right])^4\,p(b)db\,. \tag{9}$$

Let us mention that it is necessary to multiply each of these equations by the relevant order probabilistic moments of the input random variable to get the algebraic form convenient for any symbolic computations. Based on the classical definition of the variance we can calculate the coefficient of variation as fallows

$$\alpha(\sigma(b))=\frac{\sqrt{\mu_2(\sigma(b))}}{E\left[\sigma(b)\right]}\,. \tag{10}$$

Higher order moments and characteristics are determined to recognize the type of probabilistic distribution od the state functions. We compute in turn the skewness coefficients as the ratio of the third central probabilistic moment and the third power of standard deviation as

$$S(\sigma(b))=\frac{\mu_3(\sigma(b))}{\left[\sqrt{\mu_2(\sigma(b))}\right]^3}\,, \tag{11}$$

and kurtosis as

$$\kappa(\sigma(b))=\frac{\mu_4(\sigma(b))}{\left[\sqrt{\mu_2(\sigma(b))}\right]^4}-3\,. \tag{12}$$

It should be mentioned that at this stage the proposed procedure is independent from a choice of the initial probability distribution function, however a satisfactory probabilistic conver-

gence of the final results may demand various lengths of the expansions for random variables with different distributions.

The method is based on the iterative coupled deterministic FEM [5] equations as follows

$$\begin{cases} \mathbf{C}^{(\alpha)}\dot{\boldsymbol{\theta}}^{(\alpha)} + \hat{\mathbf{K}}^{(\alpha)}\boldsymbol{\theta}^{(\alpha)} = \hat{\mathbf{R}}^{(\alpha)} \\ \mathbf{K}^{(\alpha)}(\boldsymbol{\theta})\mathbf{q}^{(\alpha)}(\boldsymbol{\theta}) = \mathbf{R}^{(\alpha)} \end{cases}, \tag{13}$$

where $\mathbf{C}$ is heat capacity matrix, $\boldsymbol{\theta}$ is nodal temperatures vector, $\hat{\mathbf{K}}$ is heat conductivity matric, $\mathbf{K}$ denotes stiffness matrix, $\mathbf{R}$ is matrix of nodal loads, $\hat{\mathbf{R}}$ is a matrix of thermal loads and $\mathbf{q}$ is the solution displacement vector and α indices the test number relevant to Response Function Method [6]. We solve Eq. (13) in ABAQUS system. Further determination of the probabilistic moments from Eqs. (5÷12) thanks to the symbolic derivation of all partial derivatives with respect to the given random variable b. We carry out all these calculations in computer algebra system MAPLE.

3 NUMERICAL EXAMPLE

Numerical example consist of the necking of an axi-symmetric steel specimen (Fig. 1). Its initial length is $2L_0$ and initial radius is R_0 and $L_0 / R_0 = 4$. We make small cut of its corner $\Delta R = 0{,}005R_0$ * 0.05 mm to ensure necking in the middle of it [7].

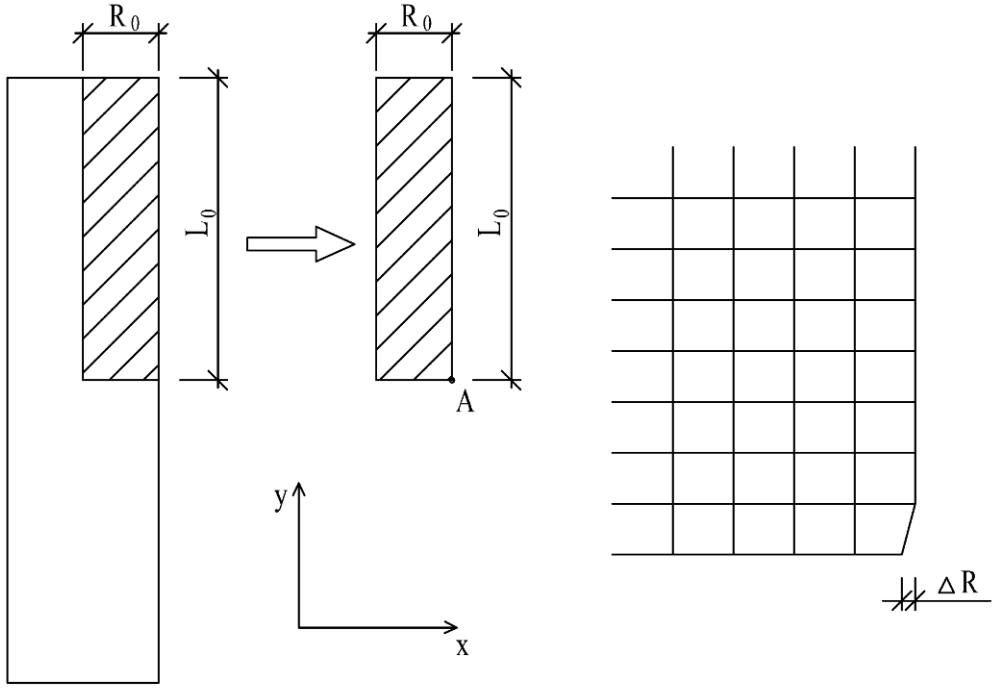

Figure 1: Geometry and imperfection of the specimen.

4-noded FEM elements [8] are used for discretization which divide the specimen into 1600 pieces called in ABAQUS system CAX4RT (Fig. 2a). Each node has 7 degree of freedom (6 mechanical and 1 thermal which is temperature). Mechanical boundary conditions are $u_x = 0$ on the left side, $u_y = 0$ on the bottom side and forced displacement $u_y = 0.125L_0$ applied to the top side (Fig. 2b).

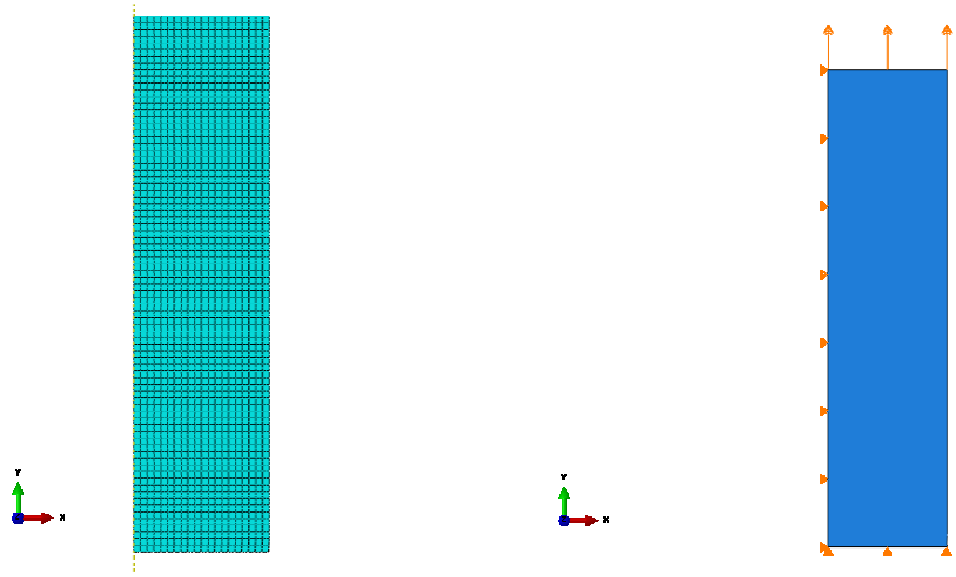

Figure 2: FEM model (a) and thermal boundary conditions (b).

Initial temperatures are set equal to $T_0 = 20\,°\mathrm{C}$ for all nodal points, while fire simulation is performed by setting surface temperatures equal to these calculated from the fire curve after ISO 834-1 statement (Fig. 3a). We set these temperature to the top and the right side of the specimen (Fig. 3b).

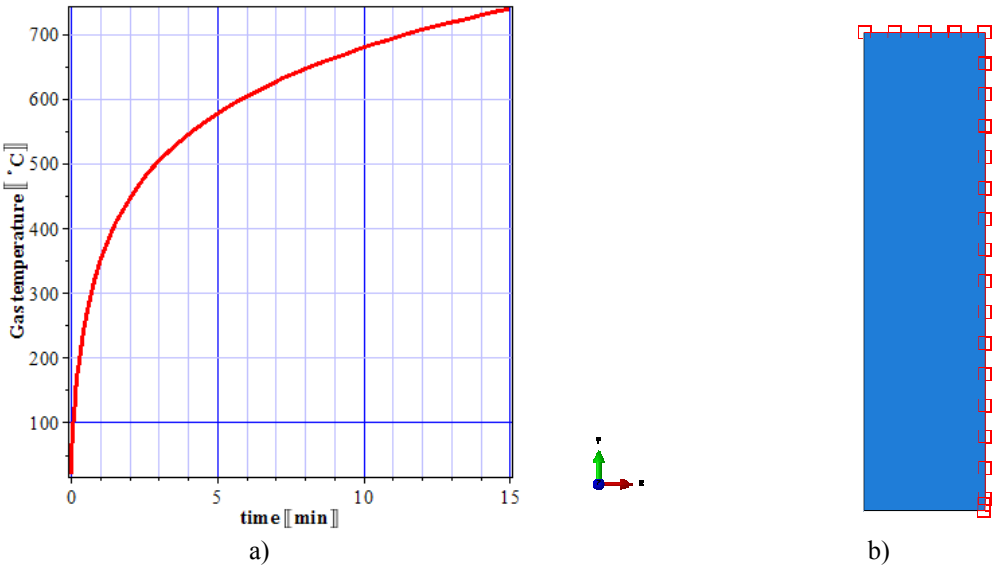

Figure 3: Time-temperature curve (a) and thermal boundary conditions (b).

Steel properties as Young modulus, yield strength, conductivity, specific heat and coefficient of thermal elongation are highly temperature-dependent according to EN 1993-1-2. Fully coupled thermal-stress analysis is used where element temperature affects stress and displacements values. 11 tests were carried out with time period equal to 15 minutes for 11 different values of random variable which was gas temperature $b \equiv T_s$ in this case. Figures 4÷6 show resulting Huber-Mises stress distribution on deformed specimen. As can be expected this distribution is not uniform. Moreover we can see precisely how necking rise.

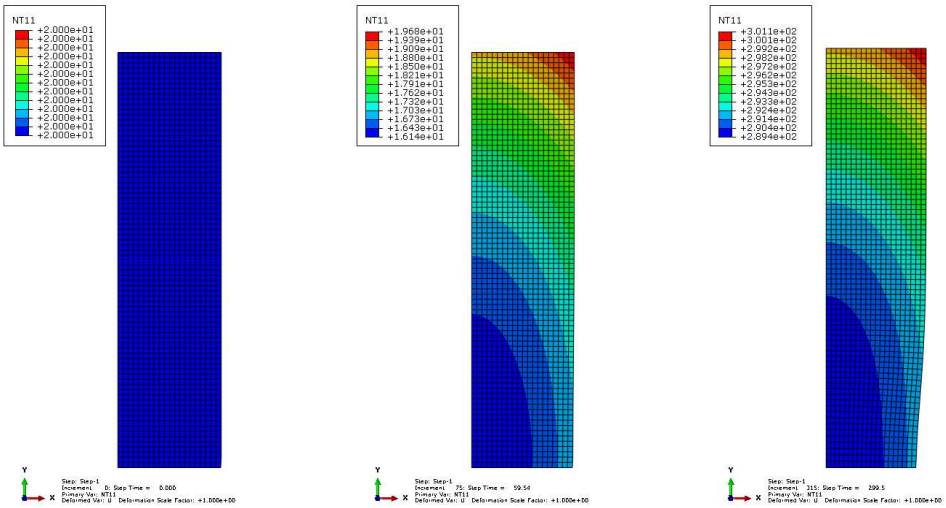

Figure 4: Stress distribution at t=0, 60, 300 s.

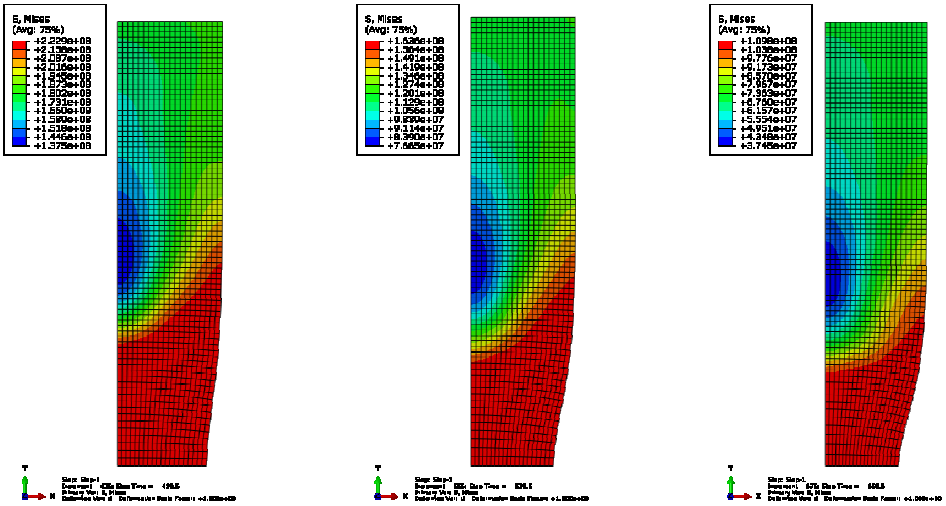

Figure 5: Stress distribution at t=420, 540, 660 s.

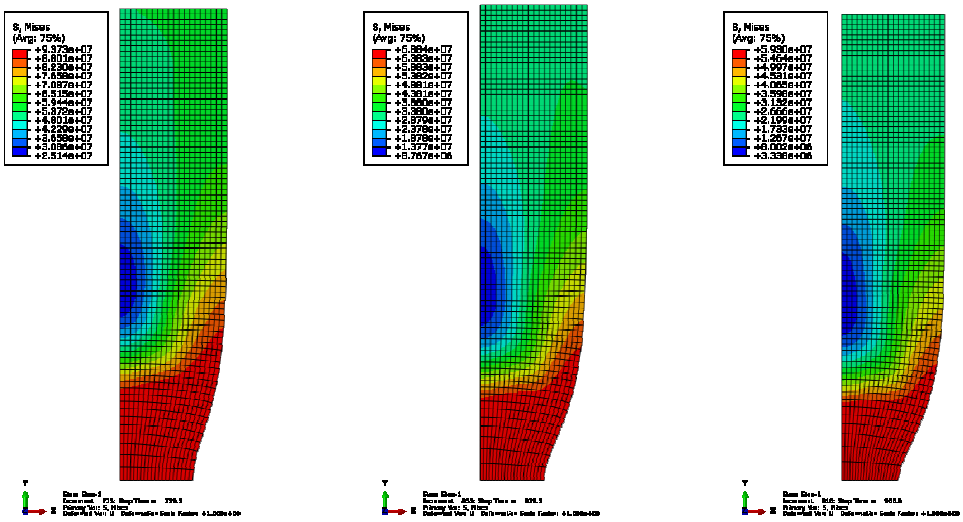

Figure 6: Stress distribution at t=720, 860, 900 s.

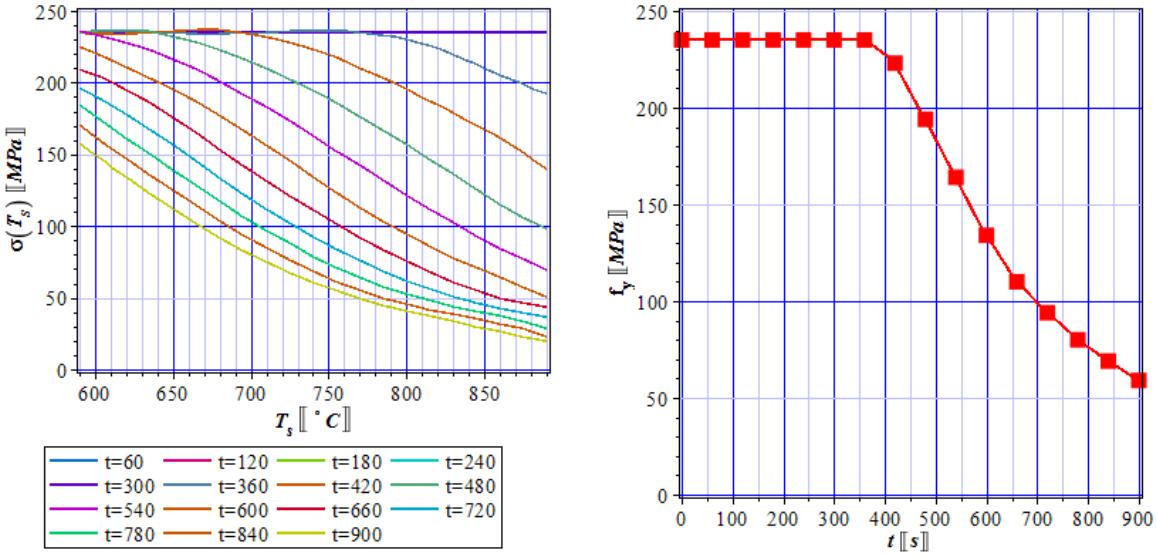
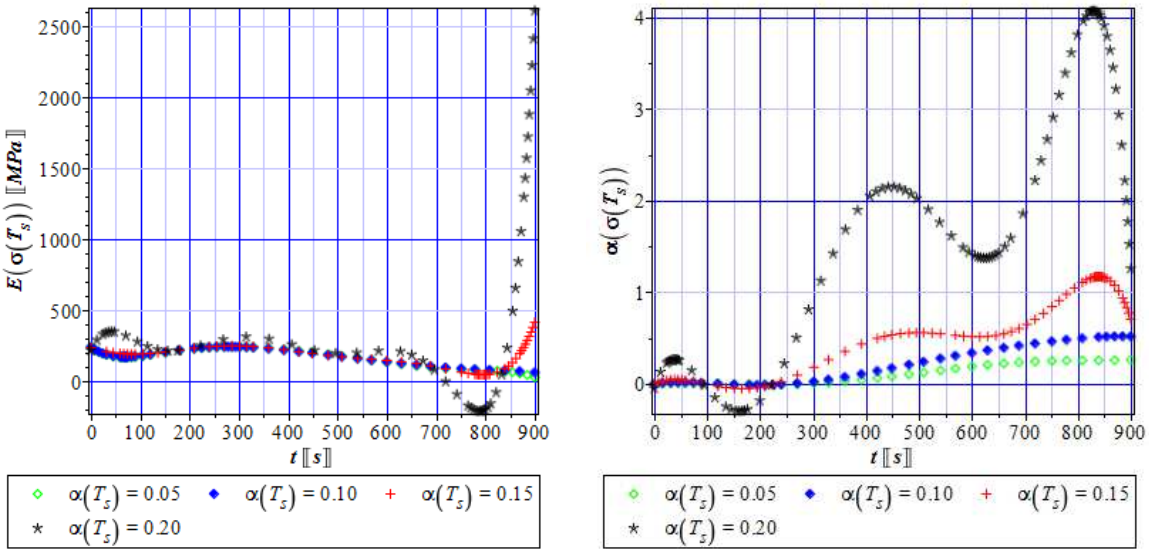
19 polynomial response functions were performed to describe the response of the structure (Fig. 7a). Based on resulting stress values taken from FEM analysis results at an interval of 60 seconds we made time-dependent Huber-Mises diagram (Fig. 7b).



a) b)

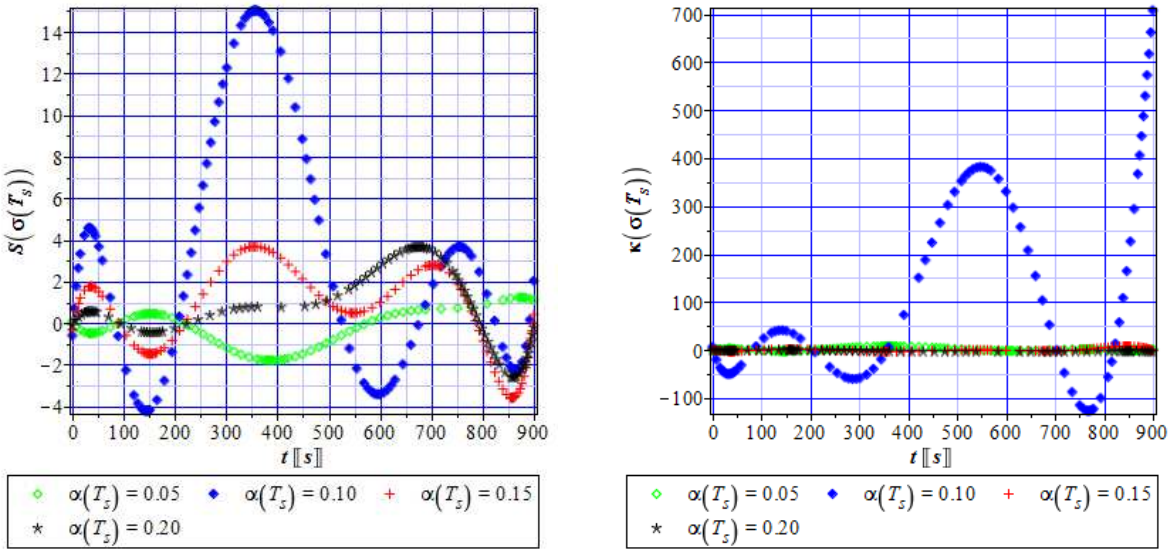
Figure 7: Response functions (a) and resulting yield strength reductions (b).

Resulting gas temperature is also random variable in this case with its input coefficient of variation $\alpha(T_s)$ in the range of [0.0,0.2]. Figures 8÷9 show expectation, coefficient of variation, skewness and kurtosis for extreme Huber-Mises stress in the point A of the specimen (Fig. 1). The biggest fluctuations of expected values and coefficient of variation could be observed for $\alpha(T_s)=0.20$. Coefficients of variation are close to zero (small dispersion) for $\alpha(T_s)\leq 0.10$ and it means that values of stress are concentrated round its means.



a) b)

Figure 8: Expectations (a) and coefficient of variation of stress (b).



a) b)

Figure 9: Skewness (a) and kurtosis of stress (b).

Studying stress and kurtosis distributions we can see fluctuations for $\alpha(T_s) = 0.10$. According to this plots we can conclude that Huber-Mises stress distribution is Gaussian when $\alpha(T_s) \leq 0.05$ because in this range skewness and kurtosis are close to zero.

This computation example has been made to determine the probabilistic characteristics for stress distribution under fire condition which is very often taken as non-Gaussian. This test illustrates the strength test cylindrical steel rod at elevated temperatures, the results of which enable determination of the yield point of the curve changes as a function of time.

4 CONCLUSIONS

Based on this computation we can say that probability distribution of reduced stress under fire condition is Gaussian only if we narrow the range for input coefficient of variation to $\alpha(T_s) < 0.05$. Moreover we shown the common usage of FEM software ABAQUS and computer algebra system MAPLE which is crucial to use Stochastic Finite Element Method [9] (SFEM). We looked at the influence of polynomial degree [10] on the results of stochastic analysis. In such non-linear problems we have to use different functions to fit the response of the structure. The information about stress distribution obtained in this study can be use in the stochastic reliability analysis of the steel structures under fire according to both First and Second Reliability Method [3].

Keywords: Stochastic Finite Element Method, hyperelasticity, rubber-like materials.

Abstract. *The main idea of this work is to demonstrate an application of the generalized iterative stochastic perturbation technique to numerical analysis of the hyperelastic materials and structures with Gaussian random parameter, where the input random variable is a magnitude of the vertical uniformly distributed load. Theoretical apparatus is connected with the general order Taylor expansion of both input and state parameters with random coefficients and analytical derivation of their first four probabilistic moments and coefficients. Our computational implementation is released with the Response Function Method having polynomial basis of the order minimizing variance and maximizing correlation of the least squares fitting to the series of numerical experiments. Computational experiment concerns the hyperelastic rubber-like prismatic beam under three-point bending discretized in the FEM system ABAQUS with the use of various 3D brick finite elements. Large deformations in the vertical symmetry plane of this structure are analyzed in the stochastic context – by determination of their expectations, coefficients of variations, skewness and kurtosis for different increments of the external load. It enables also to recover the basic probabilistic characteristics of the stress-strain curve of such a material, whose further comparison with the experiments will allow a full validation of such a probabilistic model. The entire probabilistic algorithm together with statistically optimized Weighted Least Squares Method fitting are implemented in the symbolic algebra package MAPLE. The proposed scheme of the Stochastic Finite Element Method is contrasted with the crude Monte-Carlo scheme and also with the semi-analytical calculations of the same probabilistic characteristics by direct integration of the response functions.*

1 INTRODUCTION

Modern probabilistic computational mechanics focuses on a development of the new, still more efficient theoretical and numerical methods as well as on their applications in experimentally driven models or on these research problems where the input statistics are available. Statistical nature of structural properties obviously necessary for realistic durability analysis and property prediction of materials is almost perfectly known for the area of elastic homogeneous materials but still deserves some attention in hyperelastic, visco-elastic [1], elasto-plastic, elasto-visco-plastic and especially in thermo-elasto-visco-plastic models. Although some stochastic models are known in thermal transient processes for temperature independent and dependent cases [2], a full coupling in-between elastic and thermal analysis in terms of coupled problem is still to be performed also in terms of uncertainty in temperature affecting all material and physical characteristics in terms of coupled analyses. A little bit separate problem is an identification of all material characteristics for the hyperelastic solid that needs more material constants than their elastic counterpart; the statistical point of view seems to be quite natural in this context [3], even accounting for the neural networks employed to provide such an identification [4]. Deterministic constitutive models in the area of hyperelasticity relevant to the rubber-like materials are quite well known and systematically documented. They include the Neo-Hooekan [5], Mooney-Rivlin [6], Ogden [7], Yeoh [8], Gent [9], Arruda-Boyce [10] as well as the very recent so-called extended tube model [11] resulting from molecular statistical-mechanical approach for rubber networks provided by Henrich and Kaliske. They have some Finite Element Method implementations and applications [11] that concern only an entirely deterministic case; even for a composite made of particle-reinforced rubber [12]. Probabilistic counterparts of nonlinear material models [13] are definitely less known and not systematically worked out [14] (some exceptional Monte-Carlo simulations are available but they return only quantitative results), so that such a systematic extension would be necessary. The very important aspect is that the aforementioned theories of hyperelastic behavior contain various numbers of material parameters, so that their comparisons in terms of material uncertainty will not be so straightforward as in linear elastic case; such a study needs definitely more experimental work and theoretical assumptions than before.

The main objective of this work is application of the iterative generalized stochastic 10^{th} order perturbation technique [15] implemented together with the Finite Element Method [16, 17, 18] to calculate the first four probabilistic characteristics of the ultimate vertical displacement and the corresponding Huber-Mises stress for the three-point bended hyperelastic beam. This study is undertaken to analyze the hyperelastic material with Mullins effect subjected to large deformations in a large-strain non-linear analysis with a complex contact properties and stabilization of computation. This example is also focused on numerical error determination of the FEM solution for various 3D brick finite elements and an increasing discretization density; it is also concentrated on a sensitivity analysis of the ultimate vertical displacement and the corresponding Huber-Mises stress in addition to the magnitude of an external vertical load. Probabilistic considerations included in this work are based on the Weighted Least Squares Method (WLSM) with the polynomial basis, whose order is statistically optimized and relates the displacement and stress with the uncertain external load. These optimal polynomials are then used in the iterative perturbation-based SFEM, Monte-Carlo and semi-analytical integration technique in order to determine expectations, coefficients of variation, skewness and kurtoses of the vertical deflections and the corresponding stresses in the function of the input coefficient of variation. Such a study is carried out to determine accuracy of the iterative perturbation method in analyses of hyperelastic materials and to check the probabilistic properties of the output variables, i.e. the ultimate vertical deflec-

tions and the corresponding Huber-Mises stresses. Such iterative generalized Stochastic Perturbation (SPT) method is applied here since it yields more accurate results than the classical SPT, including the negative and mixed moment terms that are absent in the linearized version. The input random parameter is chosen here as an external load in a form of the uniform pressure, whose Probability Density Function (PDF) is Gaussian. Such a parameter has been chosen here, since it is one of the most unpredictable variables included in the model. It usually cannot be exactly calculated in real structures and it varies non-monotonously with large time variations and its underestimation may certainly cause an overall failure. This is the case of civil engineering structures, machinery, vehicles or aircrafts. This work serves as a preliminary study for further expansion towards experimentally-calibrated hyperelastic material model probabilistic analysis based on a crack initiation or rubber softening.

2 HYPERELASTIC MATERIAL MODEL

Let us consider the total strain energy U in some material, which is defined as

$$U = U_{dev}\left(\lambda_i\right) + U_{vol}\left(J^{el}\right), \tag{1}$$

where U_{dev} stands for the deviatioric part of the strain energy and U_{vol} for the volumetric part of this energy. The Yeoh material definition defines these variables in a following way

$$U_{dev}\left(\lambda_i\right) = C_{10}(\overline{I}_1 - 3) + C_{20}\left(\overline{I}_1 + 3\right)^2 + C_{30}\left(\overline{I}_1 - 3\right)^3 \tag{2}$$

and

$$U_{vol}\left(J^{el}\right) = \frac{1}{D_1}\left(J^{el} - 1\right)^2 + \frac{1}{D_2}\left(J^{el} - 1\right)^4 + \frac{1}{D_3}\left(J^{el} - 1\right)^6, \tag{3}$$

in which C_{io} and D_i are temperature-dependent material parameters, $\overline{I}_1$ stand for the first deviatioric strain invariant defined as $\overline{I}_1 = \overline{\lambda}_1^2 + \overline{\lambda}_2^2 + \overline{\lambda}_3^2$ and where the stretches $\overline{\lambda}_i$ are defined as $\overline{\lambda}_i = J^{-\frac{1}{3}}\lambda_i$. J stands here for the total volume ratio and λ_i are the principal stretches. The initial shear modulus and bulk modulus are given as $\mu_0 = 2C_{10}$, $K_0 = 2/D_1$. When a thermal dependence is taken into consideration, the elastic volume ratio J^{el} relates the total volume ratio J and the thermal volume ratio J^{th} in a following manner $J^{el} = J/J^{th}$, where $J^{th} = \left(1 + \varepsilon^{th}\right)^3$. ε^{th} stands for the linear thermal expansion strain obtained from the temperature and the isotropic thermal expansion coefficient; it is not considered here.

The augmented Mullins effect strain energy density function applied in this study is following

$$U = \eta U_{dev}\left(\lambda_i\right) + \Phi\left(\eta\right) + U_{vol}\left(J^{el}\right), \tag{4}$$

where the damage variable η is defined as

$$\eta = 1 - \frac{1}{r} erf\left(\frac{U_{dev}^m - U_{dev}}{m + \beta U_{dev}^m}\right) \tag{5}$$

and the damage function is adopted here as

$$\Phi(\eta) = \int_1^n f\left(\eta, U_{dev}^n\right) d\eta + (1-\eta) U_{dev}^m, \tag{6}$$

which on the primary path $\eta = 1$ and satisfying the requirement $\Phi(1) = 0$ can be expressed as

$$\Phi'(\eta) = \left(m + \beta U_{dev}^m\right) erf^{-1}\left(r(1-\eta)\right) - U_{dev}^m. \tag{7}$$

The variables r, β and m all denote the input material constants, the first two of which are dimensionless and the latter has dimensions of energy. The error function erf used in this definition is defined as $erf(x) = \frac{2}{\sqrt{\pi}} \int_o^x \exp\left(-w^2\right) dw$ and the function $f\left(\eta, U_{dev}^n\right)$ can be further expressed as $f\left(\eta, U_{dev}^m\right) = \Phi'(\eta) + U_{dev}^m = U_{dev}^m - U_{dev} = -\Phi'(1) - U_{dev}$. Fundamental properties of this damage function are that (a) when $U_{dev}^m = U_{dev}$, then it corresponds to a point on the primary curve and $\eta = 1.0$ (b) η attains its minimum value η_m upon complete removal of deformation, i.e. when $U_{dev} = 0$ and (c) in all other cases η varies monotonously from η_m to 1.0.

3 COMPUTATIONAL EXPERIMENTS AND DISCUSSION

3.1 Computational model

A computational model applied in this study consists of three elements, the 10 m long hyperelastic beam with section of 1.5 m x 1 m, the support cylinders with diameter of 1.2 m and a 0.3 m deep loading plate having section of 1 m x 1 m (Fig. 1). The beam is supported on the two cylinders placed on each side of the beam and loaded with various magnitude of pressure of $p = 1\ Pa$ mean value, which is applied on the upper surface of the centrally placed plate. The static scheme of three-point bending is applied here firstly because it is a usual scheme used in laboratory tests, secondly since such loading is common in various applications of cyclically loaded parts and finally as it creates regions dominated by bending and shear. Both, an upper loading plate and the cylinders are deformable and much stiffer than the beam with elastic parameters set as Young modulus $E = 10\,GPa$ and Poisson ratio $\nu = 0.3$. The hyperelastic beam has a complex material definition of the Yeoh model with the following parameters: $C_{10} = 1.326$, $C_{20} = -0.326$, $C_{30} = 0.1319$, $D_1 = 0.000725$, $D_2 = 0$, $D_3 = 0$, whose Mullins effect has the following parameters: $r = 1.1$, $m = 100$, $\beta = 0.1$. This ensures a hyperelastic behavior and cyclic softening of the beam. A connection between the elements is assured by a hard contact in the normal direction enforced by the penalty method and a penalty-driven tangential contact behavior with a friction coefficient of $\mu = 0.99$ for the cylinders- and of $\mu = 0.8$ for the plate-beam boundary; the slippage of the beam from the cylinders is prevented by tying its outer edges to the cylinder surface. A possibility of separation of the model elements after an initial and repeated contact is allowed here (surfaces are not tied after the contact). In order to keep the mechanical boundary conditions for a three-point loading, bases of the cylinders are fully restrained (no displacement or rotation allowed) and the loading plate has only the vertical displacement degree of freedom (dof) active; it further supports a sym-

metry of the loading. Additionally, the beam is divided into 8 cells to shorten the surface length of both contacts, which speeds up numerical analysis.

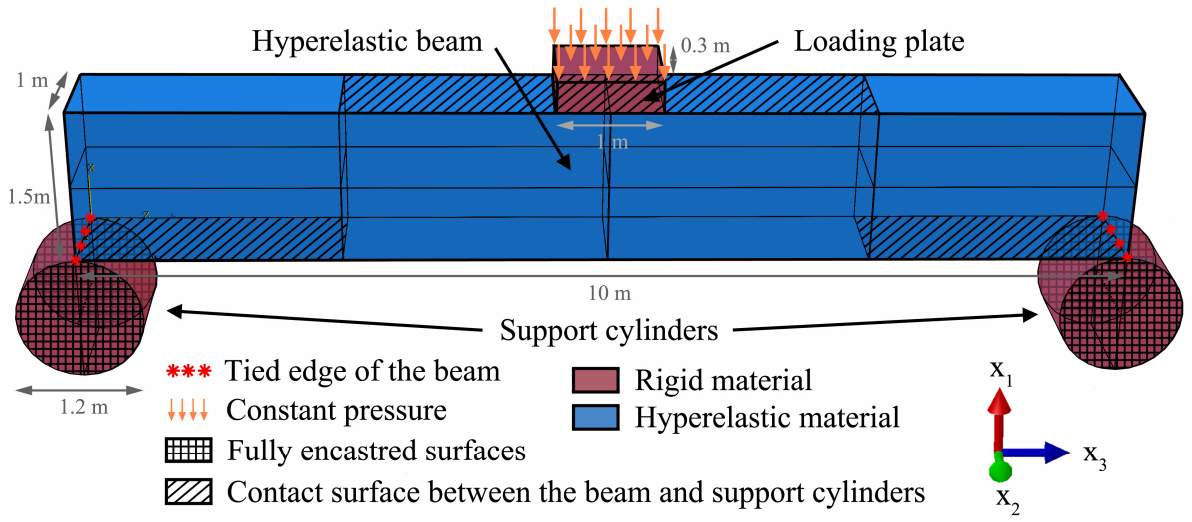

Figure 1: FEM model of the beam.

Computational model and numerical experiments are provided both in the FEM system ABAQUS with a series of beam loadings for the ultimate vertical displacement and the corresponding Huber-Mises stress of the beam. The elements are meshed with 104 397 reduced (stress) integration linear brick finite elements (C3D8R) giving a total of 418 602 independent variables (Fig. 2); the entire beam element additionally has a hybrid definition of elements of type C3D8HR, which deal with a full (or nearly full) incompressibility of this FEM domain. The type and amount of elements is selected to obtain the best possible quality of results for an acceptable computational effort via the error analysis of computational simulations presented in Fig. 4 and, separately, by a sensitivity analysis of the resulting displacements and the corresponding stress available in Fig. 5. Numerical computations include a material and contact non-linearity and are based on the non-linear theory of large strains. Completion of each simulation requires partitioning to 40-150 steps, each calculated on the basis of the result of the previous one (usually consisting of 2-16 iterations); this is a main reason for the lower amount of the Finite Elements (FEs) than in the single-step linear-elastic computations. Results of these analyses (in a form of the stress mapped on a deformed shape of the beam) show large symmetric deformations of a thick beam with also symmetric stress map – a typical work range of usual hyperelastic (rubber) materials. Predictably, the stress pattern is symmetric and the highest near the bottom of the beam; there also exist particular stress concentrations nearby the cylindrical supports and on each side of the loading plate. The stress concentrations on the support edges of the beam are disregarded in this study since they are rather enforced by the tied internal conditions and would differ for the exact type of the slippage-preventing support applied in the experiments.

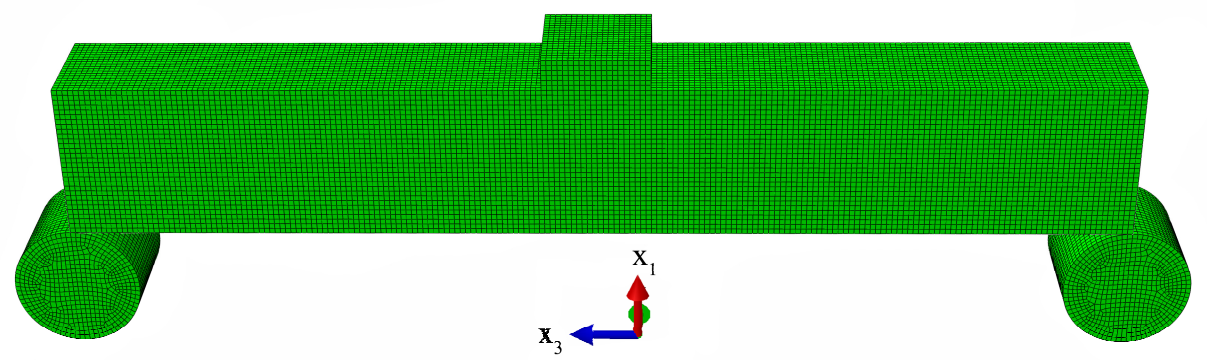

Figure 2: The finest mesh of the beam.

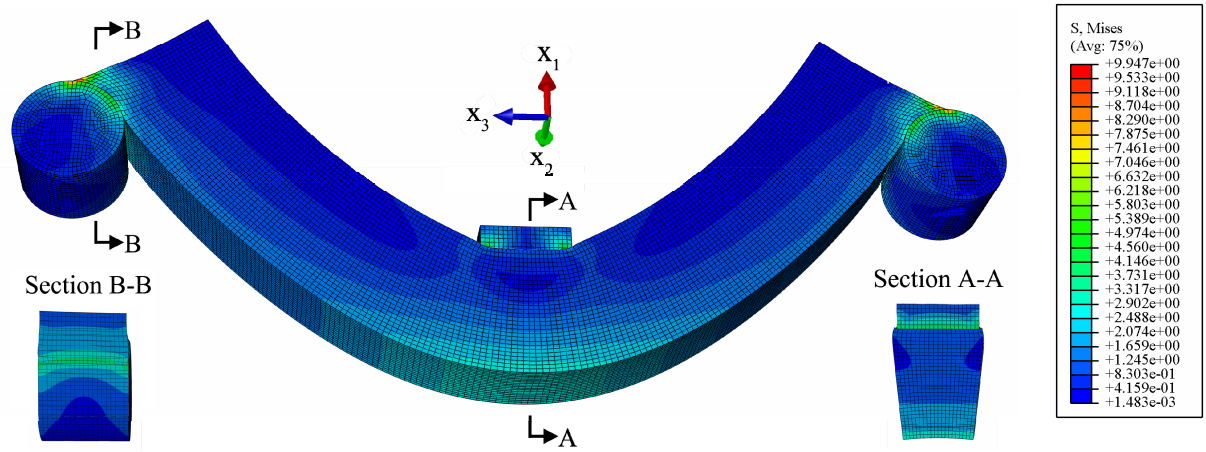

Figure 3: Map of the reduced stress plotted on deformed configuration of the beam under bending.

3.2 Computational error and sensitivity analysis

Within the error study, three types of FEs are used, i.e. the reduced integration linear brick C3D8R, the incompatible modes linear brick C3D8I and the reduced integration quadratic brick C3D20R; due to incompressibility of the material, the beam is discretized here always with the hybrid finite elements (C3D8RH, C3D8IH, C3D20RH). These particular types of elements are chosen after their best performance range, which for the linear reduced elements is large distortion in bending, for the incompatible modes – bending and for the second-order (quadratic) elements with reduced integrations - nonlinearity; all the above phenomena take place in this analysis and therefore such an error and performance study seems to be profitable here. An error graph presented in Fig. 4 firstly shows the very good convergence of results and a small error $E_r(n)$ for all the discretization densities applied, which never crosses 3% and is as small as 0.15% for the higher amount n of the FEs. The smoothness of convergence is not so evident, as in the linear analyses [20], but an overall reduction of the error together with an increase in the FEs amount is still clear. When an influence of material and contact non-linearities as well as occurrence of large strain theory is taken into consideration, this result is more than satisfactory. A secondary observable is, that in this particular case the computations of quadratic elements have a very low convergence and, additionally, that not all of the computations lead to the final result – some particular distributions of the elements are stuck in various points of the analysis. Basing on this (C3D8I brings no additional variation), the standard C3D8R elements are chosen for the further analysis. Please note, that the computational effort for the quadratic FEs is much higher than for the linear ones of the identical

amount and, therefore, Fig. 4 cannot serve for the final evaluation of time-performance of these methods.

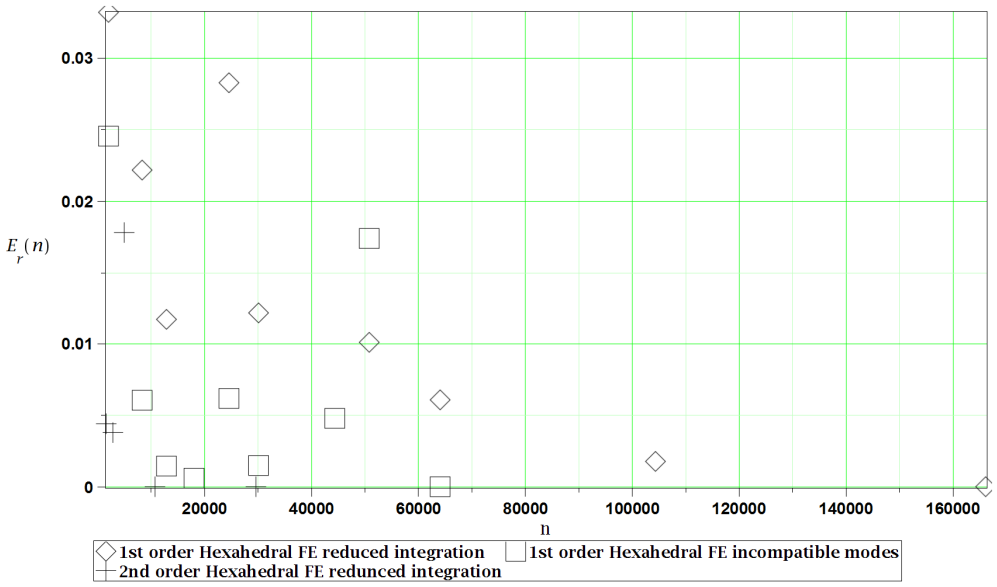

Figure 4: Computational error of the Finite Element Method results.

Sensitivity coefficients $S(p)$ of both ultimate vertical deformations and the corresponding stresses are computed by 11 separate simulations in 20% neighborhood of the mean external load, which ranges from 0.9 Pa till 1.1 Pa, via a direct algebraic differentiation based on the additional response functions (Fig. 5). These sensitivities are quite naturally all positive, since the increase of the external load should also increase both the ultimate vertical displacement and also its corresponding reduced stress. The Huber-Mises stress is much more sensitive to the fluctuations in an external load but has smaller curvature than the sensitivity of displacement in this particular load region.

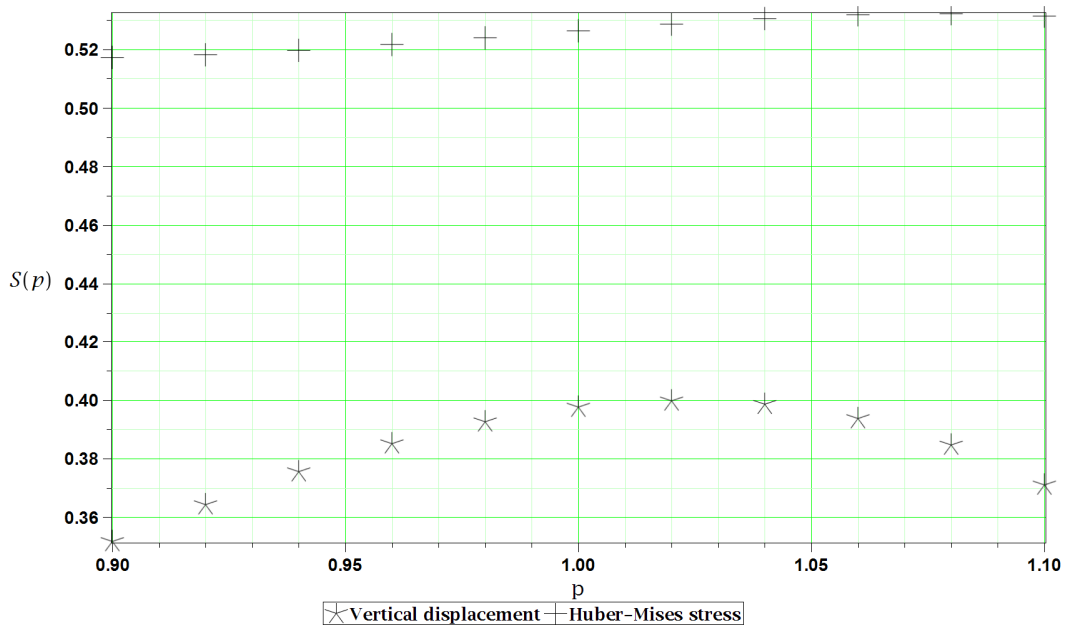

Figure 5: Sensitivity coefficients for the ultimate deformation and the corresponding von Mises stress.

3.3 Probabilistic analysis

The probabilistic computations are all carried out in the symbolic system MAPLE and are focused firstly on a determination of the optimum order of the response function of the WLSM (Tab. 1), which is then used in the main computation of the probabilistic characteristics based on the ultimate displacements and the corresponding Huber-Mises stresses. The procedure of calculation of these characteristics consists of (a) integration of the response function together with the Gaussian PDF in a semi-analytical method, (b) its insertion into the 2^{nd}, 4^{th} and 6^{th} (only for the stresses) order Taylor expansions in stochastic perturbation-based approach and (c) its sampling in a discrete Monte-Carlo analysis (with 500 000 random trials) for an increasing value of the input coefficient of variation $\alpha(p)$. The characteristics calculated in this manner include the expectation (Fig. 6), the coefficient of variation (Fig. 7), the skewness (Fig. 8) and the kurtosis (Fig. 9). The Least Squares Method is used here in its weighted form and non-linear version with a weighting scheme similar to the Dirac function – [1,1,1,1,1,10,1,1,1,1,1] – making the influence of the mean value equivalently important as the remaining test results. Maximization of the optimal polynomial order is done via simultaneous maximization of the correlation and minimization of the variance of the WLSM and the RMS error. The total number of WLSM increments equals 20 in this study and the chosen polynomial order is 4^{th} for the displacement and 5^{th} for the stress. The resulting parameters used in the optimization process are well illustrated in Tab. 1 and correlate the subsequent results with the polynomial order; all the beneath given probabilistic results (Figs 6-9) consecutively show the characteristics of the ultimate vertical displacements on the left and of the corresponding reduced (Huber-Mises) stresses on the right side. The input uncertain parameter – an external load p – varies in 20% neighborhood of the mean value of 1 Pa with 11 discrete values of $p \in [0.90, 0.92, \ldots, 1.00, \ldots, 1.10]$.

Variable		Vertical deformation			Huber-Mises stress		
Parameter		Correlation	Variance	RMS error	Correlation	Variance	RMS error

Table 1: Weighted Least Squares Method optimization results for a Dirac type of weights.

The expectations of the output variables both are a little decreasing in a concave manner together with an increase of the uncertainty. Additionally, they both have a horizontal asymptote approached at the zero uncertainty, for which they obviously must return the exact results obtained in the computational FEM experiments. These output functions are continuous, smooth and with no local inflections or discontinuities. The 2^{nd} order (based on the first two Taylor expansions) perturbation-based approach returns here a little divergent results and is

valid only for $\alpha(p) \in [0.00,\ 0.05]$, but as long as the higher order is applied, all the three separate methods yield exactly the same output.

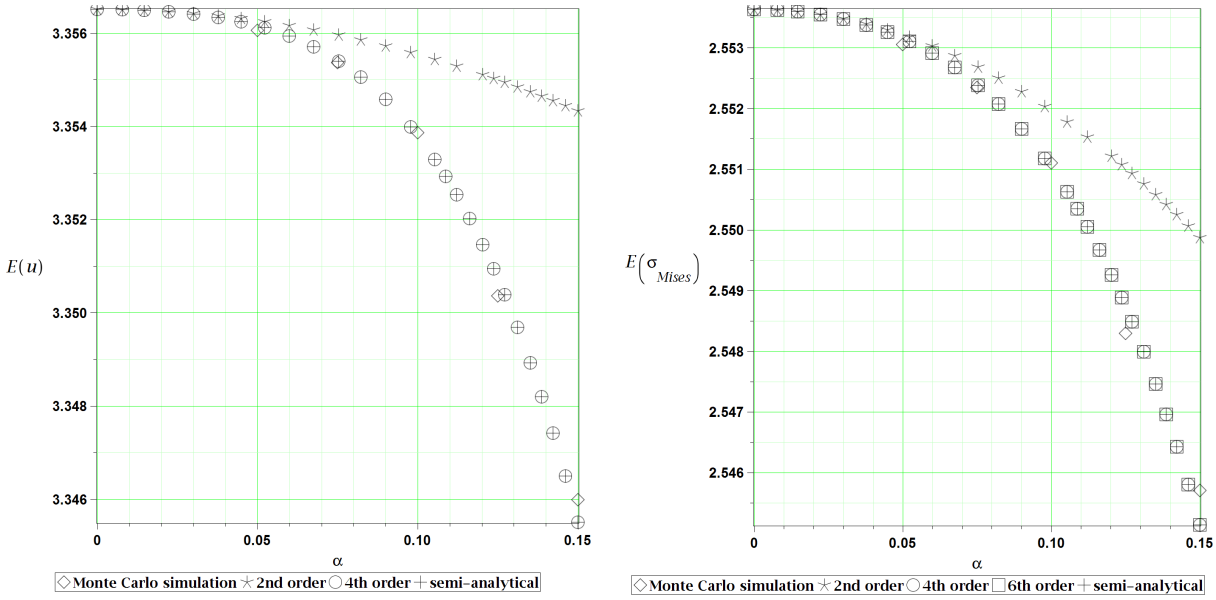

Figure 6: Expected values of
a) the ultimate deflection and b) the corresponding Huber-Mises stress
of the beam subjected to three-point bending with respect to the uncertainty in the external load.

The resulting coefficients of variation (Fig. 7) of both output variables are always increasing in the concave manner while staying lower than the input uncertainty. The differences come (a) in the curvature, which is much higher for the displacement than for the stress, (b) in the magnitude, a little smaller for the displacements, and (c) in the agreement of the probabilistic methods, being perfect for the case of the stress and not so ideal for the displacement based coefficient of variation. Predictably, the 4th order stochastic perturbation is much better correlating with the other results - up to $\alpha(p) = 0.12$, while the 2nd order – only to $\alpha(p) = 0.07$; the 6th order, available only for the stress-based characteristics, is precise for all the considered uncertainty range.

The higher order probabilistic characteristics (Figs 8-9) are generally less convergent than the previous ones. In this case not only the perturbation-based approach yields different results, but also correlation of the Monte-Carlo and semi-analytical outputs is not perfect, especially for the kurtosis based on the reduced stress. The 4th order perturbation-based approach quite early diverges – at $\alpha(p) \in [0.03,\ 0.06]$, the 6th order is much better here – it diverges only at $\alpha(p) \simeq 0.13$. Nevertheless, these higher characteristics are all smooth and without discontinuities. The 2nd order analysis disallows consideration of these higher order characteristics, since it simply vanishes. The Skewness is all negative with a rather concave manner and a small magnitude comparable for the both output characteristics. This means that both PDFs are increasingly leaning to the right side with an increase in uncertainty. Kurtoses are either only negative with an exponential manner (based on the displacement) or positive with a concave-convex curvature and an apparent inflection point at $\alpha(p) = 0.085$ (based on the stress). Since both, the kurtosis and skewness are quite close to zero, distributions of both output parameters have PDFs close, but still diverging from the normal (Gaussian) distribution for the entire uncertainty range considered here.

4 CONCLUSIONS

This study reports calculation of the first four probabilistic characteristics of the ultimate displacements and the corresponding Huber-Mises stresses based on an input uncertain variable of the external load. The output variables are computed for the three-point bended hyperelastic beam with a Yeoh definition of material, additionally augmented by the Mullins effect. An analysis not only uses a novel iterative stochastic perturbation technique, but also connects it with a hyperelastic material in a large-strain non-linear numerical simulation. The nonlinearities come from the material, contact and constitutive relation. A further extension of this study may include (a) correlation of the material characteristics with experimental results, (b) incorporation of the fracture model in the hyperelastic material definition and (c) sequential or full coupling of this study with temperature analysis; such coupling is important here because the deformation process of elastomers is exothermic and their mechanical properties depend on temperature already in the typical environmental conditions.

Numerical analysis clearly shows that the computational error is quite small for the entire range of the FEs amount and that the preferable brick element type is C3D8R, which has a relatively high precision and provides the highest convergence for a moderate computational effort. The minimum amount of elements used in such study should generally exceed 60 000 elements, since the complex support and material definitions are susceptible to the discretization density. The resulting displacements range here from 3.22 m to 3.48 m and the Huber-Mises stresses - 2.42 Pa to 2.69 Pa for the external load in form of pressure of 0.9 Pa to 1.1 Pa. Both, the stress and the strain obtained here is much below the rupture limit for elastomers, but it certainly belongs to large deformations. Sensitivities of the displacement and Huber-Mises stress to the change in an external load are all positive and much higher for the reduced stress. Probabilistic considerations show a relatively good correspondence in-between different techniques and, predictably, an increasing correlation of the stochastic perturbation-based technique together with an increase of the length of the proposed Taylor expansion. The 6th order expansion is already almost perfectly agreeing with the remaining methods with an ex-

ception of the kurtoses higher than $\kappa(p) \simeq 0.12,$ where it slightly diverges. It should be, however, noted that this order of expansion is available only for the stresses, whose optimal response polynomial has a higher order than the one for the displacements. The probabilistic distributions of the state variables may generally be considered here as close to Gaussian, since both the Kurtosis and Skewness are quite close to zero. Nevertheless, such an assumption should rather be exceptional.

Keywords: Interval Fields, Uncertainty identification, Finite Element modelling, Spatial Uncertainty

Abstract. *In the context of integrating uncertainty and variability in Finite Element (FE) models, several advanced techniques for taking both inter- (between nominally identical parts) and intra-variability (spatial variability within one part) into account have recently been introduced. In the framework of non-probabilistic variability, especially the theory of Interval Fields (IF) has been proven to show promising results. Following this approach, variability in the input parameters of the FE model is introduced as the superposition of a number of base vectors scaled by interval factors. Application of the IF concept however requires identification of these parameters. Recent work has focused on the identification of interval uncertainty for the case of inter-variability. However, to the knowledge of the authors, no such techniques for identifying interval intra-variability are present in literature.*

This work focuses on finding a solution to the inverse problem, where the variability on the output side of the model is known from measurement data, but the spatial uncertainty on the input parameters is unknown. This paper proposes a methodology to solve this inverse problem. The uncertain simulation space, created by propagating an interval field throughout an FE model, is modelled using its convex hull. The same concept is used to model the uncertainty in the measurement space. A metric to describe the discrepancy between these convex hulls, based on the difference of their volumes and overlap, is defined and minimised in order to identify the spatial variability on the input side of the model. Validation of the methodology is performed using simulated measurement data. It is shown that numerically exact identification of a simulated measured IF is possible following the proposed methodology.

1 INTRODUCTION

During the last decades, the incorporation of non-determinism in Finite Element (FE) simulations received wide acceptance among academia and the industry for taking uncertainties that are omnipresent in our everyday life, already into account in an early design phase [1]. Especially for these design purposes, the study of inter-variability (variability between different nominal identical products) as well as intra-variability (variability of model properties within a single component, also referred to as 'spatial variability') proves to be extremely valuable. In this context, non-probabilistic approaches such as Interval Finite Elements (IFE) or Fuzzy Finite Elements (FFE) were introduced, where the uncertainty is depicted as an interval or fuzzy set and thus propagated. In the IFE concept, the uncertainty is modelled as two crisp bounds on the variable between which all possible values lie, and thus propagated. The FFE concept is an extension to this principle, where the membership of a variable to an interval is considered as a continuous function, ranging from 0 (the variable is certainly no part of the interval) to 1 (the variable lies for sure in the interval). [2–5].

In the specific case of spatial uncertainty for the description of intra-variability, two extreme methodologies for the representation of the spatial character of the uncertainty are usually adopted [6, 7]. The first method consists of defining a single interval to represent a spatial varying parameter for the entire model, assuming it is homogeneous throughout the modelled geometry. The second method considers one interval per individual element in the FE model, neglecting all possible dependency throughout the model. The former method poses a serious underestimation of the complexity of the spatial nature of the uncertainty; the latter gives rise to physically infeasible realizations of the uncertainty throughout the model. Moreover, by neglecting all possible dependency, the numerical cost of evaluating the model increases drastically due to the high dimensionality of the input space. As a solution to this, the framework of Interval Fields (IF) was recently introduced [6–8]. The Interval Field concept is based on the superposition of n_b base vectors ,$\boldsymbol{\psi}_i$, which represent a set of spatial uncertainty *patterns*, scaled by independent interval factors α_i^I, which cover the uncertainty.

Despite the current availability of these very advanced techniques for the uncertainty propagation, the use of representative measurement data to quantify the input uncertainty of FE analyses remains nowadays the major challenge. Especially for a designer who is facing a substantial (and often beforehand unknown) variability in the realisation of his design, this knowledge is indispensable when creating reliable products. In literature, some techniques are available to improve the quality of non-deterministic analyses (see e.g., [9–11]). Techniques for updating IFE and FFE models on experimental data were introduced only very recently, based on the minimization of the difference between the extreme boundaries on simulation and measurement data. **Haag et al.** introduced in this context an inverse methodology for the identification of the parameters of FFE models [12]. **Khodaparast et al.** employed a Kriging predictor as a meta-model for the updating of interval [13] and fuzzy [14] finite element models. **Erdogan and Bakir** used a hybrid combination of a Genetic Algorithm and Particle Swarm as updating scheme in the context of the identification of uncertainty in Fuzzy Finite Element models [15]. **Fedele et al.** used an adjoint-based optimisation technique to estimate the bounds of a model parameter, based on uncertain raw measurements [16]. They handled overestimation of the interval width using the inclusion isotonicity property of interval arithmetic. Finally, **Fang et al.** employed interval response surface models for the inverse propagation of the interval uncertainty [17]. The proposed techniques however are incapable of dealing with spatially varying uncertainty, due to the assumption of homogeneity of the uncertainty throughout the model.

It is clear that in order to be representative for the actual intra-variability present in the final components, the Interval Field concept needs an accurate quantification of the driving parameters: the base vectors and interval factors for IF. In the specific case of elastostatic mechanical properties, this quantification is impossible to attain following traditional experimental approaches such as uniaxial tensile tests. This paper therefore focuses on the identification of the spatial uncertainty on the input parameters of an FE model following an inverse approach. The variability in the measurement data is represented as the convex hull in q-dimensions of the complete set of measurement replica. Identification is performed, based on the minimisation of the variability in the simulation output and this convex hull following an Interior-point minimisation scheme. The concept is demonstrated for Interval FE models, but is easily extendable to Fuzzy FE models. Simulated measurement data are used for demonstrating the developed principles.

2 The Interval Finite Element method

The goal of an Interval FE calculation is to find the bounds on the uncertainty in a general multidimensional result $\mathbf{y}$ of an FE calculation $f()$, based on an interval description of the uncertainty in a number of physical properties $\boldsymbol{\gamma}^{\mathbf{I}}$, which are defined as parameters on the input side of the model. Formally, the uncertainty space $\tilde{\mathbf{y}}$ on the output side of an interval FE calculation is defined as:

$$\tilde{\mathbf{y}} = \left\{ \mathbf{y} | \mathbf{y} = f(\boldsymbol{\gamma}) \wedge \boldsymbol{\gamma} \in \boldsymbol{\gamma}^{\mathbf{I}} \right\} \tag{1}$$

By definition, an interval parameter x is indicated using superscript I: x^I. Vectors are expressed as lowercase boldface characters $\mathbf{x}$, whereas matrices are depicted as uppercase boldface characters $\mathbf{X}$. Usually, $\mathbf{y}^{\mathbf{I}}$ is calculated following an optimisation approach, where the extreme responses of each dimension $\underline{y}_i$ and $\overline{y}_i$ are determined by searching the domain, defined by $\boldsymbol{\gamma}^{\mathbf{I}}$ [3]:

$$\begin{aligned} \underline{y}_i &= \min_{\boldsymbol{\gamma} \in \boldsymbol{\gamma}^I} \quad f_i(\boldsymbol{\gamma}) \qquad i = 1, ..., d \\ \overline{y}_i &= \max_{\boldsymbol{\gamma} \in \boldsymbol{\gamma}^I} \quad f_i(\boldsymbol{\gamma}) \qquad i = 1, ..., d \end{aligned} \tag{2}$$

Herein, $y_i^I = [\underline{y}_i; \overline{y}_i]$ is the result interval scalar for the i^{th} node of the model. Solution of eq. (2) returns the smallest hypercubic approximation $\mathbf{y}^{\mathbf{I}}$ of the uncertainty in the solution set $\tilde{\mathbf{y}}$. For the remainder of the text, interval parameters are either represented using the bounds of the interval $x^I = \{\underline{x}, \overline{x}\}$ or the centerpoint $\hat{x} = \frac{\underline{x}+\overline{x}}{2}$ and interval radius $r_x = \frac{\overline{x}-\underline{x}}{2}$.

In the case of spatial interval uncertainty, the input of the IFE model is given as an Interval Field (IF) $\boldsymbol{\gamma}_{\mathbf{F}}^{\mathbf{I}}(\boldsymbol{r})$. The description of an IF is based on the superposition of n_b base vectors $\boldsymbol{\psi}_i$, which represent a set of spatial uncertainty patterns, scaled by independent interval scalars α_i^I, which cover the uncertainty. In this way the dependency between locally defined intervals is given by the base vectors, while the local intervals themselves remain independent. Moreover, the dimensionality of the input space is reduced drastically as compared to defining a local interval for each node of the model. This favours the numerical cost of an evaluation of the IF FE model. Formally, an interval field for the description of spatial uncertainty in the input parameters $\boldsymbol{\gamma}_{\mathbf{F}}^{\mathbf{I}}(\mathbf{r})$ is expressed in the explicit form as:

$$\boldsymbol{\gamma}_{\mathbf{F}}^{\mathbf{I}}(\mathbf{r}) = \sum_{i=1}^{n_b} \alpha_i^I \boldsymbol{\psi}_i(\mathbf{r}) \tag{3}$$

3 Identification of interval fields

The application of the interval field approach for the representation of spatial uncertainty requires the identification of its constituting parameters. The methodology starts from the expert knowledge of the analyst on the amount and shape of the base functions necessary to represent the interval field at the input side of the model and incorporates measurement data to identify the amount of uncertainty, which is captured by the interval vector $\boldsymbol{\alpha}^I$.

The propagation of the uncertainty in the physical parameters $\boldsymbol{\gamma}_{\mathbf{F}}^{\mathbf{I}}(\mathbf{r})$ of an FE model typically yields a d-dimensional uncertainty space $\tilde{\mathbf{y}}$, of which $\mathbf{Y}_s \in \mathbb{R}^{d \times q}$ is the matrix containing all q propagated realisations of $\boldsymbol{\gamma}_{\mathbf{F}}^{\mathbf{I}}(\mathbf{r})$. In the context of identifying the input interval field, a quantification of $\mathbf{Y}_s$ is necessary to steer the updating procedure. Therefore its convex hull $\mathbf{C}_s$ and corresponding volume V_s are calculated. In general, the convex hull of a finite set of vectors in Euclidean space is defined as the set of all convex combinations of these vectors. It may also be shown that the convex hull is the smallest possible convex set, encompassing the vectors in $\mathbf{Y}_s$. The uncertainty space, spanned by the computed realizations in $\mathbf{Y}_s$, may contain any combination of output quantities, ranging from nodal output quantities such as displacements, stresses or temperatures to global quantities such as eigenfrequencies and -modes.

The measurement data are obtained trough an experimental procedure where the model is physically tested in analogy to the FE model under consideration. The scattered measurement points, having the same dimensionality d as $\tilde{\mathbf{y}}$, are grouped in $\mathbf{Y}_m \in \mathbb{R}^{d \times t}$, with t the number of test replica. In general, the dimensionality of the experimental and simulation data is not identical. However, through the usage of data interpolation for the measurement data or model reduction techniques for the simulation model, this condition can be achieved. Analogous to the simulation data, the convex hull $\mathbf{C}_m$ and its corresponding volume V_m are calculated. The QHULL library is used to compute the convex hulls. This library makes use of the "Quickhull" algorithm, as developed by **Barber et. al** [18].

Identification of $\boldsymbol{\alpha}^I$ is made through the minimisation of a cost function $\delta(\boldsymbol{\alpha}^I)$, expressing the discrepancy between the output space of the IFE simulation $\mathbf{Y}_s$ and repeated measurement data $\mathbf{Y}_m$. $\delta(\boldsymbol{\alpha}^I)$ is calculated, based on the geometrical properties of the d-dimensional convex hulls $\mathbf{C}_m$ and $\mathbf{C}_s$. More specifically, the difference between the volumes V_m and V_s of the respective hulls and the volume V_o of the intersection $\mathbf{C}_o$ of $\mathbf{C}_m$ and $\mathbf{C}_s$ is taken into account. Due to the convexity of $\mathbf{C}_m$ and $\mathbf{C}_s$, $\mathbf{C}_o$ is also convex. When there is no overlap (i.e. $\mathbf{C}_o = \emptyset$) present between $\mathbf{C}_m$ and $\mathbf{C}_s$, a descent direction for the optimisation problem is ensured by incorporating the squared L_2 norm of the difference between the center of gravity of respectively $\mathbf{C}_m$ ($\mathbf{c}_m$) and $\mathbf{C}_s$ ($\mathbf{c}_s$). Formally, $\delta(\boldsymbol{\alpha}^I)$ is defined as:

$$\delta(\boldsymbol{\alpha}^I) = \left(\left(1 - \frac{V_s}{V_m}\right)^2 + \left(1 - \frac{V_o}{V_m}\right)^2 + \|\mathbf{c}_m - \mathbf{c}_s\|_2^2 \right)^{1/2} \tag{4}$$

The goal interval vector $\boldsymbol{\alpha}^{I,*}$ is finally identified according to:

$$\boldsymbol{\alpha}^{I,*} = argmin\ \delta(\boldsymbol{\alpha}^I) \tag{5}$$

4 VALIDATION

Validation the developed methodology is performed using a dynamic model of a 1-dimensional cantilever beam, shown in figure 1. A finite element model containing 10 quadratic shell elements with 4 nodes is constructed and evaluated for the first 10 eigenfrequencies f_e. Without

the loss of generality, it is assumed that the stiffness of the beam is subjected to spatial uncertainty, which is modelled using the Interval Field concept, with $\mathbf{r}_1 = 2$ and $\mathbf{r}_2 = 7$, with locally defined intervals $\boldsymbol{\alpha}_1^I$ and $\boldsymbol{\alpha}_2^I$ capturing the uncertainty. Hyperbolic base functions $\boldsymbol{\psi}_i(\mathbf{r})$ are assumed, which are known *a priori*. This leads to a simulation space $\mathbf{Y}_s \in \mathbb{R}^{q \times d}$, with $d = 10$. In this specific case, the Interval Field FE model is solved using the vertex method, leading to $q = 2^2 = 4$ realisations of the simulation space.

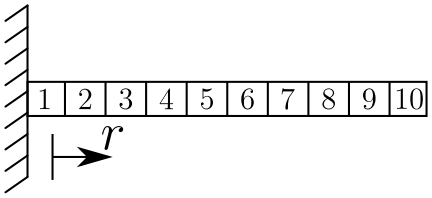

Figure 1: Illustration of the Finite-Element model of the cantilever beam on which the methodology is validated. $\mathbf{r}$ indicates the positive direction along the beam, the numbers in the finite elements indicate the element numbers.

For benchmarking purposes, measurement data is simulated using an *a priori* defined interval field, based on known local intervals $\boldsymbol{\alpha}^I \in \mathbb{IR}^2$, located at $\mathbf{r}_1$ and $\mathbf{r}_2$. Concretely, the goal local intervals are defined as $\alpha_1^I = [1.35e6; 1.55e6]$ and $\alpha_2^I = [1.65e6; 1.85e6]$.

The measurement space $\mathbf{Y}_m \in \mathbb{R}^{t \times d}$ is generated by performing $t = 500$ Monte Carlo simulations, while assuming a uniform distribution between the extreme boundaries of the local intervals $\boldsymbol{\alpha}^I$. Thus, 500 deterministic fields on the stiffness are solved for the first 10 f_e, in order to construct the 10-dimensional measurement space.

The results of the identification procedure are shown in table 1. It can be seen that the proposed methodology is capable of determining the goal interval field, with a local maximum error of 0.042%. This error could be improved by tightening the convergence criteria on the optimization process or propagating more Monte Carlo samples for the representation of the measurement data. However, because it is already negligible, it can be defined as *numerically exact*. The error listed in table 1 is defined as:

Table 1: Results of the identification procedure on an Interval Field capturing the spatial variability in the cantilever beam example.

	$\underline{\boldsymbol{\alpha}}_1^I\ [Pa]$	$\overline{\boldsymbol{\alpha}}_1^I\ [Pa]$	$\underline{\boldsymbol{\alpha}}_2^I\ [Pa]$	$\overline{\boldsymbol{\alpha}}_2^I\ [Pa]$
Goal	$1.35 \cdot 10^6$	$1.65 \cdot 10^6$	$1.55 \cdot 10^6$	$1.85 \cdot 10^6$
Initial	$1.00 \cdot 10^6$	$1.1 \cdot 10^6$	$1.81 \cdot 10^6$	$2.30 \cdot 10^6$
Initial error (%)	15.5%	35.5%	9.7%	24.3%
Result	$1.356 \cdot 10^6$	$1.652 \cdot 10^6$	$1.554 \cdot 10^6$	$1.849 \cdot 10^6$
Error (%)	0.042%	0.025%	0.001%	0.007%

Figure 2 shows the convergence plots. Absolute convergence is obtained after 37 iterations of the optimization process, whereas the locally defined input intervals do not change significantly after 22 iterations. The discrepancy metric δ, defined in equation 4 decreases over the optimization from 8.99 to 0.017.

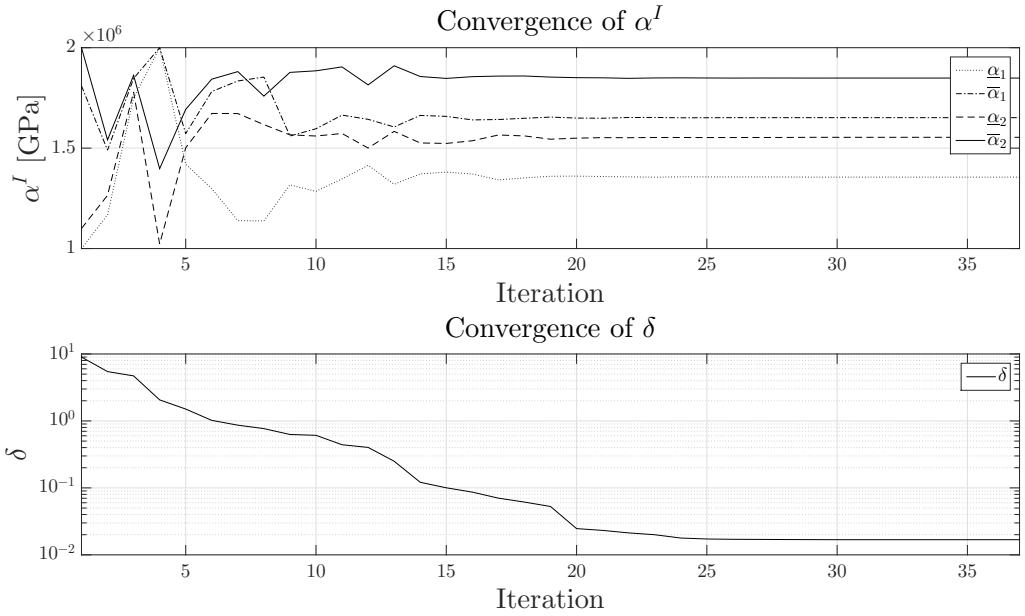

Figure 2: Convergence of the updating procedure. As can be noted, convergence is approximately obtained after 20 iterations. Absolute convergence is only obtained after 37 iterations.

Finally, figure 3 shows a selection of the convex hull over 4 sets of eigenfrequencies before and after the updating procedure. The accurate identification of the interval field encompassing the measurement data is also evident from these plots.

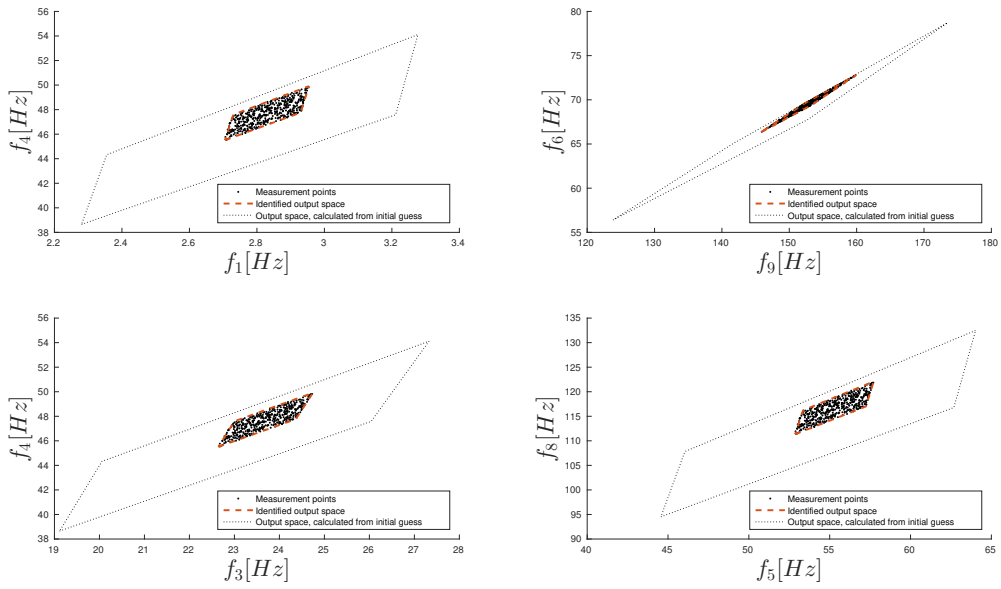

Figure 3: Illustration of the extreme realizations of the input field $\boldsymbol{\gamma}_F^I(\mathbf{r})$ before and after identification, as well as the *goal* input field as a function of the element number.

5 CONCLUSIONS AND FUTURE WORK

In order to represent spatial uncertainty in the physical model parameters constituting the input of a Finite Element (FE) model, the Interval Field theorem proves to deliver accurate results with a limited set of data. The use of this concept however, requires the identification of its driving parameters, the interval factor $\boldsymbol{\alpha}^I$ and a number n_b of base vectors $\boldsymbol{\psi}_i(\mathbf{r})$. A general methodology to identify $\boldsymbol{\alpha}^I$, based on the incorporation of measurement data was introduced. The concept of the identification is based on the convex properties of the uncertainty space, stemming from propagating the input interval field through the interval FE solver on the one hand, and the calculation of the convex hull of the measurement data on the other hand. A measure of discrepancy is defined, and identification is performed by minimising this measure.

The methodology was validated on an industrially sized case study of an axisymmetric model of a pressure vessel using simulated measurement data. It was found that $\boldsymbol{\alpha}^I$ could be identified up to *numerically exact*, using the proposed methodology, within a limited number of iterations.

Future work will be aimed at extending the developed methodology towards the identification of base vectors $\boldsymbol{\psi}_i(\mathbf{r})$ and dimensionality of input space n_b, based on the defined discrepancy measure. Also techniques for the reduction of the output dimensionality will be considered for speeding up the updating process. Finally, also the incorporation of real life measurement data, e.g. coming from full-field strain measurement techniques for elastostatic applications or eigenfrequencies for structural dynamic applications is foreseen in the near future.

Abstract. *Deterministic optimisations result in optimum designs for the specified load case but in unstable designs when load cases change. Limitations or uncertainties have to be taken into account leading in design optimisations which will then be insensitive to small fluctuations of geometric or input parameters. Such a stochastic analysis is often referred to as robust design optimisation.*

This paper presents a Robust Design Optimisation for the illustrative example of a cylindrical metal crash tube. The goal of the optimisation is to attain a crash structure which is insensitive to small fluctuations in the magnitude of the crash load, the direction of the velocity, as well as the mass of the impactor. The tilting of the impactor is modelled with a stochastic approach. The geometry of the crash tube shall be insensitive to uncertainties by optimising the wall thickness and by introducing beadings into the tube. Robust design optimisation was conducted with LS-OPT, combining ALTAIR HYPERMORPH for small geometrical adaptions and LS-DYNA for finite element method simulations. To reduce the computational effort, the optimisation is based on metamodels as this allows for mathematical optimisation.

Robust design optimisation allows for results less sensitive to small system fluctuations and hence the geometric tube tolerances can be reduced or the field of application (e.g. vehicle class) can be increased.

For the presented crash tube this advantage results in more stable crash results for scenarios departing from the standard. This in turn leads to increased safety levels of life protection systems. The use of robust design optimisations on the presented crash tube leads to geometries being 6% heavier than the ideal optimum results, but being more robust towards geometric or load fluctuations.

1 INTRODUCTION

The safety level of automotive industry increases steadily in order to accomplish stringent regulations at reduced weight. To attain these targets crash structures have to be refined and optimised. These optimisations are mostly performed with deterministic approaches, assuming that the optimisation systems behave idealistically. But, as Weigert [1] illustrated (figure 1), the input as well as output parameters face fluctuations (blue and greens bars), which are neglected by a state-of-the-art deterministic analysis (red dots). Stochastic optimisations can be used considering statistical distributions of input and output parameters to improve the optimisation and its results.

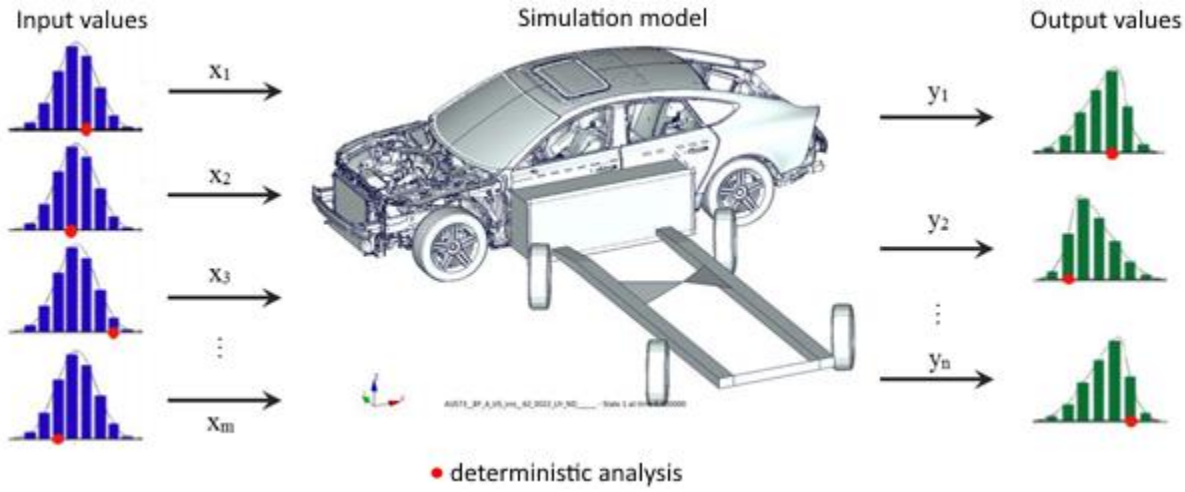

Figure 1: Illustration of a finite element simulation model and its fluctuations of the input values (blue bars) and the output values (green bars) which are neglected by a deterministic analysis (red dots) [1]

Robust Design Optimisation (RDO) is a stochastic optimisation method investigating the robustness of components or assemblies. A robust design is not susceptible to small fluctuations or uncertainties in the observed system. These uncertainties may occur through environment (e.g. ambient temperature), the Finite Element (FE) model (e.g. material parameters) or in the sensors and measurements (e.g. measuring errors) [2, 3]. RDO considers such uncertainties as noise variables with statistical measures as for example the normal distribution of the yield strength.

The aim of such an RDO is a design which is insensitive to these uncertainties and which is ideally leading to a fail-safe system. The influence of the noise variables shall be minimised by optimising the control parameters (e.g. the wall thickness, a parameter controllable by the design engineer).

A deterministic optimum is mostly located near the limit given by the constraints. As a consequence a deterministic design tends to failure, if small fluctuations occur in the system. Therefore a robust design is very important for safety of critical systems.

The following sections will focus on the process necessary to develop a robust design optimisation. Section two deals with the optimisation setup and its methodology. Section three presents the FE model, particularly its boundary conditions and loadings, while the forth section shows and discusses the results. The final section concludes the present paper.

2 OPTIMISATION SETUP AND METHODOLOGY

As the idea of the robust design originates in Taguchi [4], his methods are widely spread. Taguchi's idea was to reduce the impact of uncertainties in the system rather than to control them which is hardly possible. In order to reduce the computational effort the mean value and variance of the parameters are then combined into one variable. This simplification is not necessary for today's standards and does not meet the grown demands. Current optimisation programmes use the Dual Response Surface Methodology (DRSM) [5], as for example LS-OPT [6], which was applied in the course of this paper. DRSM uses a response surface for both the mean value and the variance. This simplifies the optimisation process and enables multi-criteria optimisation, in contrast to the Taguchi approach where detailed information of the variables is lost by combining them.

The robust parameter design method of LS-OPT is a metamodel-based optimisation [7]. A metamodel is a surface, describing the systems response. As the metamodel can be analysed by mathematical methods, the optimisation is very fast. This can be seen in the timing information shown in figure 2. The comparison of clock time shows that the completion of the FE simulations needs 75% of the total time, whereas the metamodeling (0.12%) and its optimisation (0.22%) needed together 0.34% of the total time.

Figure 2: Timing information for a robust design optimisation

In this paper robust optimisations are presented whose aim is to gain a better performance of a crash tube, insensitive to uncertainties in the loading and boundary conditions, through introducing beadings to the crash tube and optimising the wall thickness.

ALTAIR HYPERMORPH [8] was used to introduce beadings into the crash tube. This programme allows the morphing of an existing mesh hence enabling small changes of the geometry by displacement of nodes. Figure 3a shows the original mesh. The mesh is sectioned with morph volumes (green boxes). The red dots are handles which are used to change the position of the tube's nodes (see Figure 3b). The displacement of the tube's nodes can be parameterised. Due to a specific interface between HYPERMORPH and LS-OPT handle parameters can be changed by LS-OPT. This enables a fully automated optimisation of the mesh within the given boundaries.

The morphed mesh models are then transferred to the LS-DYNA solver and simulations are calculated. Again the input decks are parameterised for an automated optimisation. The setup for the FEM simulations will be discussed in the following section.

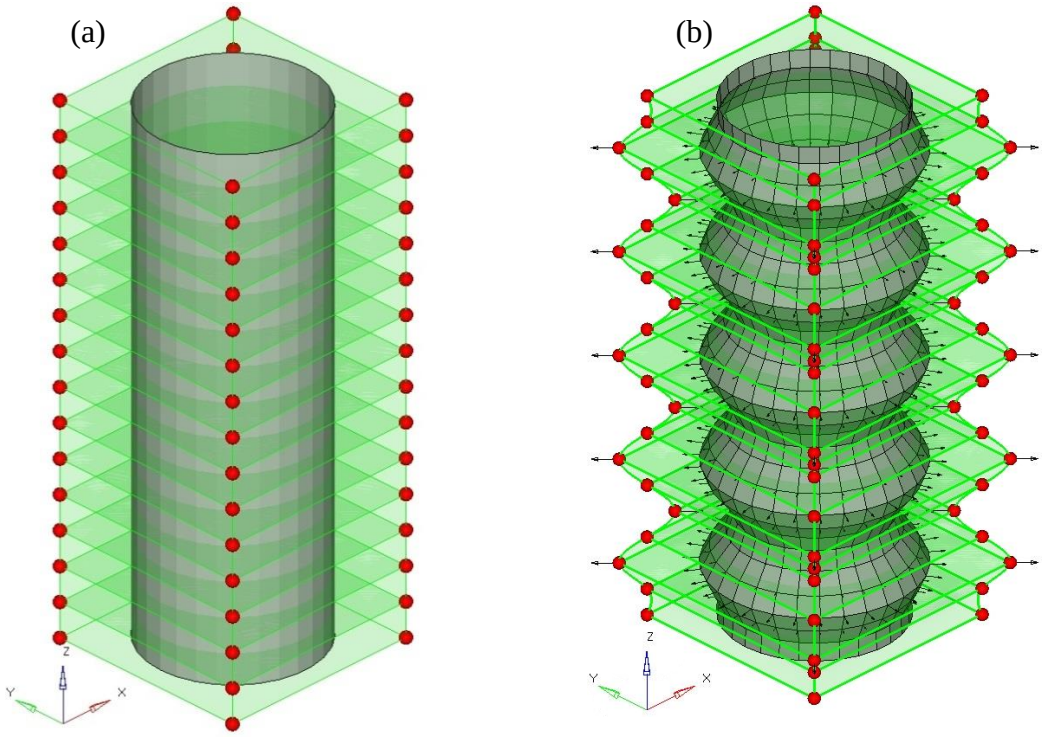

Figure 3: Illustration of the morphing with ALTAIR HYPERMORPH; (a) display of the morph volumes (green boxes) and the handles (red dots); (b) illustration of moved handles and morphed mesh

3 FINITE ELEMENT MODEL

The basic FE model (Figure 4a) describes a crash tube with a mid-section diameter of 100 mm, a height of 300 mm and a wall thickness of 3 mm. The mesh of the tube consists of quadratic shell elements with an edge length of 10 mm. The tube is fixed in space on a solid base plate with a groove to support the tube and prevent it from sideward sliding. The load is applied via a top rigid plate, which has an artificial mass of 1.5 tons and a velocity of about 30 km/h. The present FE model is a fictional example and not based on any standard crash procedure.

The crash tube is modelled as a steel component. The used material is a carbon steel A572 with a yield strength of 315 MPa and an ultimate strength of 683 MPa. The maximum elongation of this material is about 60%. The material data are taken from Varmint [9], due to the possibility to absorb the loads without material failure. It would be possible to consider material failure, but this would increase the simulation time enormously without further information concerning RDO. MAT_PIECEWISE_LINEAR_PLASTICITY was chosen to model this material in LS-DYNA. The impactor and the solid plate are modelled as rigid components with MAT_RIGID definition.

The FEM model is parameterised in the wall thickness. The wall thickness is controlled by separate parameters for each node over the height of the tube. The parameters for the wall thickness can be used to weaken or strengthen the tube through the introduction of beadings. The wall thickness and the beadings introduced by HYPERMORPH are the defined control parameters, which shall decrease the influence of the noise parameters.

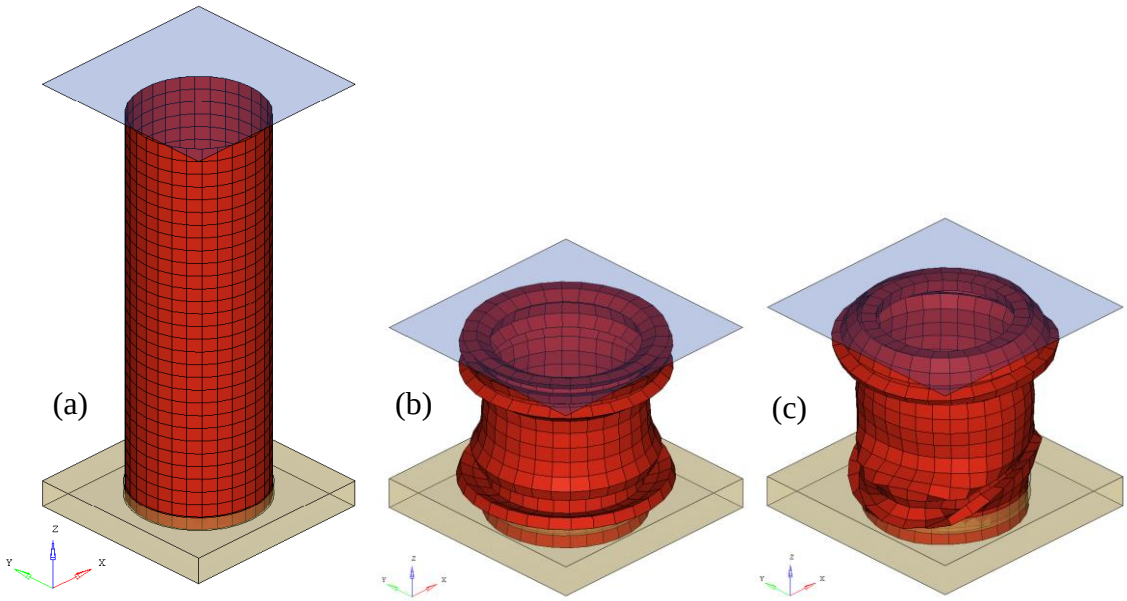

Figure 4: (a) FE model of crash tube and set up for a RDO (b) crash pattern of the original geometry and (c) crash pattern of the robust geometry

The noise parameters (=fluctuations) are the impactor mass, its velocity in terms of magnitude and direction, as well as a small tilting of the impactor. All of the noise parameters are described with a Gaussian distribution. The impactors mass has a mean value of 1.5 tons with a standard deviation of ±0.1 tons. The normal distribution of the magnitude of the velocity is described with a mean value of 8340 mm/s and a standard deviation of ±200 mm/s. The direction of the velocity is modified in a spherical coordinate system, where φ describes the angle between the x-axis and the projection of the vector on the x-y-plane and ϑ describes the angle between the vector and the z-axis. A mean value of 0^o and a standard deviation of $\pm 0.5^o$ build up the normal distribution of ϑ. The angle φ is described with a truncated normal distribution with a mean value of 0^o and a standard deviation of $\pm 0.5^o$.

4 RESULTS

Figure 5 illustrates the force displacements curves of the different optima (solid lines) as well as their mean values (dashed lines).The initial tube geometry (black line) has a maximum load capacity of 450 kN and an energy absorption of 38 kJ (at a deformation length of about 160 mm). The deterministic design optimisation (green lines) increases the maximum load capacity by 18% to 540 kN by varying the wall thickness and introducing beadings. In contrast, the robust design optimisation (blue lines) achieves an increase of 8% to 495 kN for the maximum load capacity. The energy absorption is increased by 21% for the deterministic design and by 13% for the robust design.

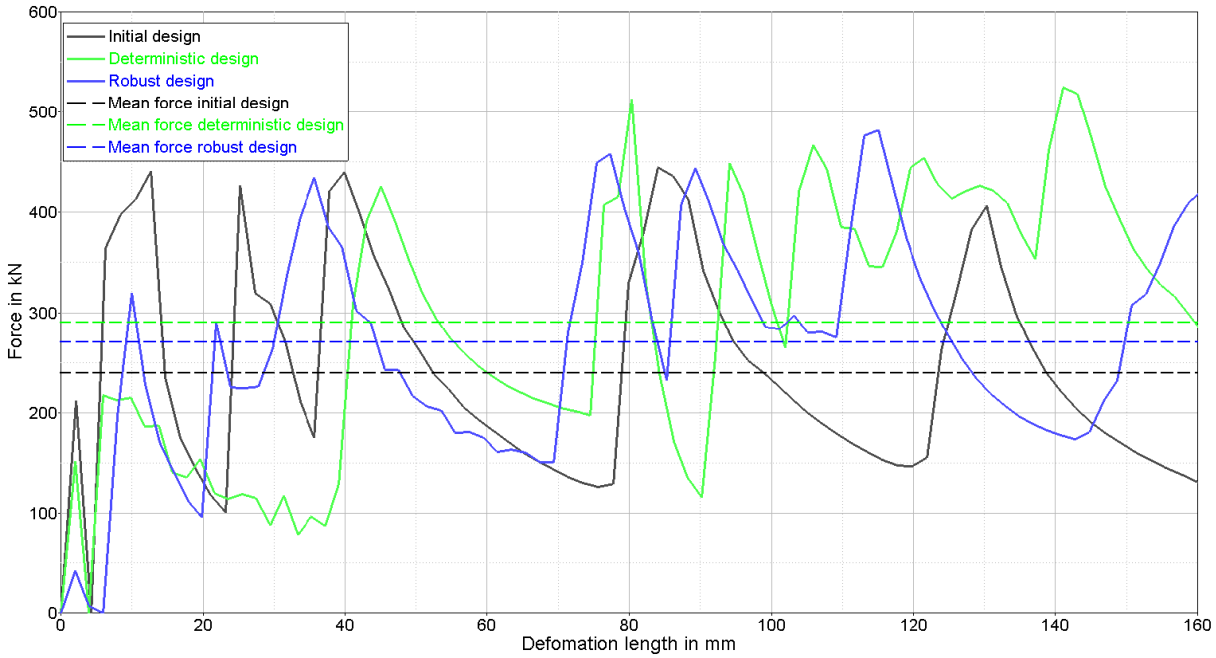

Figure 5: Force-displacement curves (solid lines) and corresponding mean force values (dashed lines)

Figure 6 shows the comparison of the beading depth of the robust and the deterministic optimum. The beading depth of the deterministic optimum is more pronounced compared to the robust optimum (with a difference of about 0.25 mm).

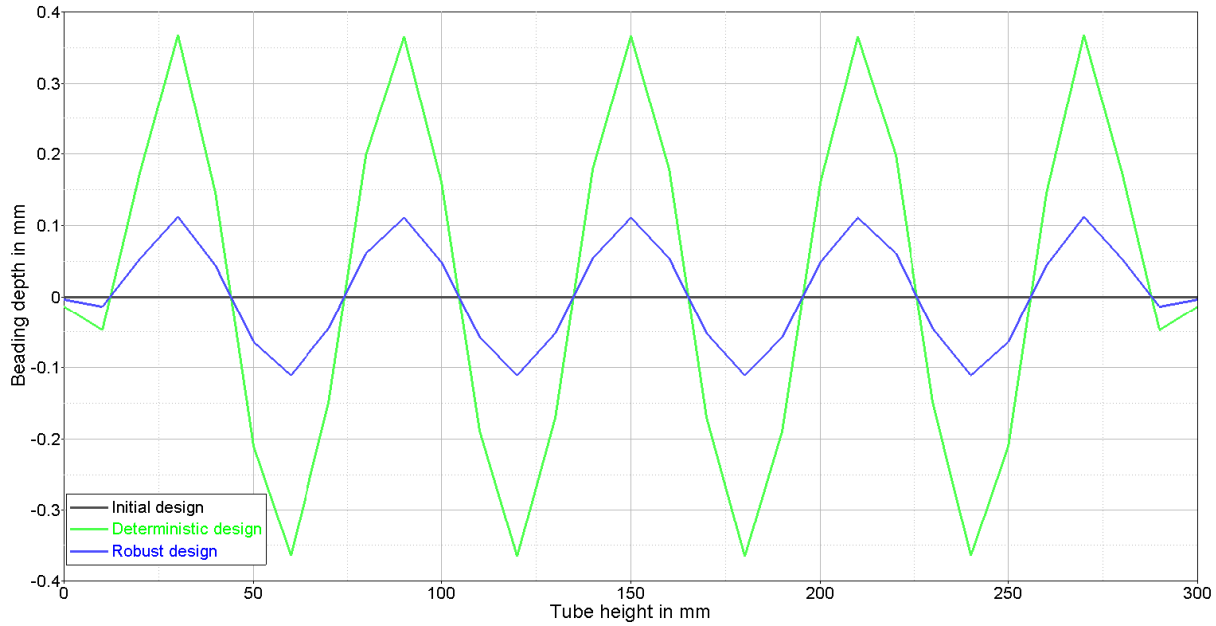

Figure 6: Illustration of the beading depth of the optimised designs compared to the initial design

Figure 7 compares the resulting wall thicknesses along the height of the tube. The curves of the deterministic and the robust design follow similar paths. Nevertheless the maximum wall thicknesses vary significantly from 1.2 mm to 4.8 mm in the case of the deterministic optimum but only from 1.5 to 4.7 mm in the robust optimum.

The robust optimum allows for a better resistance against non-standard loads, while the deterministic optimum optimises the folding behaviour for the ideal load scenario.

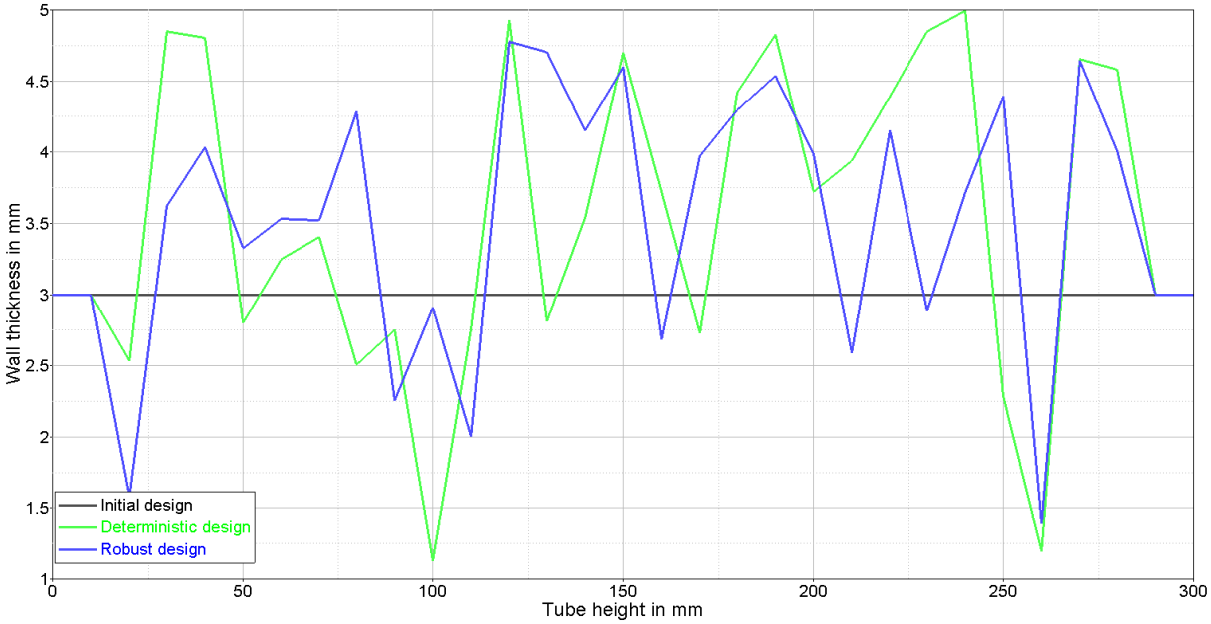

Figure 7: Illustration of the wall thickness along the height of the tube

5 CONCLUSION

Robust optimisation leads to an optimal design, which is better convertible to real life than deterministic designs as being robust against fluctuations. The present paper shows that the robust optimum design achieves increased maximum load capacity as well as a better overall energy absorption compared to the initial design. However, the optimal deterministic design achieves better results for the ideal load case. If there are deviations from the standard scenario, the deterministic optimum tends to failure. This happens, because a deterministic optimum is very often near the border of the constraints. Consequently a small modification of the optimised system may lead to constraint violation and therefore failure of the system.

Investigations show that the robust design optimisation does not necessarily result in the global optimum. It results in a local optimum, which is less sensitive to small system fluctuations. As a result the geometric tube tolerances (=process tolerances) can be reduced or the field of application (e.g. vehicle class) can be increased. For the presented crash tube, this advantage results in more stable crash results for scenarios departing from the standard. This in turn leads to increased safety levels of life protection systems.

Keywords: possiblistic analysis, interval analysis, interval fields, Finite Element analysis

Abstract. *In uncertainty quantification, interval arithmetic provides an appropriate procedure when little knowledge is available on the nature of the probability distribution of uncertain or imprecise quantities. This commonly occurs in engineering applications due to subjective knowledge or incomplete availability of test data. Intervals are by definition unable to take into account dependent input and output quantities, which forces the assumption of independency when applying them. This is a severe limitation on the accuracy of the analysis as dependency is always present to some extent. The concept of interval fields (IF) [1] provides a solution by defining non-deterministic fields using interval parameters. In its simplest form [2], the field is expressed as a weighted sum of basis functions, the weights being modelled using interval parameters. The dependency within the field is then captured by the basis functions, which describe the spatial nature of dependency, whereas the magnitude of uncertainty is captured by the weights. Field parameters are usually associated to geometric quantities (such as plate thickness), but they can be applied generally whenever multiple uncertain input or output quantities are involved. Both at the input and output side of a numerical analysis, IF can be used for a more realistic description of the estimated uncertainty. At the input side, taking into account dependency reduces overestimation on the output uncertainty bounds. At the output side, it is important that a realistic uncertain set of output quantities is represented as closely as possible without adding conservatism, as this corrupts the results of possible postprocessing or follow-up analysis. The application of IF here provides an important step towards achieving this goal.*

This paper aims to apply IF to analyse structural Finite Element models with uncertain structural properties. The property of interest in this paper will be the E-modulus. The concept of IF will be used to model spatial dependency within this parameter and will lead to a more accurate estimation of the output uncertainty.

1 INTRODUCTION

1.1 Possibilistic uncertainty analysis

In numerical modelling, Uncertainty Analysis (UA) concerns the identification and quantification of possible sources of uncertainty within a model, with the purpose of obtaining information on the uncertainty present in the model's relevant output. In this context, a non-deterministic approach of the modelling process is essential. Instead of the classical deterministic representation of model parameters, non-deterministic concepts are used to open up the possiblity of representing uncertainty on the parameters. These concepts can be divided in two groups. Firstly, *probabilistic analysis* uses probability distributions and stochastic parameters to assign a finite probability to a parameter having a certain value. Secondly, *possiblistic analysis* omits the concept of probability and only concerns the possiblity of a parameter having a certain value. Intervals, fuzzy numbers and convex regions are commonly used for this purpose. The choice of which approach to follow is usually based on the availability of knowledge on the uncertainty that is present. The definition of probability functions requires extensive knowledge on the uncertain parameter of interest. In practise, the Gaussian distribution is often assumed to estimate the stochastic moments, but the infinite base of this distribution poses a fundamental objection to this. Also, to accurately estimate stochastic parameters, a lot of experimental data is required. When experimental data is hard or expensive to obtain or their quality is questionnable, possibilistic analysis becomes an interesting alterative. The interval approach provides a much lower threshold to perform a non-determistic analysis than the stochastic approach. Also numerically, experiments can be expensive in terms of computational time, limiting the use of sample based stochastic techniques such as Monte Carlo Sampling. This paper will focus on the interval approach as basic tool for possibilistic analysis, and apply it in the context of a structural Finite Element (FE) model.

1.2 Modelling geometric uncertainty

Uncertain parameters in FE models typically have a spatial character: material properties such as density and Young's modulus or geometric properties such as plate thicknesses are geometrically oriented in space. In uncertain context, these parameters can show variability over the spatial domain, referred to as *geometric variability*. In FE-models, such a geometric parameter is discretised to the elements, leading to a set of discrete variables representing that variable in each element of the model. According to the possibility of geometric variability, the value in each element can vary separately, leading to different values in each element. However, some degree of dependency will usually be present and the value in different elements can not vary independently. Here the interval concept poses a problem. The uncertainty in each element could be captured by an interval parameter marking the bounds of the variation, but interval parameters are by definition incapable of incorporating the dependency present in the spatial domain. To mark the uncertainty present in such *field parameters* using a possiblistic technique, the *interval field* technique can be used as illustrated in equation 1. In its simplest form, an interval field consists of basis functions $\phi(\mathbf{r})$ representing the dependency and interval coefficients α^I representing the uncertainty.

$$y^I(\mathbf{r}) = \sum_{i=1}^{n} \alpha^I \phi_i(\mathbf{r}) \tag{1}$$

1.3 Dependency in a possibilistic context

For non-deterministic field parameters, a parameter needs to be defined that represents the level of dependency within the field. In stochastic FE context, as dictated by the theory of random fields (RF) [3], the correlation length is often used as measure for the dependency in the spatial domain. In this case, the correlation between values in different points is made a function of the distance between the points, with the correlation length $L_\rho$as governing parameter. The example of an exponential relationship is given in equation 2.

$$COV(x(\mathbf{r}_1), x(\mathbf{r}_2)) = \exp\left(\frac{\|\mathbf{r}_1 - \mathbf{r}_2\|}{L_\rho}\right) \tag{2}$$

As correlation is only defined in stochastic context, use of this parameter in possibilistic context is not straightforward. The authors proposed the use of the *maximum gradient* as parameter governing the dependency in the field, as this better fits the possiblistic approach than the correlation. The subject of this paper will be to apply this approach to identify the variability of the natural frequencies of a steel plate with geometrically varying Young's modulus.

2 MODELLING THE INPUT UNCERTAINTY: THE LOCAL INTERVAL FIELD DECOMPOSITION

2.1 General concept

Referring to [4], the Local Interval Field Decomposition (LIFD) was introduced to incorporate the maximum derivative constraint in a 1D non-deterministic field. This decomposition method puts a radial-based basis function and corresponding interval parameter in each element of the FE model. Therefore, *the dimensionality of the uncertainty is equal to the number of elements*. The reason for this approach is that, regardless of the level of dependency, each element can (at least partially) determine its own value and as a result, the dimensionality is equal to the number of elements. However, the issue of the dependency between the elements still stands. Through the LIFD, the initial interdependent interval set is transformed to an interval set of (at least) equal size that is *independent*, while still obeying the maximum derivative constraint. The following section considers the expansion of the LIFD to 2D non-deterministic fields.

2.2 Derivation of the LIFD in 2 dimensions

Suppose we have a field parameter $u(x, y)$ with x, y the spatial coordinates in a 2D-plane. We define the gradient $\nabla u(x, y)$ and its norm G as:

$$\nabla u(x, y) = \left(\frac{\partial u(x, y)}{\partial x}, \frac{\partial u(x, y)}{\partial y}\right) \tag{3}$$

$$G = \sqrt{\left(\frac{\partial u(x, y)}{\partial x}\right)^2 + \left(\frac{\partial u(x, y)}{\partial y}\right)^2} \tag{4}$$

For a certain realisation $\tilde{u}(x, y)$, the maximal and minimal value for that specific realisation are defined as $\max_{x,y} \tilde{u}(x, y) = \overline{u}$ and $\min_{x,y} \tilde{u}(x, y) = \underline{u}$. The LIFD in 2D will write the non-determistic field $u(x, y)$ as an interval field $u^I(x, y)$ in the form of equation 1 that obeys the following statements:

1. $\forall(\tilde{x}, \tilde{y}) \in \Omega : U_{min} \leq u(\tilde{x}, \tilde{y}) \leq U_{max}$

2. $\forall(x,y) \in \Omega : \sqrt{\left(\frac{\partial u(x,y)}{\partial x}\right)^2 + \left(\frac{\partial u(x,y)}{\partial y}\right)^2} \leq G_{max}$

3. $\forall \tilde{u}(x,y) : \overline{u} - \underline{u} \leq D_{max}$

The parameters G_{max}, U_{min}, U_{max} and D_{max} can be independently set. The first statement demands that the absolute bounds on the field parameter U_{min} and U_{max} are never exceeded. The second statement demands that the norm of the gradient never exceeds a preset value. This statement accounts for the dependency in the field. The third statement puts a bound on the difference between the maximal and minimal value of any realisation of the interval field. The objective of the LIFD is to obey the statements using the four governing uncertainty parameters mentioned above with an explicit interval field description with *independent* interval coefficients.

The only freedom we have is the shape of the basis functions. In the 2D-case, the basis functions have the following properties:

1. All ϕ_i are identically shaped radial basis functions.

2. A single ϕ_i is positioned at each element at location $\mathbf{r}_i$ of the FE mesh.

3. All ϕ_i are piecewise second order polynomial functions so the first derivatives are continuous.

figure 1 illustrates the shape of a basis function. For a basis function centered at element i with coordinates x_i and y_i, the mathematical definition is given by equation 5.

$$\phi_i(x,y) = \begin{cases} 0 & R < \sqrt{(x-x_i)^2 + (y-y_i)^2} \\ \frac{2(r-r_i+R)^2}{R^2} & \frac{R}{2} < \sqrt{(x-x_i)^2 + (y-y_i)^2} \leq R \\ 1 - \frac{2(r-r_i)^2}{R^2} & 0 \leq \sqrt{(x-x_i)^2 + (y-y_i)^2} \leq \frac{R}{2} \end{cases} \tag{5}$$

with $r = \sqrt{x^2+y^2}$ and $r_i = \sqrt{x_i^2+y_i^2}$. To comply with all demands, the following explicit field is proposed:

$$u^I(x,y) = C^I + \sum_{i=1}^{n} a \cdot 1_i^I \cdot \phi_i(x,y,R), \tag{6}$$

with $C^I = \left\langle \underline{C} | \overline{C} \right\rangle$ and $1_i^I = \langle 0|1 \rangle$ defined as the *unity* interval. The four controllable parameters are $\underline{C}$, $\overline{C}$, a and R. A unique mapping between these parameters and the four global uncertainty pararmeters is given by equation 7:

$$\begin{aligned} U_{max} &= \frac{7\pi \cdot a \cdot R^2}{24 \cdot dx \cdot dy} + \overline{C} \\ U_{min} &= \underline{C} \\ G_{max} &= \frac{a \cdot R}{dx \cdot dy} \\ D_{max} &= \frac{7\pi \cdot a \cdot R^2}{24 \cdot dx \cdot dy} \end{aligned} \tag{7}$$

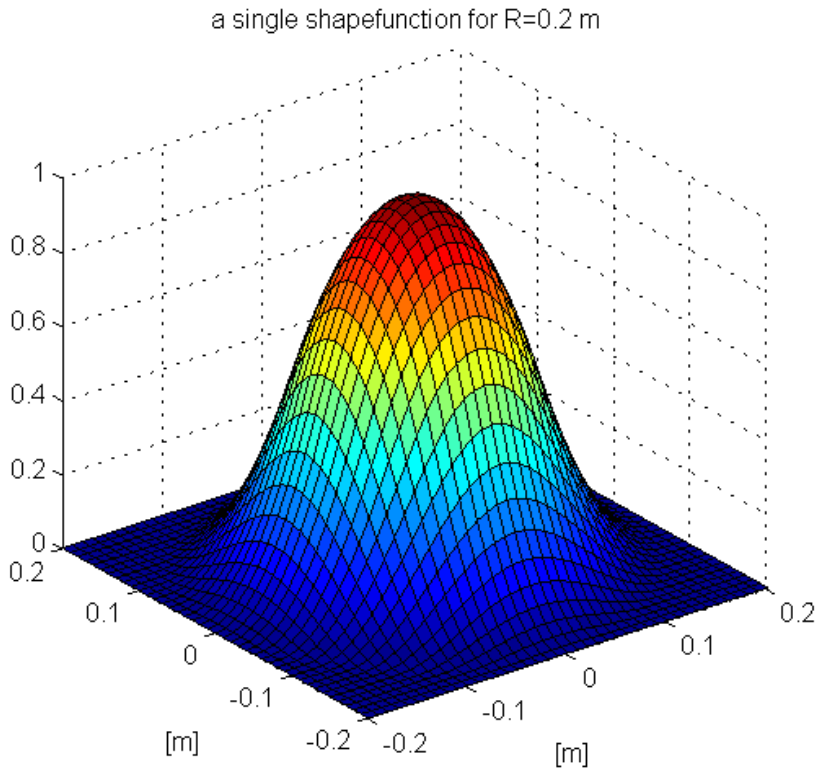

Figure 1: shape of a 2D radial basis function. Beyond a radius R from the center point, the basis function equals zero.

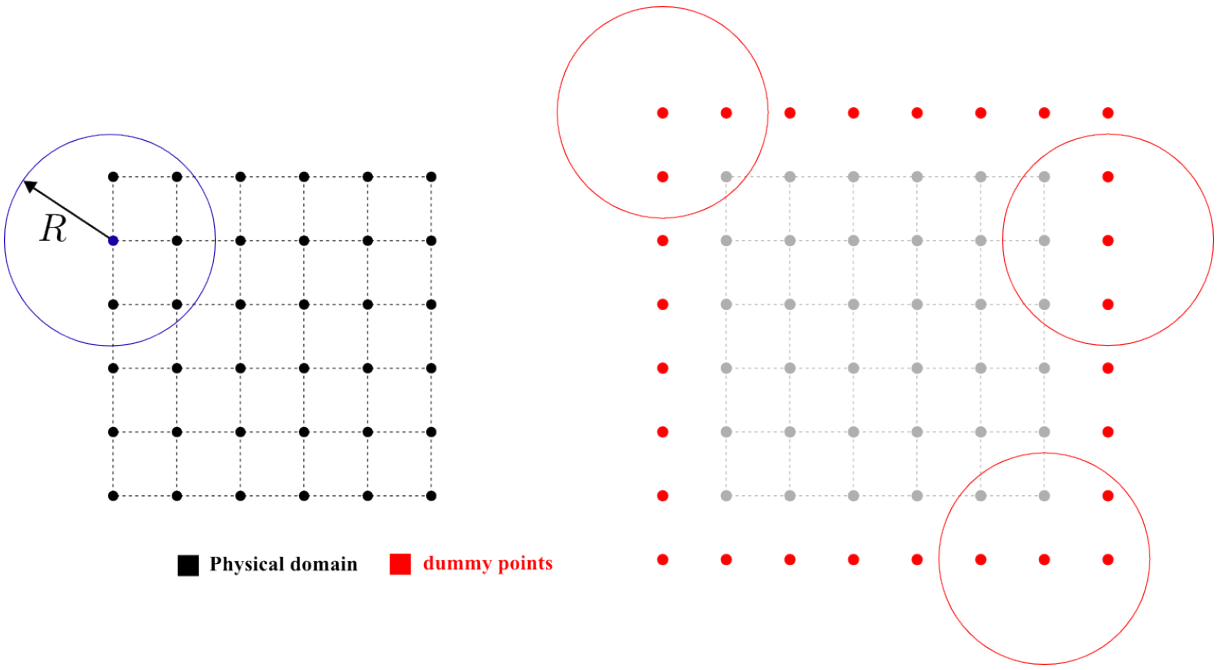

Figure 2: Illustration how dummy points are added beyond the physical domain to keep the maximum gradient constraint valid close to the edges.

With these relations, the four global uncertainty parameters can be independently set, leading to a unique field definition as in equation 6.

To ensure the maximum gradient constraint is kept over the entire domain, an adjustment is needed close to the edge of the domain. For points that lie within a distance R from a domain edge, the maximum constraint does not hold, because fewer basis functions have an effect in these points, leading to a smaller interval on the gradient in these points. To counter this, *dummy points* are added **beyond** the physical domain up to a distance R. The basis functions placed in these points lie partly in the physical domain and will ensure that the maximum gradient constraint is kept over the entire physical domain. Figure 2 shows the dummy points beyond the physical domain.

Figure 3 shows some realisations of a field within a rectangular plane for different values of R and a. One can clearly see how the combined choice of a and R produce more or less spatially dependent realisations.

3 PROPAGATING THE UNCERTAINTY: THE CONTINUOUS FIELD RESPONSE SURFACE

The analysis case in this paper will be the natural frequencies of a simple plate model with uncertain Young's modulus. The plate has a total of $20 \times 20 = 400$ elements, which leads to (at least) 400 interval parameters in the input field. To propagate this uncertain field to the output, a response surface will be defined. Assume we define a second order polynomial model on an output w within an input space $u_1, u_2, ..., u_n$ given by equation 8.

$$w = w_0 + \sum_{i=1}^{n} a_i u_i + \sum_{i=1}^{n} \sum_{j=1}^{n} b_{ij} u_i u_j \tag{8}$$

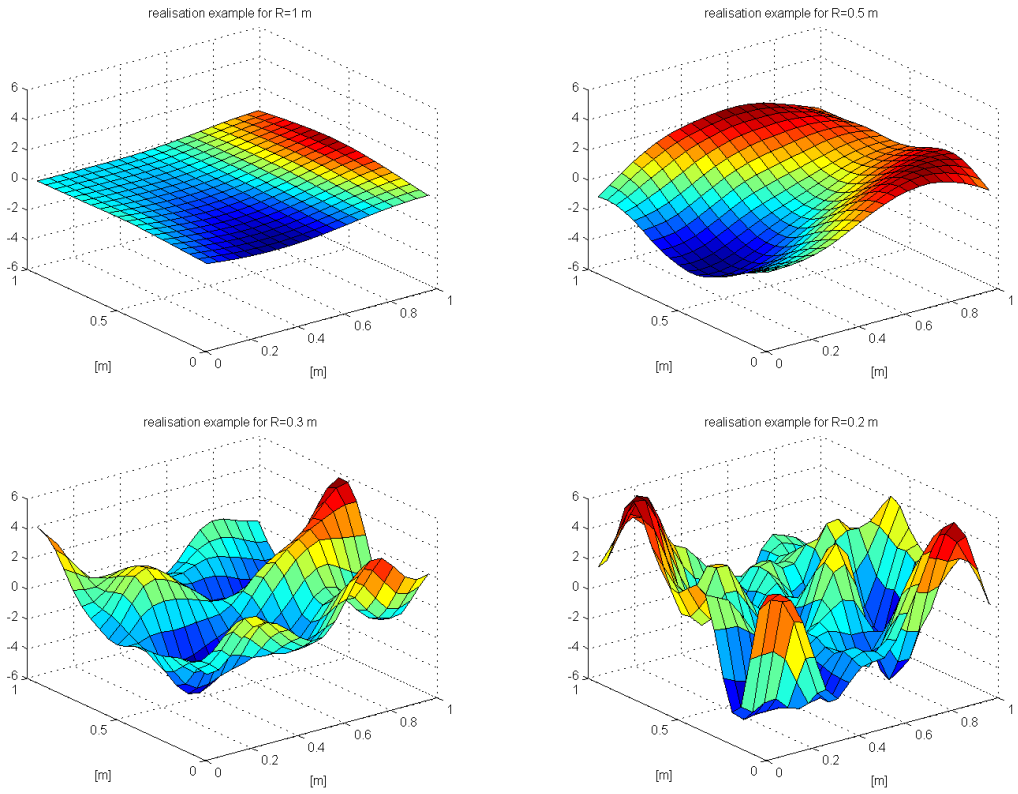

Figure 3: realisation examples for different values of R.

We assume n is a very large number, but all input parameters are instances of the same geometric parameter at different locations, e.g. the Young's modulus in each element of the FE-model. Obviously, determining the coefficients of such a high-dimensional model would require a very large amount of training samples, especially when the interaction terms are considered. To reduce the actual dimension of the response surface, we will take into account the high similarity of the input parameters. For example, the coefficients corresponding to the parameter value in adjacent elements have to be quite similar. The fact that the *coefficients are correlated in space* leads to a response surface description in terms of the spatial coordinates x and y, which the authors introduced earlier in [5], and is given by equation 9.

$$w = C + \iint_{x,y} a(x,y)u(x,y)dxdy + \iint_{x,y} b(x,y)u^2(x,y)dxdy + \iint_{x,y,\Delta x,\Delta y} q(x,y,\Delta x,\Delta y)u(x,y)u(x+\Delta x, y+\Delta y)dxdyd\Delta xd\Delta y \tag{9}$$

The discrete coefficients of the discrete model have been replaced by continuous *coefficient fields* that are defined over the spatial domain. The function also includes an interaction term which includes the product of the geometric parameter $u(x,y)$ at different elements in the model. Based on the first order approximation:

$$u(x_i + \Delta x, y_i + \Delta y) = u(x_i, y_i) + \Delta x \frac{\partial u(x,y)}{\partial x} + \Delta y \frac{\partial u(x,y)}{\partial y}, \tag{10}$$

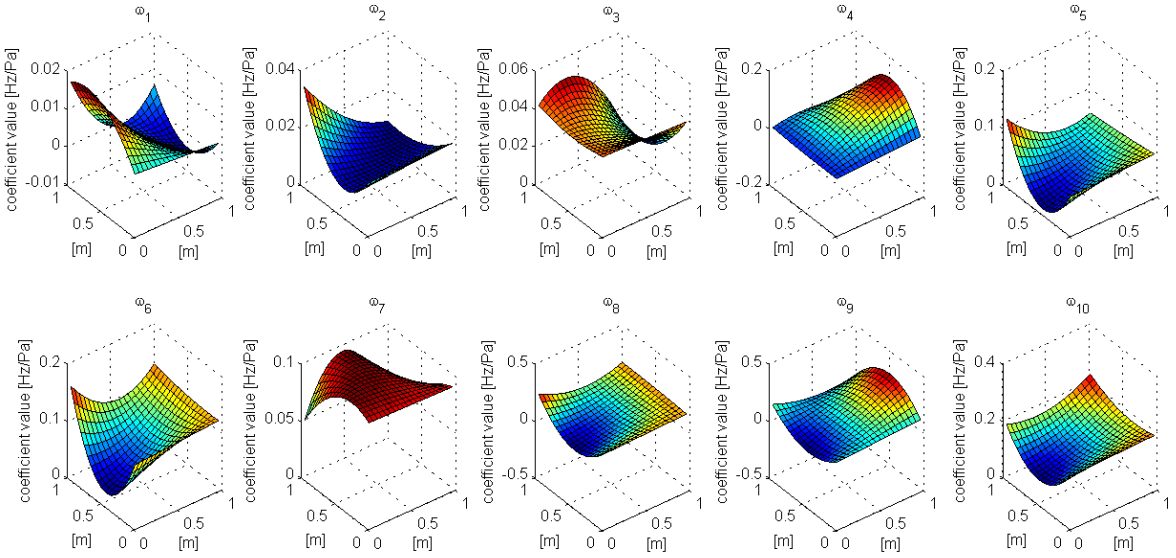

Figure 4: coefficient fields corresponding to each of the first 10 natural frequencies.

we replace this term by 2 terms including the product of the geometric parameter and its derivatives, leading to equation 11.

$$y = C + \iint_{x,y} a(x,y)u(x,y)dxdy + \iint_{x,y} b(x,y)u^2(x,y)dxdy + \iint_{x,y} q_x(x,y)u(x,y)\frac{\partial u(x,y)}{\partial x}dxdy) + \iint_{x,y} q_y(x,y)u(x,y)\frac{\partial u(x,y)}{\partial y}dxdy) \tag{11}$$

For the training process, we assume that the *coefficient fields* $a(x,y)$, $b(x,y)$ etc. are continuous functions in the spatial domain, thereby transforming the training process to a much lower actual dimension. For example, a coefficient field a(x,y) with 400 discrete locations can be written with a 2D polynomial as in equation 12.

$$a(x,y) = a_{00} + a_{10}x + a_{01}y + a_{11}xy + a_{20}x^2 + a_{02}y^2 \tag{12}$$

This representation only has 6 unknown coefficients, so instead of determining all 400 coefficients independently, redefining the problem reduces this number to only 6.

4 APPLICATION: STEEL PLATE WITH UNCERTAIN STIFFNESS PROPERTIES

4.1 Coefficient functions

We now continue towards applying this continuous model on our analysis case. The coefficient fields $a(x,y)$, $b(x,y)$, etc. are determined by using a linear least-squares based algorithm. For the specific case of the plate frequencies, first order polynomials lead to errors of only 1%. The coefficient function for each of the 10 first eigenfrequencies are given in figure 4.

4.2 Resulting output field

With the response surface defined, we can very easily make the step towards an output interval field description. The interval field can be written as

$$u^I(x,y) = u_0(x,y) + \sum_{i=1}^{N_{ext}} \cdot 1_i^I \cdot \phi_i(x,y) \tag{13}$$

with N_{ext} the total number of elements and dummy points (figure 2). If we put this in equation 9, we obtain the following description of the output field:

$$\boldsymbol{\omega}^I = \boldsymbol{\omega}_0 + \sum_{i=1}^{N_{ext}} a \cdot \boldsymbol{\xi}^{(i)} \cdot 1_i^I \tag{14}$$

with $\boldsymbol{\omega}^I$ an interval vector with the 10 first natural frequencies in it. $\boldsymbol{\xi}^{(i)}$ are vectors with elements:

$$\boldsymbol{\xi}_j^{(i)} = \iint_{x,y} a_i(x,y)\phi_j(x,y)dxdy \tag{15}$$

4.3 Identifying the uncertain region

The resulting interval field has a total of N_{ext} terms. For ease of calculation, the interval parameters are depicted by normalized intervals $1_i^I = \langle 0|1 \rangle$.

The interval field mentioned above corresponds to an uncertain region of frequency combinations. Because the example considers only the first 10 natural frequencies, this is a 10-dimensional region. If we look at 2D projections of this region on all possible (ω_i, ω_j)-subspaces, we observe 'shuttle'-shaped regions, an example of which is given in figure 5. This is due to the monotonous behaviour of natural frequency w.r.t increasing stiffness. Such a shuttle shape has two cornerpoints corresponding to the input points where al inputs are at their lowest or highest value respectively. Between these points, two curves bound the uncertain region, an *upper* and a *lower* curve.

From the fields $\boldsymbol{\xi^{(i)}}$ we can reconstruct the 2D projections of the uncertain region. For frequencies ω_p and ω_q, we define the vector $\boldsymbol{\rho^{(pq)}}$ with elements $\rho_i^{(pq)} = \frac{\xi_i^{(p)}}{\xi_i^{(q)}}$. Define $\overset{+}{\boldsymbol{\rho}}^{(pq)}$ as the vector with the elements of $\boldsymbol{\rho}^{(pq)}$ sorted in ascending order, and $\overset{-}{\boldsymbol{\rho}}^{(pq)}$ as the vector with the elements of $\boldsymbol{\rho}^{(pq)}$ sorted in descending order. Additionally, we rearrange $\boldsymbol{\xi^{(p)}}$ and $\boldsymbol{\xi^{(q)}}$ so that (equation 16)

$$\overset{+}{\rho}_i^{(pq)} = \frac{\overset{+}{\xi}_i^{(p)}}{\overset{+}{\xi}_i^{(q)}} \quad \text{and} \quad \overset{-}{\rho}_i^{(pq)} = \frac{\overset{-}{\xi}_i^{(p)}}{\overset{-}{\xi}_i^{(q)}}. \tag{16}$$

To each element in $\overset{+}{\boldsymbol{\rho}}^{(pq)}$ and $\overset{-}{\boldsymbol{\rho}}^{(pq)}$, we assign coordinates $\overset{+}{\phi}_i = \frac{\sum_{k=1}^{i} \overset{+}{\xi}_k^{(q)} - \overset{+}{\xi}_i^{(q)}/2}{\sum_{k=1}^{N_{ext}} \overset{+}{\xi}_k^{(q)}}$ and $\overset{-}{\phi}_i = \frac{\sum_{k=1}^{i} \overset{-}{\xi}_k^{(q)} - \overset{-}{\xi}_i^{(q)}/2}{\sum_{k=1}^{N_{ext}} \overset{-}{\xi}_k^{(q)}}$. Finally, we define the continuous functions $\overset{+}{h}\ (\overset{+}{\phi})$ and $\overset{-}{h}\ (\overset{-}{\phi})$ that interpolate

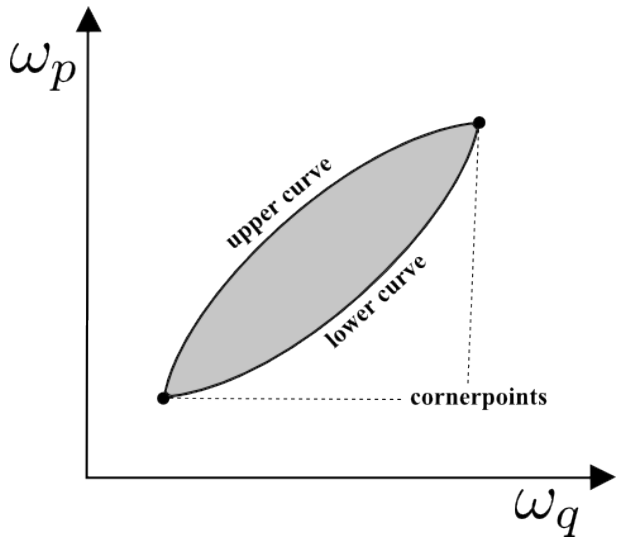

Figure 5: Example of a 'shuttle'-shaped uncertainty region.

the points $\left(\overset{+}{\rho}{}_i^{(pq)}, \overset{+}{\phi}_i\right)$ and $\left(\overset{-}{\rho}{}_i^{(pq)}, \overset{-}{\phi}_i\right)$. The lower and upper curve are then described by equation 17.

$$\begin{aligned} \text{lower curve}: \quad \overset{+}{c}\,(\overset{+}{\phi}) :\rightarrow & \begin{cases} \omega_p(t) = \int_{\overset{+}{\phi}=0}^{t} \overset{+}{h}\,(\overset{+}{\phi}) d\,\overset{+}{\phi} \\ \omega_q(t) = \int_{\overset{+}{\phi}=0}^{t} d\,\overset{+}{\phi} \end{cases} \\ \text{upper curve}: \quad \overset{-}{c}\,(\overset{-}{\phi}) :\rightarrow & \begin{cases} \omega_p(t) = \int_{\overset{-}{\phi}=0}^{t} \overset{-}{h}\,(\overset{-}{\phi}) d\,\overset{-}{\phi} \\ \omega_q(t) = \int_{\overset{-}{\phi}=0}^{t} d\,\overset{-}{\phi} \end{cases} \end{aligned} \tag{17}$$

Figure 6 illustrates the process described above.

4.4 Observations

In the 2D-projections of the uncertain region we can clearly see the effect of a varying Young's modulus. We examine 7 cases of increasing maximum gradient. The extreme values of the Young's modulus are 210 GPa and $1.2 \cdot 210 = 252$ GPa. From figures 7 to 10, that show some 2D projections for all 7 cases, a few observations can be made:

1. Increasing the maximum gradient does not change the cornerpoints, as these depend on the extreme values of the Young's modulus itself, but the uncertain region does change. The shuttle-shaped regions become wider, effectively decreasing the dependency between the frequencies as the gradient increases.

2. For lower frequencies, the effect of increasing the gradient on the uncertain region appears to saturate. This saturation effect is much less outspoken for higher frequencies.

3. Some frequencies, such as 5 and 8 (figure 9), appear to be much more interdependent than others, which can be seen from the relatively slim shuttle shape. The increased maximum gradient appears to have little effect on the dependency between these frequencies.

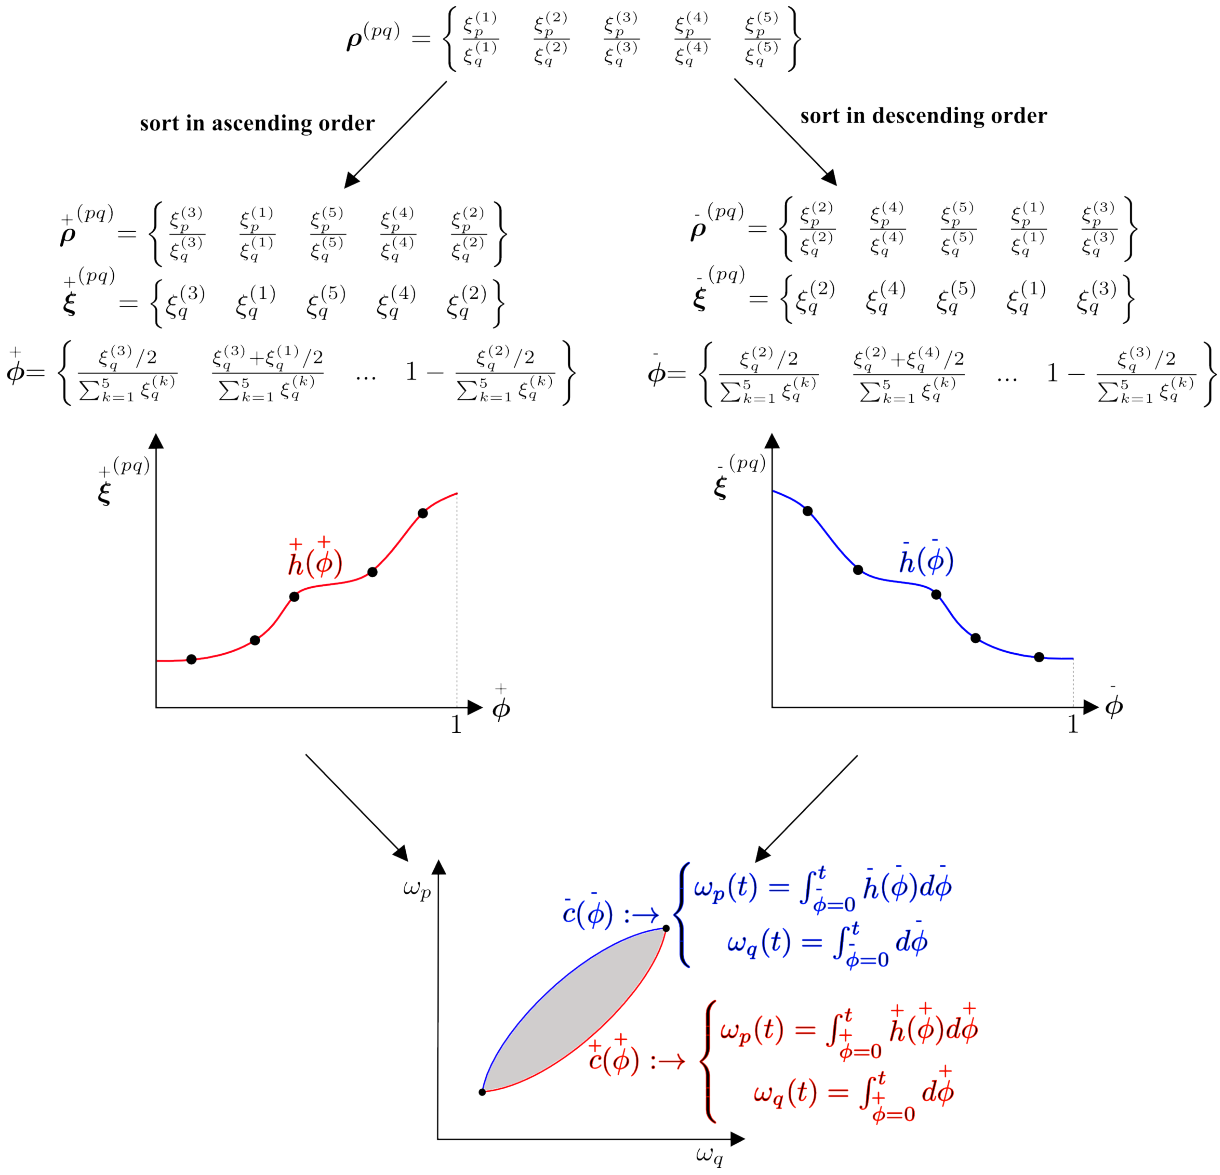

Figure 6: illustration of the process to determine the uncertain region, for the case of only 5 fields $\boldsymbol{\xi}^{(i)}$.

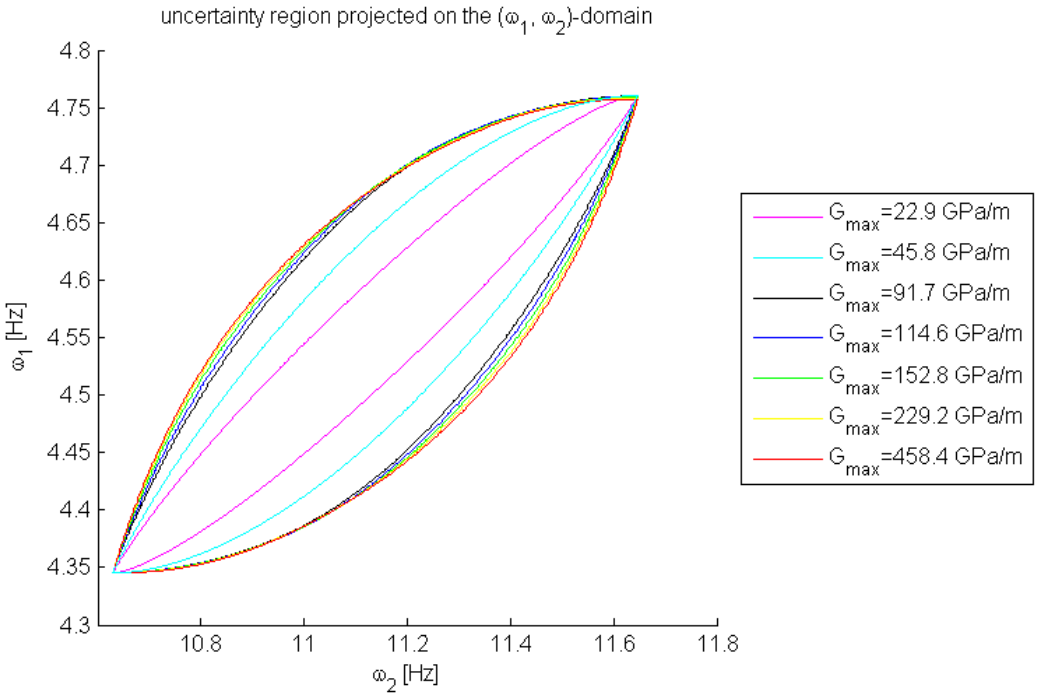

Figure 7: uncertainty region projected on the (ω_1, ω_2)-plane.

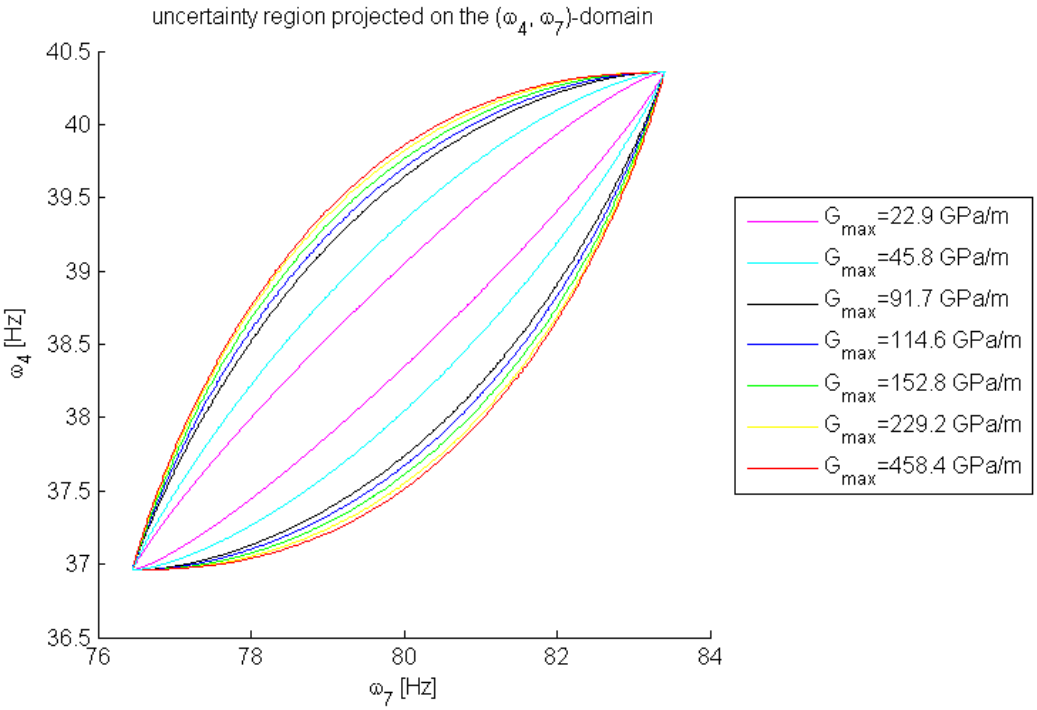

Figure 8: uncertainty region projected on the (ω_4, ω_7)-plane.

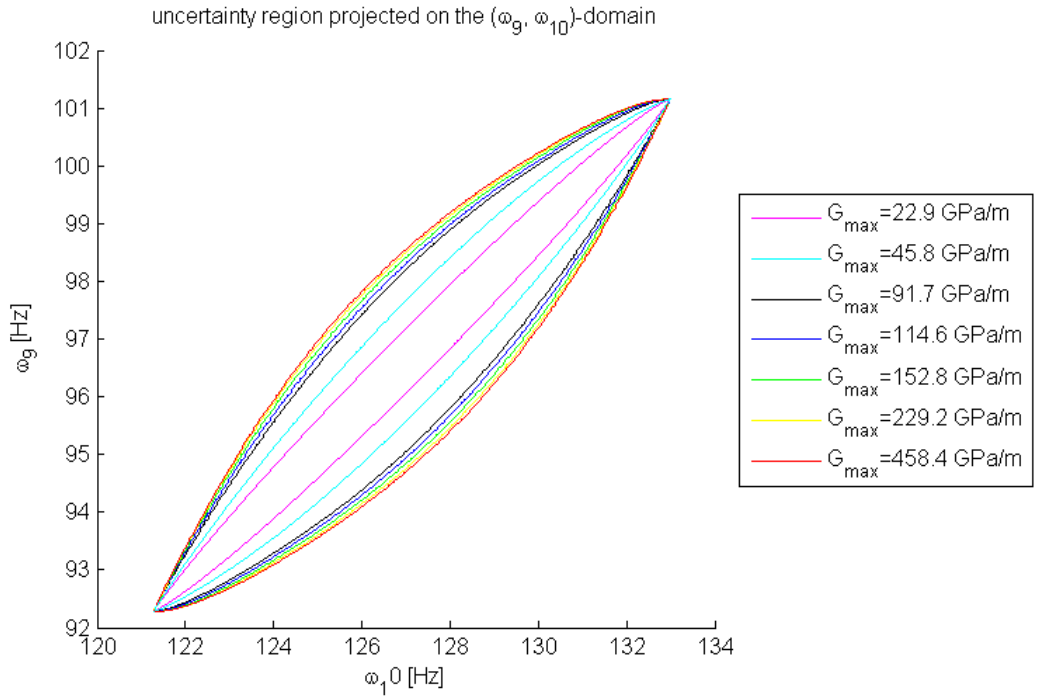

Figure 10: uncertainty region projected on the (ω_9, ω_{10})-plane.

5 CONCLUDING REMARKS & FUTURE RESEARCH TOPICS

In a possiblistic framework, the inability to use correlation forces us to look at dependency at a more general level. According to the authors, the shape of the uncertain region itself holds the most information not only on the degree of dependency between parameters, but also on the nature of it. In this paper, the interval concept is specifically designed towards the fast computation of these regions. For the purpose of monotonous and linear behaviours, which lead to so-called 'shuttle'-shaped uncertain regions, this paper introduced an easy way of computing them without the need of additional simulations. Further research will be done towards formulating relationships between interval field formulations and uncertain region shapes, for non-linear and also non-monotonous input-output relations.

Keywords: Power Grid Robustness, Vulnerability Metrics, Spectral Graph Analysis, Cascading Failures, Uncertainty.

Abstract. *Power grids are generally regarded as very reliable systems, nevertheless outages and electricity shortfalls are common events and have the potential to produce significant social and economic consequences. It is important to reduce the likelihood of those severe accidents by assuring safe operations and robust topologies. The grid safety relies on accurate vulnerability measures, control schemes and good quality information. For instance, in power network operations, contingency analysis is used to constrain the network to secure operative states with respect to predefined failures (e.g. list of single component failures). An exhaustive failure list is often not treatable, therefore a selection or ranking is performed to help in the choice. In order to better understand the power network weakness and strengths a variety of robustness metrics have been introduced in literature, although many do not account or partially account for uncertainties which might affect the analysis. In this work power network vulnerability to failure events is analysed and single line outages (N-1 contingencies) have been ranked using different metrics (i.e. topology-based, flow-based and hybrid metrics). Sources of uncertainty such as power demand variability and lack of precise knowledge on the network parameters have been accounted for and its effect on the component ranking quantified. A modified version of the IEEE 118 bus power network has been selected as representative case study. The assumption underpinning the methodologies and the vulnerability results also accounting uncertainty are discussed.*

1 INTRODUCTION

Robustness of power grids is defined as the degree to witch the network is able to withstand an unexpected event without degradation in performance [1]. A closely related concept is the vulnerability, which is sometime regarded as lack of robustness. Robustness and vulnerability are nowadays major concerns for the future power networks. Historically, power networks were developed to distribute electricity from large size isolated power plants to the various end-user loads (e.g. industry or residences) by means of power transmission and distribution networks. Distribution grids topologies were usually designed in radial fashion to comply with the needs of a simple one-way flow of electricity, i.e. from the main grid to the local users.

In the last decades this traditional design has deeply changed, the allocation of renewable energy sources are making its behaviour less predictable and vulnerability assessments less reliable, mainly due to the considerable amount of uncertainty injected in the system [2]. Non-radial meshed topologies and not classical structures are likely to became more common in the future [3]. The presented scenario highlights the need of develop more reliable and robust frameworks for power grid vulnerability analysis (i.e. adopting sophisticated uncertainty quantification techniques), as well as the need of define enhanced metric for the assessment and identification of operational and structural risks. In order to improve robustness it is important to understand the role played by the variability the grid state variables (e.g. power produced, loads, voltage phases, magnitudes.) and by the imprecisely known network parameters (flow and voltage limits, topology, line resistances, etc.). Structural weaknesses have to be identified to design better topologies (e.g. by efficient ranking of components failures) and mitigate likelihood of unexpected hazardous situations .

In literature, a wide range of indexes have been proposed for vulnerability and robustness assessment, e.g. using realistic simulation of network response and power-flow solution ("power-flow-based metrics") or based on topological analysis of networks, using techniques founded on complex network theory [4]. The latter are computed using pure topological approaches (i.e. 'topology-based metrics') or enhanced by including electrical engineering concepts in the analysis (i.e. 'hybrid metrics'). Examples of recently applied metrics are the effective resistance ($R_{\mathcal{G}}$), network spectral radius ($\rho_{\mathcal{G}}$), algebraic connectivity ($\Lambda_{\mathcal{G}}$) and extended betweenness ($\mathcal{B}_e$) M. Ouyang et al. [6] analysed correlation of six topology-based vulnerability metrics respect to multiple components failure. E. Bompard et al. [5] compared two hybrid metrics (i.e. extended betweenness and net-ability) in their ability to rank components failures. Power-flow-based metric, such as system cascading index (CEI), has been applied to estimate likelihood and extent of cascading failures [7].

To the Authors knowledge, few among the reviewed works quantified the effect of uncertainty in the metrics and compared the different ranks of component failures. Hence, further comparison between different indices, with particular regard to the uncertainties affecting the different approaches seems to be needed. In this survey vulnerability metrics are compared, with particular regard to the line failures ranking. Power demand uncertainty and system parameters (line power flow limits) uncertainty are analysed and their effect quantified. In addition, different power-flow models (i.e. alternate current and direct current power-flows) have been compared in the results. The work aim is to better understand strength and limitations of the different metrics in ranking critical components and spot network weaknesses, also accounting

uncertainty.

The paper is structured as follows:
Power network modelling is introduced in Section 2. Contingency analysis and uncertainty modelling are described in in Section 3. In Section 4 robustness and vulnerability concepts are discussed and the metrics defined. A case study is defined in Section 5 and results displayed. Limitation faced and further discussions are presented in Section 6. Section 7 close the paper.

2 BACKGROUND AND POWER NETWORK MODELLING

A power network structure can be represented by an unweighed graph $\mathcal{G} = \{\mathcal{N}, \mathcal{L}\}$, where $\mathcal{N}$ is the set of network nodes (or busses) and $\mathcal{L}$ is the set of links (branches or feeders). The topology of the graph is identified by a squared symmetric matrix called adjacency matrix A, which elements $a_{i,j}$ are equal 1 if the node i is linked to the node j or 0 if no direct link exists. Links can be associated to some measure of interest (e.g. length, traffic, power flow, line resistance, etc.) and the adjacency matrix rewritten in its weighted form W, where the matrix elements $w_{i,j}$ are the weights of the links between nodes i and j and 0 if not linked.

Spectral graph theory can be used analyse spectral graph proprieties of networks such as its eigenvalues eigenvectors. Spectral proprieties of graph $\mathcal{G}$ bears valuable information about the network the graph represent and some eigenvalues can be associated to its robustness [8]. Further details are going to be discussed in Section 4.
The Laplacian L_A of the adjacency matrix A is defined as [9]:

$$L_A = D_A - A \tag{1}$$

where A is the adjacency matrix and D_A is the diagonal matrix of degrees for A. The matrix Laplacian can be computed using the weighed adjacency matrix W (i.e. including electrical concepts such as susceptances).

AC and DC Power Flow

Power flow methods are commonly used to solve problem in power grid analysis, as example the energy dispatch problem, i.e. optimal schedule of power production, or security constrained optimal power scheduling. The AC power flow is a non linear solver accounting both active and reactive power flows without neglecting loses. In the AC formulation the active and reactive nodal equations are as follow [10]:

$$P_k = \sum_{i}^{N} |V_i||V_k|[G_{i,k}cos(\theta_{i,k}) + B_{i,k}sin(\theta_{i,k})] \tag{2}$$

$$Q_k = \sum_{i}^{N} |V_i||V_k|[G_{i,k}sin(\theta_{i,k}) - B_{i,k}cos(\theta_{i,k})] \tag{3}$$

where P_k and Q_k are active and reactive power injected in the node k, respectively, $|V_i|$ is the voltage magnitude of node i and $\theta_{i,j}$ is the voltage angle difference between node i and k. The elements $G_{i,k}$ and $B_{i,k}$ are the conductance and susceptance of the link connecting node i and k, respectively.The Equations 2-3 are solved for each $k \in \mathcal{N}$ by some iterative techniques (e.g. Newton-Raphson method) although convergence is not always assured.

The DC power flow is a linear approximation of the AC power flow which account for just active power flows, neglecting power loses and reactive power management. It has been widely used to alleviate the computational cost of numerically intensive codes and it has always a feasible solution. The majority of works which aimed at including electrical engineering concepts in graph theoretical approaches made use of the DC assumption, e.g. in defining weighted adjacency matrix of the graph. The DC power flow formulation can be written as follows [10]:

$$P_k = \sum_{i}^{N} |V_i||V_k|B_{i,k}sin(\theta_{i,k}) \approx \sum_{i}^{N} B_{i,k}\theta_{i,k} \tag{4}$$

were the equation 4 is obtained under the following DC power flow assumptions:

- Flat voltage profile $|V_i| = 1$ per unit. $\forall\, i \in \mathcal{N}$
- Small voltage angle differences$sin(\theta_{i,k}) \approx \theta_{i,k}$;
- $R \ll X$ negligible resistance;

It is worth remarking that DC model although useful in reducing computational time, might result in a poor approximation [10]. In order to obtain good quality results, grid voltage profile should be as flat as possible and ratio X/R relatively high. This means that the quality of the DC solution is system dependent and operative state dependent, hence its validity should be carefully assessed before use. The vast majority of topology-based metrics when enhanced by using electrical concepts made use of the DC assumptions [4].

3 TREATMENT OF UNCERTAINTY

Generally speaking, uncertainty can be separated in two groups, the so called aleatory and epistemic uncertainties [11]. The aleatory is related to stochastic behaviours and randomness in events and variables. The epistemic is commonly related to lack of knowledge about a particular behaviour, imprecision in measurement and poorly designed models. Adequately model uncertainty is paramount to improve robustness of the analysis accounting for both lack of information and inherent randomness (e.g. environmental conditions, future power demand, power produced by renewable generators, etc.). In the power grid context well-recognized sources of uncertainty are electricity price volatility, load power demand and environmental variability, model assumption (e.g. DC or AC power flow, contingency selection). The sources of uncertainty investigated in this work are:

- Uncertainty in the line emergency rating (line power flow constrain) which might be due to, e.g. neglected effect of ambient wind and temperature. The lack of precise knowledge on the emergency ratings of network lines have been modelled using uniform distributions around a given design value [12]. The uniform distribution has been used consistently with the principle of maximum entropy.
- Load demand uncertainty and variability. The aggregated load connected to a node i ($P_{L,i}$) can be described by a Normal distribution [13].The parameter of the distribution can be estimated from historical records of load demand per node.

A Monte Carlo sampling procedure have been used to propagate uncertainty from the input to the output quantities of interest. Within each Monte Carlo run, sampling procedure (e.g. inverse transform sampling) is used to obtain a random realization for each uncertain parameter

(nodal loads and line loading limits). The samples are forwarded to the system for further vulnerability assessment and contingency ranking. The algorithm allows obtaining a probabilistic description of the outputs variability, i.e. the output probability distribution functions with respect to the input uncertainties and wider prospective on the result of the ranking.

A contingency in power networks is defined as the unexpected failure of one of its components (e.g. links, nodes, generators, transformers) [13]. Contingency analysis is commonly used to constrain the network to safe operational states if a contingency occurs. Generally speaking, even if the network has modest size (e.g. small distribution grid), a complete analysis of all possible failures is infeasible. An exhaustive contingency list will has to include $\sum_{k=1}^{N} N!/k!(N-k)!$ failures, where k is the number of failed components. In power grid reliability and risk assessment, common practice consists in selecting a subset of the more threatening contingencies based on expert opinion or by some identification procedure [15]. In this work, the $N-1$ single line trips are analysed and the most threatening failures ranked using different metrics.

4 ROBUSTNESS AND VULNERABILITY METRICS

Robustness in power grid is defined as the degree to witch the network is able to withstand an unexpected event without degradation in performance [6]. Vulnerability is used to score low reliability power grids by assessing drops in performance metrics. The network vulnerability $\mathcal{V}(C_i)$ after the contingency (C_i) occurs can be quantified as follows [4]:

$$\mathcal{V}(C_i) = \frac{\mathcal{M} - \mathcal{M}(C_i)}{\mathcal{M}} \tag{5}$$

where $\mathcal{M}(C_i)$ is the network vulnerability metric after contingency Ci and $\mathcal{M}$ is the metric value for the undamaged network.

Power flow-based metrics

Flow-based indexes can be obtained by simulating network in normal and damaged states and using power flow solvers (e.g. DC or AC). In this work a cascading metric ($CEI(C_i)$) is obtained simulating the outages by both AC power flow contingency analysis and its linear DC approximation. Generally speaking, a "cascading" is a sequential successions of dependent events [18].The metric adopted to assess the cascading overload vulnerability is defined as follows [18]:

$$CEI(C_i) = \sum_{l \in \mathcal{L}} \mathcal{P}(C_l|C_i) SevOL_l(C_i) \tag{6}$$

where $\mathcal{P}(C_l|C_i)$ is the probability of secondary trip of line l after line i contingency occurs and $SevOL_l(C_i)$ is the severity function for line l overload if failure C_i occurs. Severity functions are used to quantify the extent of the failure and different definitions are available [13]. The continuous severity function for overload is specifically defined for each link l (distribution lines and transformers) and it measures the extent of violation in terms of excessive power flow ratio PR_l. PR_l is the ratio between active power flowing in the line P_l and its emergency rating $P_{emerg,l}$. The expression for the continuous severity due to overload ($SevOL_l$) of a line l is findable in [13].

$$SevOL_l = d * PR_l + c \quad \textit{for} \quad PR_l \geq PR_l^{min} \tag{7}$$

where $SevOL_l$ is zero for values of the flow rating less than a safety limit PR_l^{min}=0.9. The deterministic limit for the violation of line l is PR_l=1, the near violation region is 0.9$\leq PR_l <$1, and the value PR_l under 0.9 is regarded as safe, d=10 and c=-9.

Continuous severity functions, if compared with discrete severity functions, have the advantage of providing non zero risk results for scenarios close to the performance limits, but not failure, which reflects the realistic sense that near violation scenarios have not null risk. The probability of cascading trip of line k after an initiating contingency i can be expressed as in [7]:

$$\mathcal{P}(C_j|C_i) = \frac{P_j(C_i,\zeta) - P_{0,j}(\zeta)}{P_{\textit{trip},j}(C_i,\zeta) - P_{0,j}(\zeta)} \tag{8}$$

where $P_j(C_i,\zeta)$ is the post-contingency flow on circuit j given contingency i and operative-environmental condition ζ, $P_{\textit{trip},j}(C_i,\zeta)$ is defined as the flow leading to a certain trip of the line j (assumed to be 125% of its maximum capacity) and $P_{0,j}(\zeta)$ is the pre-contingency flow in the line j if condition ζ holds. Equation 8 is related to the fact that higher load levels and larger transients increases the likelihood of cascading event on circuit k after initiating event on circuit i. The probability $\mathcal{P}(C_j|C_i)$ is zero for $P_j(C_i,\zeta) \geq 0.9P_{\textit{emerg},j}$.

Topology-based and hybrid metrics

Power network vulnerability can by pure topological analysis of the grid structure. These approach use unweighted adjacency matrix A, components are regarded as identical and no rough electrical concept is included in the analysis [4]. Similarly, hybrid metrics adopt complex network concepts often include concepts such as DC approximation and electrical concepts such as line emergency rating $P_{\textit{emerg},l}$ or link impedances. For these approaches the weighted adjacency matrix W is built using the matrix of susceptances $B_{i,k}$. The analysed metrics in this paper are: graph spectral radius, algebraic connectivity, effective graph resistance, graph global efficiency [22] and extended betweenness [5].

In spectral analysis of graphs, the largest eigenvalue of the adjacency matrix is known as graph spectral radius ($\rho_{\mathcal{G}}$). Few works attempted to relate spectral radius to the power grid vulnerability and relatively small values have been considered as indicator of robustness [8]. Another important metrics obtained through spectral analysis of the network graph is the second smallest eigenvalue of the Laplacian matrix L, also known as the algebraic connectivity ($\Lambda_{\mathcal{G}}$). The metric $\Lambda_{\mathcal{G}}$ is used as indicator of the level of connection between nodes in a graph,and is regarded as a basic indication of the network robustness level [16]. The effective graph resistance ($R_{\mathcal{G}}$) is an hybrid metric which have been sometimes related to the power grid vulnerability [8]. The effective resistance $R_{i,j}$ between a pair of nodes i and j is the potential difference between these nodes when a unit current is injected at node i and withdrawn at node j.$R_{\mathcal{G}}$ can be obtained as follows:

$$R_{\mathcal{G}} = \sum_{i=1}^{N-1} \frac{1}{\mu_i} \tag{9}$$

were μ_i are the eigenvalues of the L obtained from the weighted adjacency matrix of susceptances. Others vulnerability indicators commonly used in the power network topological analysis are global efficiency ($\mathcal{E}_\mathcal{G}$) and betweenness. The efficiency of a network is defined as the average of inverses of the distance for all nodes. For calculation of $\mathcal{E}_\mathcal{G}$ the reader is reminded to [22]. Betweenness has been recently used in [14] to identify most vulnerable lines in power systems. The extended betweenness ($T_e(l)$) has been introduced in [5] as fast metric to spot most critical lines in terms of system vulnerability. The metric $T_e(l)$ is based on both complex network and electrical concepts. For the line l is defined as:

$$T_e(l) = max(|\sum_{g \in G} \sum_{d \in Ld} C_g^d f_l^{gd}|) \; l \in \mathcal{L} \tag{10}$$

where Gn and Ld are set of generation nodes and load nodes, C_g^d is the power transmission capacity from generator g to load d and f_l^{gd} is the linearised power flow sensitivity in the line l with respect to an injection in generation node g and withdraw in the demand node d. C_g^d and df_l^{gd} are computed as described in [5].

5 CASE STUDY

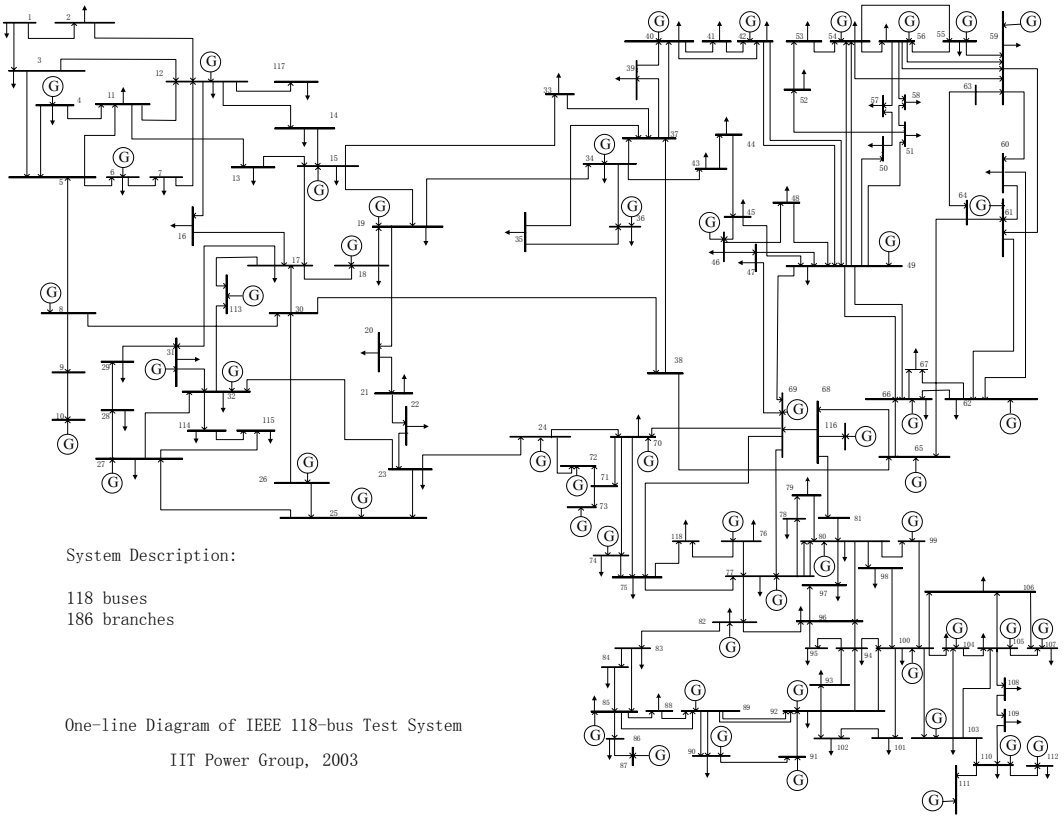

Figure 1: The IEEE 118 bus test system [21].

The selected case study is a modified version of the IEEE 118 nodes test system. The network counts 118 nodes, 186 lines and 54 generators which makes it fairly complex and suitable for the analysis. Within the gird there are 55 PV nodes (i.e. generators nodes g) and 64 PQ nodes

(i.e. load nodes d). The network model and load demand and lines emergency ratings data are available in [20]-[21]. Figure 1 displays the network structure and generators location. The original network data have been modified in order to simulate a condition of higher stress for the network. Increment in the load demand of 30 $\%$ and $P_{emerg,l}$ for all the lines l in the links set $\mathcal{L}$ reduced of 20$\%$.

Results power-flow-based metrics

The AC and its linearised version are used to simulate the network in normal and contingency states the cascading indices CEI computed and line outages ranked. The analysis is performed as follows:

- First, AC or DC approach is used to compute the optimal power production subject to line flow limits, generation constraints and load demanded.
- The contingency analysis is performed by removing one line at a time from the system. The AC or DC methods simulate the power flows redistribution in the branches given the optimal power scheduled.
- Finally, the $CEI(l)$ are computed for each contingency based on the equation 6. Line vulnerability are ranked and ordered based on the CEI values.

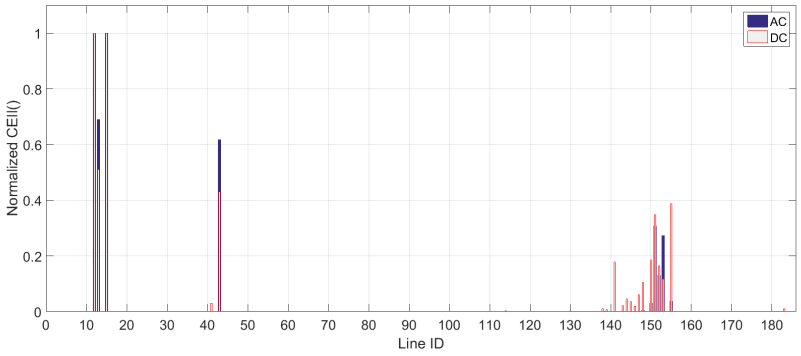

Figure 2: Normalized CEI results comparison between AC solution and and its DC approximation. On the X-axis the failed line (Line ID).

Figures 2 shows the optimal power production computed by means of the AC and DC method, respectively. The Y-axis shows the normalized CEI results and the X-axis the line identification number (ID). It can be noticed that DC power flow, when compared to AC power flow, overestimate the cascading indices for some of the contingency listed (e.g. lines ID 141-150) and underestimate them for others e.g line ID 13, 43, 153 (l_{8-5}, l_{26-30}, l_{89-92}). This is mainly due to the approximate percentage of rating PR_k obtained in the DC approach. Nevertheless, the results are in relatively good agreement, therefore it might be argued that DC solutions approximate AC solutions fairly well in both undamaged and damaged network conditions. Results are summarized in Table 5 which displays the 10 most vulnerable lines in the system, with respect to all the metrics analysed. In both AC and DC flow-based approaches the ranking results are fairly similar and similar to previous studies, see as example [19]. The most threatening lines result to be l_{9-10}, l_{8-9}, l_{8-5}, l_{26-30} for both cases.

Uncertainty Quantification for the AC and DC Solutions

The AC and DC cascading indexes have been obtained by propagation of the uncertainty in the load and in the emergency ratings. In accordance with previous studies, but with different aims, the load demand $P_{L,i}\ \forall i \in \mathcal{N}$ has been modelled as normal random variable distributed around mean μ_i and with σ_i equal to 10 $\%$ of μ_i. Uniform distributions are assumed to model lack of precision in the line maximum allowed flows. The upper and lower bounds have been set equal to 0.98 $\%$ and 1.02 $\%$ of the design values. A single loop Monte Carlo has been employed to sample input uncertainty and quantify its extent in the output. The number of MC samples for each uncertain variable have been set equal to 2x10^3, each run counts 64 samples of load demand $P_{L,d}$ and 185 samples of emergency rating $P_{emerg,l}$ one for each demand node and each line $\in \mathcal{G}$ in the network. Samples have been forwarded to the AC and DC system solver and $CEI(l)$ values obtained as described in the previous subsection. The contingencies have been ranked based on the expected value of the cascading metric and the 10 most vulnerable links have been selected. The ranking scores accounting uncertainty results slightly different compared to the deterministic case. Nevertheless, metrics drops are affected by uncertainty and some of the lines failures are more affected than others. The CEI variabilities boxes for the 10 most vulnerable lines are shown in figure 3. It can be noticed that for the DC approximation CEI for lines l_{9-10} and l_{8-9} (rank 1 and 2) bear less uncertainty if compared to the AC case. In Table 1 are displayed coefficients of variation (Cov) for the 5 most dangerous lines. Coefficient of variation is computed as ratio between standard deviation and expected value and it is a standardized measure of dispersion for the CEI distribution. The higher values confirm that AC solutions are more sensitive to the input uncertainty, which is probably due to the assumption made in order to apply the DC solver.

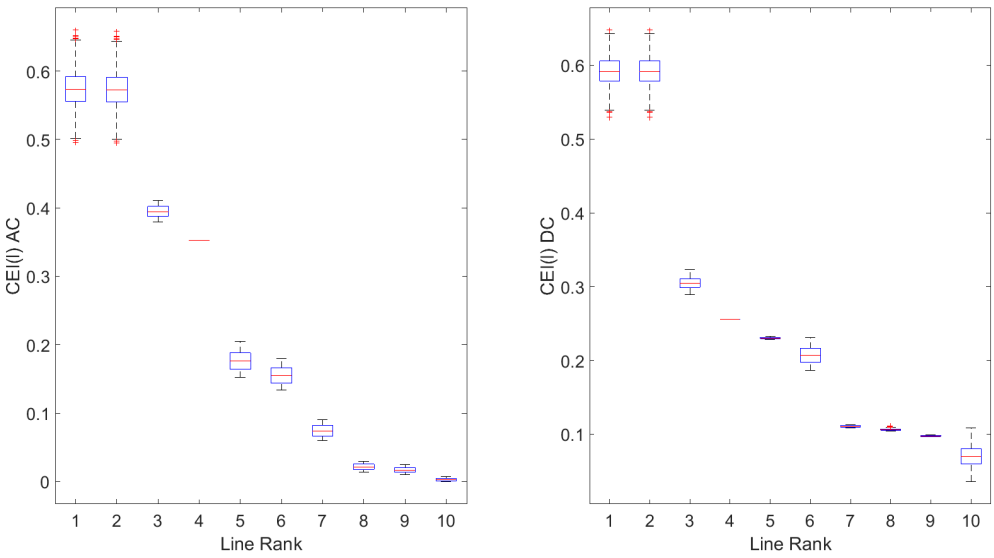

Figure 3: Variability in the normalized cascading index CEI for the 10 most vulnerable lines. Comparision between AC and DC power flow solutions.

Topology-based metrics and hybrid metrics results

Topology-based and extended hybrid metrics have been computed in both damaged and undamaged states. The analysis is carried as follows:

- First, adjacency matrix A and weighted adjacency matrix W are obtained for the undamaged network.
- The considered metrics $\mathcal{M}_A$ and $\mathcal{M}_W$ are computed for adjacency matrix A and W respectively, as described in section 4.
- The contingency analysis is performed by removing lines from the network. The matrix A and W corresponding to the graph of the damaged network are obtained and $\mathcal{M}(l)$ computed.
- Finally, vulnerabilities $\mathcal{V}(l)$ are computed as in equation 5 for each line failure. Topology-based and hybrid approach used A and W matrix respectively. The line failure are ranked based on normalized increment in the system vulnerability.

The topology-based metric which have been obtained in the approach are the graph global efficiency $\mathcal{E}_\mathcal{G}$, $\Lambda_\mathcal{G}(A)$ and $\rho_\mathcal{G}(A)$. These are computed using the unweighted adjacency matrix A in a purely topological way. Similarly, the extended hybrid metrics have been computed using the weighted adjacency matrix W built using susceptance matrix. These approaches account for both topology and electrical concepts. In this work $R_\mathcal{G}$, $\Lambda_\mathcal{G}(W)$ and $\rho_\mathcal{G}(W)$ are the hybrid metrics being analysed. Furthermore, normalized $T_e(l)$ have been computed fore each line as in equation 10, used as an additional metric for branch ranking. Table 5 shows metric values for the undamaged IEEE 118 power network.

$\mathcal{E}_\mathcal{G}(A)$	$\rho_\mathcal{G}(W)$	$\rho_\mathcal{G}(A)$	$\Lambda_\mathcal{G}(W)$	$\Lambda_\mathcal{G}(A)$	$R_\mathcal{G}(W)$
0.216	259.56	4.112	0.3	0.0274	1565.6

Table 2: Topology-based and hybrid metrics results for the undamaged original network.

Table 5 shows the 10 most relevant links with respect to $T_e(l)$ and the variation in the vulnerability. Although different vulnerability metrics produce different scores, the most vulnerable lines are successfully spotted. For instance, critical lines are l_{38-65}, l_{23-24}, l_{65-68}, l_{30-38} all ranked among the top 10 in 6 of the considered metrics. Similarly, lines l_{81-80} and l_{68-81} have been identified as critical by 5 metrics. This result suggest that for the components ranking purposes few differences can be found between hybrid and topology-based metrics.

Relative metrics drops and increments are displayed in figure 4, the results have been normalized for graphical reasons. It can be noticed that some of the lines failure cause a drop below

Table 3: Ten most vulnerable lines for the IEEE 118 system. Ranking comparison with respect to different metrics and normalized drops in the vulnerability.

zero some of the normalized vulnerability index (e.g. algebraic connectivity). A drop below zero means an increment in the robustness of the grid which is caused by the lines removal (e.g. line ID 146). The capability of the metrics to spot components which have unexpected negative effects for the network robustness can have an interesting features of hybrid and topology based metrics, exploitable to improve network robustness and future topology design.

Uncertainty Quantification for Topology-based and hybrid vulnerability metrics

Single loop Monte Carlo sampling procedure has been adopted as in the previous analysis and uncertain input variable propagated and effects quantified in the output. The Monte Carlo simulation approach and input distributions used are the same as for the AC and DC power flow uncertainty quantification. The results obtained for the IEEE 118 power system shows that the rankings are the same as in the deterministic case. For sake of synthesis, only results for one of the metrics are displayed, the extended betweenness. Coefficient of variation for the $T_e(l)$ have been displayed in Table 4.

The results shows that considered sources of uncertainty affect less these approaches, i.e. the

Rank	1	2	3	4	5	6	7	8	9	10
$Cov\ T_e(l)$	0.5 %	0.3%	0.5%	0.5%	0.3%	0.3%	0.4%	0.5%	0.4%	0.3%

Table 4: Comparison of coefficients of variations for the ten most vulnerable lines ranked using extended betweenness $T_e(l)$.

maximum value for the Cov 0.5 $\%$ for the ten most vulnerable lines. This is a rather expected result if considered that the load demand variability do not influence any of the considered topology-based and hybrid metrics.

6 DISCUSSION AND LIMITATIONS

A modified version of the IEEE 118 nodes power network has been analysed and lines sorted with respect to their contribution to the grid vulnerability. The comparison between topology-based and hybrid approaches shows similarities in the ranking results. Spectral analysis of the network require higher computational cost for obtaining a full spectrum of eigenvalues and eigenvector for each damaged condition (and relative W, A and L).

Contingency analysis has been used to obtain a power flow-based cascading metrics, the CEI indices. Both AC and DC power flow solver have been adopted for the calculation and comparison between line ranking showing minor differences between the approaches. This has been regarded as a confirmation of well-founded DC hypothesis for the system in exam. The comparison of the CEI indices with topology-based and hybrid metrics suggest significant differences in the ranking. The differences can be explained by lack of considerations about nodal power injections and withdraw of some of the approaches. The considered topology-based metrics even if enhanced in hybrid metrics cannot capture in full the operational vulnerabilities in the network. On the other hand, power-flow-based approaches included power injection and demands magnitudes in the calculation and hence able to identify critical components accounting changes in the operational state. Nevertheless, many of the lines ranked using CEI index resulted in a null contribution to the system vulnerability (due to null post-failure overload severity). This might be seen as a limitation of the CEI metric which has not been able to capture all the relevant aspect and information enclosed in the line failures.

Uncertainty propagated through the AC and DC methods have been quantified in the $CEI(l)$ indexes. Ranking results show good agreement with the deterministic solution and between the different power flow solvers. The AC output seems to be more sensitive to the uncertainties in the input, which can be due to the less restrictive assumptions compared to the DC method. The largest majority of the hybrid approaches make use of the DC assumptions. Generally the goodness of DC approximation should be tested and model adopted carefully[10]. Especially in scenarios where grid stress is high, such as sudden component failures or attacks, the approximation might result poor and not represent adequately the reality. Comparisons between hybrid metrics and pure topological metrics show a good agreement in the line ranking although some of them, i.e. ranking based on drops in spectral radius, differs substantially. This might be due to limitation of the latter metric or computational inaccuracies.

7 CONCLUSIONS

The future electric power grid is a complex network which have to deal with uncertainty from different sources. The correct functioning of the system and components will strongly depend on the operational context. Therefore providing easy to follow guidances and robustness metrics is uttermost important point. The metrics have to be capable of capturing uncertainties and variability in the network dynamic and as well intrinsic topological weaknesses in a reliable way. In this paper different vulnerability metrics have been compared in their ability to spot system criticality and ranking important components.The effects of uncertainty have been

analysed and relative drops or increments in the metrics discuses and compared to the same approaches with no uncertainty accounted for. The IEEE 118 power grid has been used as case study. The AC and DC power flow cascading metrics showed higher uncertainty in the outputs if compared to topology based metrics. This is due to operational variability not fully accounted in the latter approaches and to the different assumptions. In conclusion, the selection of metrics for vulnerability assessment of power grids have o be selected carefully. The analyst should account both influence of the underling model assumptions and system variability. Wrong consideration of uncertainty can lead to imprecise considerations on the system vulnerability and in the worst case to misleading results on its robustness and reliability.

Keywords: Uncertainty quantification, Reduced-Order Model, Structural dynamics

Abstract. *We present the construction of a multilevel stochastic reduced-order model devoted to the robust prediction of frequency response functions of complex linear dynamical systems that are characterized by the presence of several structural scales in which there are local displacements in addition to the usual global displacements, and which are associated with the distinct low-, medium-, and high-frequency bands. As the levels of uncertainties are different in the three frequency bands, a multilevel stochastic reduced-order model using several orthogonal subspaces associated with the several types of displacements is developed. The objective of the paper is to demonstrate the capability of the multilevel stochastic reduced-order model to adapt the stochastic modeling of uncertainties to each one of the three frequency bands.*

1 Introduction

We present a new method for the robust prediction of frequency response functions (FRF) of complex linear dynamical structures exhibiting a high modal density. Commonly, the low-frequency range [1] is characterized by the presence of a few dozen isolated eigenfrequencies that are associated with global modes, in which case the modal analysis method [2, 3, 4] allows an effective and efficient small-dimension reduced-order model (ROM) to be obtained. In contrast, the complex structures we deal with can exhibit more than hundreds or thousands modes in low frequencies. This unusual feature is due to the presence of several structural scales within the complex geometry of the structure. Small flexible components attached to the stiff skeleton of the structure induce the presence of numerous local modes intertwined with the usual global modes of the stiff skeleton. For such complex structures, besides the absence of separation of scales, the global displacements (or global modes) cannot easily be identified because coupled with the large-amplitude local displacements (or local modes). For constructing an adapted reduced-order model of such complex structures, a first version of a two-levels reduced-order model has been proposed [5], and then has been extended and applied to complex mechanical systems [6, 7]. Then the methodology has been generalized [8] for constructing multilevel reduced-order models. This paper is mainly devoted to the stochastic aspects and their implementation in the multilevel reduced-order model.

First, the proposed method allows for constructing a ROM of smaller dimension, which is obtained by introducing a subspace of global displacements. The construction of the latter is based on the introduction of high-degree polynomial shape functions. The vector basis of the global-displacements subspace is constituted of the eigenmodes calculated using such an approximation for the kinetic energy. The choice of the polynomial degree allows for controlling the filtering between the so-called global and local displacements, as well as the resulting dimension and accuracy of the so-called global ROM. Furthermore, it is well known that local displacements are in general more sensitive to uncertainties than global displacements. The nonparametric probabilistic approach [9] allows all sources of uncertainty to be globally accounted for by randomizing each reduced matrix whose probability density function, constructed applying the maximum entropy principle [10, 11], is parameterized by a unique dispersion hyperparameter. In order to separately control the uncertainty level of the displacements of each of the scales, we propose to use a multilevel ROM, based on the introduction of orthogonal subspaces. The basis of each of these subspaces is constructed by using, notably, the aforementioned polynomial approximation for the kinetic energy, with an adapted polynomial degree. Each basis is constituted of displacements associated with a given structural scale. Then, the multilevel stochastic ROM is obtained by using the nonparametric probabilistic approach for each scale. This stochastic model is then controlled by some dispersion hyperparameters devoted to each scale. The method is applied to the complex computational model of a car. The objective of this work is to present a sensitivity analysis of the multilevel stochastic ROM with respect to the

dispersion hyperparameters in order to demonstrate the capability of the method proposed to adapt the stochastic modeling to the level of uncertainties as a function of the frequency bands.

2 Classical nominal reduced-order model

Let $[\mathbb{M}]$, $[\mathbb{D}]$, and $[\mathbb{K}]$ denote the $(m \times m)$ positive-definite real symmetric mass, damping and stiffness matrices of a m-dimensional finite element model of a linear damped structure with bounded domain, Ω. The m-dimensional complex vector $\mathbb{U}(\omega)$ of the displacements satisfies, for all ω in the frequency band $\mathcal{B}$, the matrix equation,

$$(-\omega^2[\mathbb{M}] + i\omega[\mathbb{D}] + [\mathbb{K}])\mathbb{U}(\omega) = \mathbb{F}(\omega)\,, \tag{1}$$

in which the m-dimensional complex vector $\mathbb{F}(\omega)$ represents the external forces. For $\alpha = 1, \ldots, m$, the elastic modes $\boldsymbol{\varphi}_\alpha$ are the eigenvectors of the following generalized eigenvalue problem associated with the conservative dynamical system,

$$[\mathbb{K}]\boldsymbol{\varphi}_\alpha = \lambda_\alpha[\mathbb{M}]\boldsymbol{\varphi}_\alpha\,, \tag{2}$$

in which λ_α is the eigenvalue associated with mode $\boldsymbol{\varphi}_\alpha$ such that $\lambda_\alpha = \omega_\alpha^2$ and $\omega_\alpha = 2\pi f_\alpha$, with f_α the associated eigenfrequency in Hz. The classical nominal reduced-order model (C-NROM) is obtained by projecting Eq. (1) onto the subspace, $\mathcal{S}_c \subset \mathbb{C}^m$, spanned by the first n elastic modes (associated with the n smallest eigenfrequencies). Normalizing the eigenmodes with respect to the mass matrix, the associated reduced-order basis (ROB) is given by $[\Phi] = [\boldsymbol{\varphi}_1 \ldots \boldsymbol{\varphi}_n]$ and verifies $[\Phi]^T[\mathbb{M}][\Phi] = [I_n]$ as well as $[\Phi]^T[\mathbb{K}][\Phi] = [\Lambda]$, with $[\Lambda]$ the matrix of the first n eigenvalues. In the rest of this paper, the eigenvectors of any eigenvalue problem such as in Eq. (2) will follow the same normalization. Introducing the generalized damping matrix $[\mathcal{D}] = [\Phi]^T[\mathbb{D}][\Phi]$ and the vector $\mathcal{F}(\omega) = [\Phi]^T\mathbb{F}(\omega)$ of the generalized forces, the vector $\mathbf{q}(\omega) = (q_1(\omega) \ldots q_n(\omega))$ of the generalized coordinates of the C-NROM is the solution of the reduced-matrix equation,

$$(-\omega^2[I_n] + i\omega[\mathcal{D}] + [\Lambda])\mathbf{q}(\omega) = \mathcal{F}(\omega)\,, \tag{3}$$

and allows displacements $\mathbb{U}(\omega)$ to be approximated by

$$\mathbb{U}(\omega) \simeq [\Phi]\mathbf{q}(\omega) = \sum_{\alpha=1}^{n} q_\alpha(\omega)\,\boldsymbol{\varphi}_\alpha\,. \tag{4}$$

In the rest of this paper, several ROMs will be constructed. For simplicity, the notations will be introduced only for the associated ROB, since any ROM is straightforwardly obtained, using its ROB, by projection of Eq. (1) and by recovering the physical degrees of freedom (DOF) $\mathbb{U}(\omega)$ such as in Eq. (4).

For the complex structures under consideration, due to the presence of numerous local displacements, dimension n of the C-NROM is quite large. We propose the

construction of a global-displacements ROB, from which local displacements are removed. Such filtering relies on the introduction of a reduced kinematics for the mass matrix.

3 Reduced-kinematics mass matrix

The proposed filtering of local displacements is based on the use of polynomial shape functions defined on domain Ω, the filtering being controlled by the degree, $\mathcal{D}$, of the polynomial approximation. The construction of the polynomial basis is detailed in [8]. Let $[B]$ denote the $(m \times N_p)$ real matrix constituted of the concatenation of the $N_p = (\mathcal{D}+1)(\mathcal{D}+2)(\mathcal{D}+3)/2$ polynomials, which are orthogonal such that

$$[B]^T[\mathbb{M}][B] = [I_{N_p}]\,. \tag{5}$$

The polynomials are only used for approximating the kinetic energy (the elastic energy remains exact). Let $\mathbb{V}(t)$ denote a time-dependent real vector of dimension m. The orthogonal projection $\mathbb{V}^r(t)$ of $\mathbb{V}(t)$ onto the subspace spanned by the polynomials basis is given by

$$\mathbb{V}^r(t) = [\mathbb{P}]\mathbb{V}(t)\,, \tag{6}$$

in which the projector $[\mathbb{P}]$ is a $(m \times m)$ real matrix which is written [8] as

$$[\mathbb{P}] = [B][B]^T[\mathbb{M}]. \tag{7}$$

Then, the kinetic energy $E_k(\mathbb{V}(t)) = \frac{1}{2}\mathbb{V}(t)^T[\mathbb{M}]\mathbb{V}(t)$ is replaced by the reduced kinetic energy $E_k^r(\mathbb{V}(t)) = \frac{1}{2}\mathbb{V}^r(t)^T[\mathbb{M}]\mathbb{V}^r(t) = \frac{1}{2}\mathbb{V}(t)^T[\mathbb{M}^r]\mathbb{V}(t)$ in which the $(m \times m)$ reduced-kinematics mass matrix $[\mathbb{M}^r]$ is positive-semidefinite symmetric real of rank N_p and such that

$$[\mathbb{M}^r] = [\mathbb{M}][B][B]^T[\mathbb{M}]\,. \tag{8}$$

For constructing the global-displacements ROB, matrix $[\mathbb{M}^r]$ is used instead of $[\mathbb{M}]$.

4 Global-displacements reduced-order basis

4.1 Definition

Let $\boldsymbol{\psi}_\alpha^g$ ($\alpha = 1, \ldots, N_p$) be the eigenvectors and let σ_α^g be the associated eigenvalues such that

$$[\mathbb{K}]\boldsymbol{\psi}_\alpha^g = \sigma_\alpha^g[\mathbb{M}^r]\boldsymbol{\psi}_\alpha^g\,, \tag{9}$$

for which the kinetic energy is subjected to the polynomial approximation and which allows the $(m \times \nu)$ real matrix $[\Psi^g] = [\boldsymbol{\psi}_1^g \ldots \boldsymbol{\psi}_\nu^g]$ to be constructed, with $\nu \leq N_p$. Then, the ROB associated with the global nominal reduced-order model (G-NROM) is

given by $[\Phi^g] = [\Psi^g][R]$, where $[R] = [\mathbf{r}_1 \dots \mathbf{r}_{n_g}]$ is constituted of the n_g eigenvectors $\mathbf{r}_\alpha$ of the small-dimension generalized eigenvalue problem

$$\left([\Psi^g]^T[\mathbb{K}][\Psi^g]\right)\mathbf{r}_\alpha = \lambda^g_\alpha \left([\Psi^g]^T[\mathbb{M}][\Psi^g]\right)\mathbf{r}_\alpha\,, \tag{10}$$

where dimension n_g of the G-NROM is chosen as minimum under the constraint $f^g_{n_g} \geq f^c$, with $f^g_\alpha = \sqrt{\lambda^g_\alpha}/2\pi$. Frequency f^c is related to the upper bound of frequency band of analysis $\mathcal{B}$. The global-displacements subspace, spanned by the n_g columns of $[\Phi^g]$, is denoted by $\mathcal{S}_g$. The matrix $[\Lambda^g]$ of the associated eigenvalues is such that $[\Lambda^g] = [\Phi^g]^T[\mathbb{K}][\Phi^g]$.

4.2 Numerical implementation

The proposed method is adapted so as to be non-intrusive with respect to commercial software for which extraction of mass and stiffness matrices can be difficult or even impossible. Given the considered approximation for constructing mass matrix $[\mathbb{M}^r]$, replacing consistent mass matrix $[\mathbb{M}]$ by a lumped approximation in order to construct $[\mathbb{M}^r]$ is legitimate. We then propose an indirect method for constructing the global-displacements ROB.

Let $\mathcal{S}_0$ be a subspace spanned by the n_0 columns of a ROB $[\Phi^0]$, which can, for instance, be constituted of elastic modes, available through commercial software. We suppose having $[\Phi^0]^T[\mathbb{M}][\Phi^0] = [I_{n_0}]$ and $[\Phi^0]^T[\mathbb{K}][\Phi^0] = [\Lambda^0]$ with $[\Lambda^0]$ a diagonal matrix with positive elements. Then, considering the approximation $\mathcal{S}_g \subseteq \mathcal{S}_0$ obtained writing $\boldsymbol{\psi}^g_\alpha = [\Phi^0]\mathbf{s}_\alpha$ for all $\alpha = 1, \dots, N_p$, Eq. (9) leads us to the reduced-order generalized eigenvalue problem

$$\left([\Phi^0]^T[\mathbb{K}][\Phi^0]\right)\mathbf{s}_\alpha = \sigma^g_\alpha \left([\Phi^0]^T[\mathbb{M}^r][\Phi^0]\right)\mathbf{s}_\alpha\,. \tag{11}$$

Since $[\Phi^0]^T[\mathbb{K}][\Phi^0] = [\Lambda^0]$, the latter eigenvalue problem does not require having $[\mathbb{K}]$ but $[\Lambda^0]$ instead. Moreover, denoting as $[\mathbb{M}^\ell]$ a lumped approximation of $[\mathbb{M}]$, the generalized mass matrix of Eq. (11) is approximated as

$$[\Phi^0]^T[\mathbb{M}^r][\Phi^0] \simeq [N^0][N^0]^T\,, \tag{12}$$

with $[N^0] = [\Phi^0]^T[\mathbb{M}^\ell][B^\ell]$, in which $[B^\ell]$ denotes the orthonormalization of $[B]$ with respect to $[\mathbb{M}^\ell]$. Matrix $[S] = [\mathbf{s}_1 \dots \mathbf{s}_\nu]$ is such that $[\Psi^g] = [\Phi^0][S]$ and we then have $[\Phi^g] = [\Phi^0][Q^g]$ with $[Q^g] = [S][R]$. Furthermore, reduced matrices involved in Eq. (10) are given by

$$[\Psi^g]^T[\mathbb{K}][\Psi^g] = [\Sigma^g]\,, \qquad [\Psi^g]^T[\mathbb{M}][\Psi^g] = [S]^T[S]\,, \tag{13}$$

with $[\Sigma^g]$ the matrix of the first ν eigenvalues σ^g_α.

4.3 Complementary local-displacements reduced-order basis

The complementary basis of local displacements belonging to subspace $\mathcal{S}_0$ spans a subspace $\mathcal{S}_\ell$ that is such that

$$\mathcal{S}_0 = \mathcal{S}_g \oplus \mathcal{S}_\ell \,, \tag{14}$$

which means that $\mathcal{S}_g$ and $\mathcal{S}_\ell$ are in direct sum. The construction of the associated ROB, $[\Phi^\ell]$, is proposed as follows. It verifies $[\Phi^g]^T[\mathbb{M}][\Phi^\ell] = [\,0\,]$ (orthogonality of the local basis vectors, $\boldsymbol{\varphi}^{\boldsymbol{\ell}}_{\boldsymbol{\alpha}}$, and the global basis vectors, $\boldsymbol{\varphi}^{\boldsymbol{g}}_{\boldsymbol{\alpha}}$, with respect to the mass matrix) as well as $[\Phi^\ell] = [\Phi^0][Q^\ell]$ (the local basis vectors belong to $\mathcal{S}_0$), with $[Q^\ell]$ a real matrix of generalized coordinates that is defined hereinafter. The orthogonality condition is written as $[C][Q^\ell] = [\,0\,]$, where matrix $[C]$ is given by $[C] = [\Phi^g]^T[\mathbb{M}][\Phi^0]$, and can be rewritten as

$$[C] = [Q^g]^T \,. \tag{15}$$

Let $[C] = [U_C][\Sigma_C][V_C]^T$ be the singular value decomposition (SVD) of $[C]$. Let $[Z]$ be the concatenation of the columns of $[V_C]$ associated with the zero singular values (zero diagonal elements of $[\Sigma_C]$). Then, the columns of $[Z]$ constitute a vector basis of the kernel of $[C]$ and matrix $[Z]$ verifies $[Z]^T[Z] = [I_{n_\ell}]$, where $n_\ell = n_0 - n_g$ is the dimension of the kernel of $[C]$. Orthogonality condition $[C][Q^\ell] = [\,0\,]$ leads us to $[Q^\ell] = [Z][U]$, with $[U]$ a matrix of generalized coordinates. The columns $\mathbf{u}_\alpha$ of $[U] = [\mathbf{u}_1 \ldots \mathbf{u}_{n_\ell}]$ are the solutions of the reduced-order generalized eigenvalue problem

$$\Big([Z]^T[\Phi^0]^T[\mathbb{K}][\Phi^0][Z]\Big)\,\mathbf{u}_\alpha = \lambda^\ell_\alpha \Big([Z]^T[\Phi^0]^T[\mathbb{M}][\Phi^0][Z]\Big)\,\mathbf{u}_\alpha \,, \tag{16}$$

which can be more simply rewritten as the eigenvalue problem

$$\Big([Z]^T[\Lambda^0][Z]\Big)\,\mathbf{u}_\alpha = \lambda^\ell_\alpha\,\mathbf{u}_\alpha \,. \tag{17}$$

5 Multilevel nominal and stochastic reduced-order models

To sum up, for a given polynomial degree $\mathcal{D}$ and a given truncation order ν for $[\Psi^g] = [\boldsymbol{\psi}^g_1 \ldots \boldsymbol{\psi}^g_\nu]$, global-displacements subspace $\mathcal{S}_g$ and local-displacements subspace $\mathcal{S}_\ell$ of any given space $\mathcal{S}_0$ can be constructed such that $\mathcal{S}_0 = \mathcal{S}_g \oplus \mathcal{S}_\ell$. Dimension $n_g \leq \nu$ of $\mathcal{S}_g$ also depends on cutting frequency f^c. Therefore, there is a function $\mathcal{G}$ such that

$$\mathcal{G} : (\mathcal{S}_0, \mathcal{D}, \nu, f^c) \longmapsto (\mathcal{S}_g, \mathcal{S}_\ell) \,, \tag{18}$$

which includes the described construction in a compact form.

5.1 Definition of the orthogonal subspaces

For the multilevel nominal reduced-order model (ML-NROM), three subspaces $\mathcal{S}_{\mathcal{L}}$, $\mathcal{S}_{\mathcal{M}}$, and $\mathcal{S}_{\mathcal{H}}$ associated with the low-, medium-, and high-frequency bands (LF, MF, and HF) are constructed. These subspaces are such that $\mathcal{S}_g = \mathcal{S}_{\mathcal{L}} \oplus \mathcal{S}_{\mathcal{M}} \oplus \mathcal{S}_{\mathcal{H}}$. Space $\mathcal{S}_g$ corresponds to a filtering of local displacements that allows the final dimension (and thus the computational cost) of the ML-NROM to be reduced. Subspaces $\mathcal{S}_g$ and $\mathcal{S}_\ell$ are given by

$$(\mathcal{S}_g, \mathcal{S}_\ell) = \mathcal{G}(\mathcal{S}_c, \mathcal{D}_g, \nu_g, f_g^c)\,, \tag{19}$$

where we recall space $\mathcal{S}_c$ to be spanned by the first n elastic modes that would be used in a classical modal analysis, with f_g^c a cutting frequency associated with the upper bound of frequency band of analysis $\mathcal{B}$, and where parameters $\mathcal{D}_g$ and ν_g allow the filtering to be controlled. It should be noted that, for constructing the ML-NROM, the construction of $\mathcal{S}_\ell$ that is such that $\mathcal{S}_c = \mathcal{S}_g \oplus \mathcal{S}_\ell$, is not needed.

We then introduce a second filtering, using $\mathcal{D}_{\mathcal{LM}} \leq \mathcal{D}_g$ and $\nu_{\mathcal{LM}} \leq n_g$ as well as a cutting frequency $f_{\mathcal{LM}}^c$ associated with the upper bound of the MF band. The associated global-displacements and local-displacements subspaces $\mathcal{S}_{\mathcal{LM}}$ and $\mathcal{S}_{\mathcal{H}}$ are given by

$$(\mathcal{S}_{\mathcal{LM}}, \mathcal{S}_{\mathcal{H}}) = \mathcal{G}(\mathcal{S}_g, \mathcal{D}_{\mathcal{LM}}, \nu_{\mathcal{LM}}, f_{\mathcal{LM}}^c)\,, \tag{20}$$

and satisfy $\mathcal{S}_g = \mathcal{S}_{\mathcal{LM}} \oplus \mathcal{S}_{\mathcal{H}}$.

For obtaining subspaces $\mathcal{S}_{\mathcal{L}}$ and $\mathcal{S}_{\mathcal{M}}$, a third filtering parameterized by $\mathcal{D}_{\mathcal{L}} \leq \mathcal{D}_{\mathcal{LM}}$ and $\nu_{\mathcal{L}} \leq \dim(\mathcal{S}_{\mathcal{LM}})$ as well as a cutting frequency $f_{\mathcal{L}}^c$ associated with the upper bound of the LF band is introduced. The associated global-displacements and local-displacements subspaces $\mathcal{S}_{\mathcal{L}}$ and $\mathcal{S}_{\mathcal{M}}$ are given by

$$(\mathcal{S}_{\mathcal{L}}, \mathcal{S}_{\mathcal{M}}) = \mathcal{G}(\mathcal{S}_{\mathcal{LM}}, \mathcal{D}_{\mathcal{L}}, \nu_{\mathcal{L}}, f_{\mathcal{L}}^c)\,. \tag{21}$$

Since $\mathcal{S}_{\mathcal{LM}} = \mathcal{S}_{\mathcal{L}} \oplus \mathcal{S}_{\mathcal{M}}$, we thus have $\mathcal{S}_g = \mathcal{S}_{\mathcal{L}} \oplus \mathcal{S}_{\mathcal{M}} \oplus \mathcal{S}_{\mathcal{H}}$.

5.2 Multilevel nominal reduced-order model

Due to the orthogonality property, it can be shown that the reduced mass matrix of the ML-NROM, $[M]$, is such that $[M] = [I_{n_g}]$. In contrast, the reduced stiffness matrix $[K]$ of the ML-NROM is a full matrix that is written as

$$[K] = \begin{bmatrix} [K^{\mathcal{LL}}] & [K^{\mathcal{LM}}] & [K^{\mathcal{LH}}] \\ [K^{\mathcal{ML}}] & [K^{\mathcal{MM}}] & [K^{\mathcal{MH}}] \\ [K^{\mathcal{HL}}] & [K^{\mathcal{HM}}] & [K^{\mathcal{HH}}] \end{bmatrix}\,, \tag{22}$$

in which, for $\mathcal{I}$ and $\mathcal{J}$ in $\{\mathcal{L}, \mathcal{M}, \mathcal{H}\}$, the matrix block $[K^{\mathcal{IJ}}]$ is given by $[K^{\mathcal{IJ}}] = [\Phi^{\mathcal{I}}]^T [\mathbb{K}]\, [\Phi^{\mathcal{J}}]$, with $[\Phi^{\mathcal{I}}]$ the ROB of $\mathcal{S}_{\mathcal{I}}$. The damping matrix $[D]$ of the ML-NROM is also a full matrix with the blocks $[D^{\mathcal{IJ}}] = [\Phi^{\mathcal{I}}]^T [\mathbb{D}] [\Phi^{\mathcal{J}}]$.

5.3 Multilevel stochastic reduced-order model

The construction of the multilevel stochastic reduced-order model (ML-SROM) is based on the nonparametric probabilistic approach of uncertainties. This approach consists in replacing any positive-definite symmetric real $(N \times N)$ matrix $[X]$ of a ROM by an associated random matrix $[\mathbf{X}]$ whose probability density function is obtained applying the maximum entropy principle under the constraints (available information)

- Matrix $[\mathbf{X}]$ is with values in the set of all the positive-definite symmetric real $(N \times N)$ matrices.
- $E\{[\mathbf{X}]\} = [X]$, where E is the mathematical expectation: the mean value is chosen as the value of the nominal model.
- $E\{||[\mathbf{X}]^{-1}||_F^2\} < +\infty$, with $||.||_F$ denoting the Frobenius norm.

Given the Cholesky factorization $[X] = [L_X]^T[L_X]$ with $[L_X]$ an upper triangular matrix, random matrix $[\mathbf{X}]$ is written as

$$[\mathbf{X}] = [L_X]^T[\mathbf{G}][L_X]\,, \tag{23}$$

in which the algebraic construction of the positive-definite symmetric real $(N \times N)$ random matrix $[\mathbf{G}]$ is given in [9] and only depends on a scalar (dispersion) hyperparameter, δ, verifying

$$\delta^2 = \frac{1}{N}\, E\{||[\mathbf{G}] - [I_N]||_F^2\}\,. \tag{24}$$

In general, the local displacements are more sensitive to uncertainties than the global displacements. The ML-SROM allows the variability of each type of displacements (belonging to either subspace $\mathcal{S}_\mathcal{L}$, subspace $\mathcal{S}_\mathcal{M}$, or subspace $\mathcal{S}_\mathcal{H}$) to be modeled separately. For each random matrix $[\mathbf{A}] = [\mathbf{M}], [\mathbf{D}], [\mathbf{K}]$ of the ML-SROM, three dispersion hyperparameters $\delta_\mathcal{L}^A$, $\delta_\mathcal{M}^A$, and $\delta_\mathcal{H}^A$ are thus introduced (with $A = M, D, K$ referring to each deterministic matrix of the ML-NROM). For $\mathcal{I} = \mathcal{L}, \mathcal{M}, \mathcal{H}$ and $A = M, D, K$, let $[\mathbf{G}_\mathcal{I}^A]$ denote the random matrix with the same construction as $[\mathbf{G}]$ and verifying $(\delta_\mathcal{I}^A)^2 = \frac{1}{n_\mathcal{I}}\, E\{||[\mathbf{G}_\mathcal{I}^A] - [I_{n_\mathcal{I}}]||_F^2\}$, in which $n_\mathcal{I} = \dim(\mathcal{S}_\mathcal{I})$. Given the Cholesky factorization $[A] = [L_A]^T[L_A]$ of each deterministic matrix $[A]$ of the ML-NROM, each random matrix $[\mathbf{A}]$ of the ML-SROM is defined as

$$[\mathbf{A}] = [L_A]^T[\mathbf{G}^A][L_A]\,, \tag{25}$$

in which the $(n_g \times n_g)$ positive-definite symmetric real random matrix $[\mathbf{G}^A]$ is given by

$$[\mathbf{G}^A] = \begin{bmatrix} [\,\mathbf{G}_\mathcal{L}^A\,] & [\;0\;] & [\;0\;] \\ [\;0\;] & [\mathbf{G}_\mathcal{M}^A] & [\;0\;] \\ [\;0\;] & [\;0\;] & [\,\mathbf{G}_\mathcal{H}^A\,] \end{bmatrix}. \tag{26}$$

Denoting as $[\Psi] = [\,[\Phi^{\mathcal{L}}]\,[\Phi^{\mathcal{M}}]\,[\Phi^{\mathcal{H}}]\,]$ the ROB of the multilevel ROM and introducing the deterministic vector $\mathbf{f}(\omega) = [\Psi]^T \mathbb{F}(\omega)$ of generalized forces, the random generalized coordinates $\mathbf{Q}(\omega) = (Q_1(\omega) \ldots Q_{n_g}(\omega))$ of the ML-SROM are the solutions of the small-dimension matrix equation

$$(-\omega^2[\mathbf{M}] + i\omega[\mathbf{D}] + [\mathbf{K}])\mathbf{Q}(\omega) = \mathbf{f}(\omega)\,, \tag{27}$$

which is solved using the Monte-Carlo simulation method [12], and allow the random response $\mathbf{U}(\omega)$ associated with $\mathbb{U}(\omega)$ to be obtained from

$$\mathbf{U}(\omega) = [\Psi]\mathbf{Q}(\omega)\,. \tag{28}$$

6 Application to the complex computational model of a car

6.1 Nominal reduced-order models

The nominal finite element model is used for constructing the multilevel stochastic ROM. The finite element model has $m = 8,000,000$ DOF and the C-NROM is constructed using the first $n = 16,192$ elastic modes as a ROB (we have $f_n = 1,600$ Hz). Then, the global-displacements nominal ROM associated with subspace $\mathcal{S}_g$ is constructed choosing $\mathcal{D}_g = 31$, $\nu = 7,000$ and $f_g^c = 1,525$ Hz. Follow the construction of subspaces $\mathcal{S}_{\mathcal{LM}}$ and $\mathcal{S}_{\mathcal{L}}$ obtained choosing $\mathcal{D}_{\mathcal{LM}} = 15$, $\nu_{\mathcal{LM}} = 1,950$, $f_{\mathcal{LM}}^c = 1,000$ Hz and $\mathcal{D}_{\mathcal{L}} = 4$, $\nu_{\mathcal{L}} = 400$, $f_{\mathcal{LM}}^c = 300$ Hz. Dimensions n_g , $n_{\mathcal{LM}}$ and $n_{\mathcal{L}}$ of subspaces $\mathcal{S}_g$, $\mathcal{S}_{\mathcal{LM}}$, and $\mathcal{S}_{\mathcal{L}}$ are $n_g = 6,984$, $n_{\mathcal{LM}} = 1,919$, and $n_{\mathcal{L}} = 344$.

6.2 Multilevel stochastic reduced-order model

The objective of the stochastic model is to take into account the variability as well as the uncertainties in the computational model (due to both the model-parameter uncertainties and the modeling errors). The global displacements, which usually correspond to resonances in the low-frequency band, are more robust with respect to small design changes, variability, and model uncertainties. We recall the multilevel ROM to be constituted of the following three orthogonal subspaces:

- $\mathcal{S}_{\mathcal{L}}$, constituted of displacements obtained using degree $\mathcal{D}_{\mathcal{L}} = 4$ for the kinetic energy and associated with the frequencies below $f_{\mathcal{L}}^c = 300$ Hz, thus expected to consist in low-frequency global displacements.

- $\mathcal{S}_{\mathcal{M}}$, constituted of displacements obtained using degree $\mathcal{D}_{\mathcal{LM}} = 15$ for the kinetic energy, associated with the frequencies below $f_{\mathcal{LM}}^c = 1,000$ Hz and orthogonal to $\mathcal{S}_{\mathcal{L}}$, thus expected to consist in combinations of a few global displacements in presence of many local displacements in the low- and mid-frequency bands.

- $\mathcal{S}_{\mathcal{H}}$, constituted of displacements obtained using degree $\mathcal{D}_g = 31$ for the kinetic energy, associated with the frequencies below $f_g^c = 1,525$ Hz and orthogonal to both $\mathcal{S}_{\mathcal{L}}$ and $\mathcal{S}_{\mathcal{M}}$, thus expected to mainly consist in local displacements present

throughout the entire band with an increasing density towards higher frequencies.

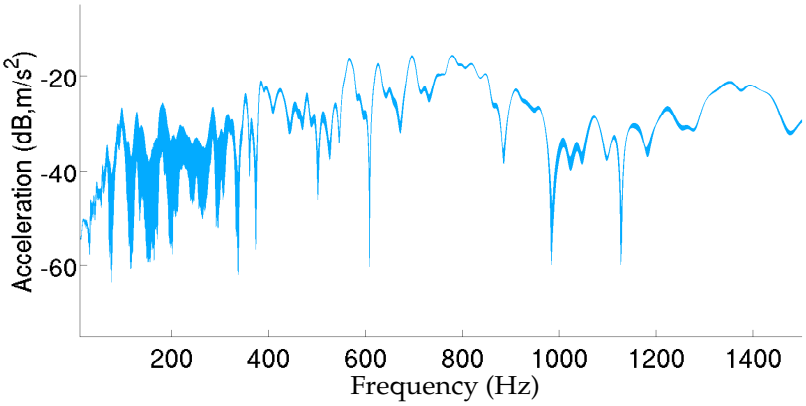

Figure 1: Random response using the ML-SROM with $\delta_{\mathcal{L}}^{M} = 0.1$ and for all other dispersion hyperparameters set to zero (95% confidence interval).

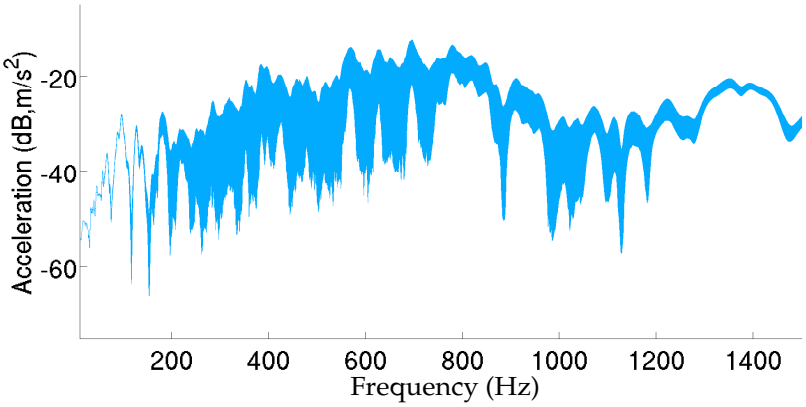

Figure 2: Random response using the ML-SROM with $\delta_{\mathcal{M}}^{M} = 0.1$ and for all other dispersion hyperparameters set to zero (95% confidence interval).

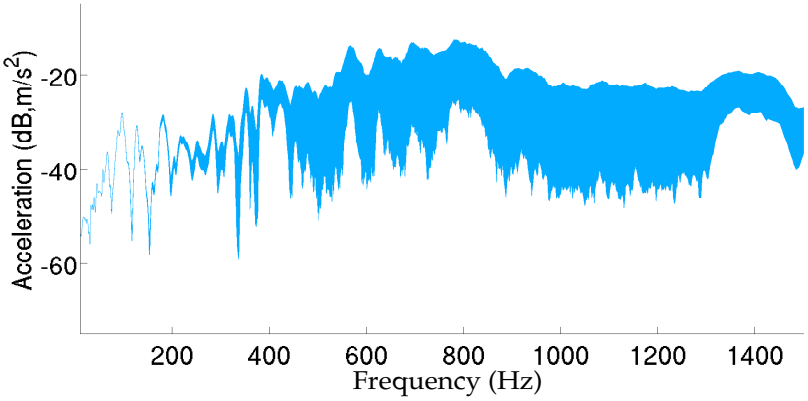

Figure 3: Random response using the ML-SROM with $\delta_{\mathcal{H}}^{M} = 0.1$ and all other dispersion hyperparameters set to zero (95% confidence interval).

The ML-SROM allows statistical dispersion levels to be controlled within each subspace. A sensitivity analysis of the ML-SROM with respect to the dispersion parameters is carried out. We are interested in performing a sensitivity analysis of frequency response functions for structural accelerations over the frequency band $\mathcal{B} = [10, 1500]$ Hz. To do so, the modulus in dB of the random normal acceleration in one point of the car (that is distant from the excitation point) is calculated using Eq. (28) with $n_{sim} = 300$ Monte-Carlo realizations. The 95% confidence intervals of the random response are plotted:

- in Fig. 1 for $\delta_{\mathcal{L}}^M = 0.1$ and for all other dispersion hyperparameters set to zero.
- in Fig. 2 for $\delta_{\mathcal{M}}^M = 0.1$ and for all other dispersion hyperparameters set to zero.
- in Fig. 3 for $\delta_{\mathcal{H}}^M = 0.1$ and for all other dispersion hyperparameters set to zero.

For only nonzero $\delta_{\mathcal{L}}^M$, the confidence interval is larger in the low-frequency band whereas it is very thin elsewhere. For only nonzero $\delta_{\mathcal{M}}^M$, the confidence interval is larger in the mid-frequencies although the dispersion also propagates around. For only nonzero $\delta_{\mathcal{H}}^M$, the confidence interval is larger in the high-frequency band although it is also large in the mid-frequency band. These results tend to agree with the qualitative expectations made hereinbefore. For $\delta_{\mathcal{M}}^M = 0.1$, the propagation of uncertainties in the high-frequency band is explained by the coupling between subspaces $\mathcal{S}_{\mathcal{M}}$ and $\mathcal{S}_{\mathcal{H}}$, which are not orthogonal with respect to the stiffness matrix.

7 Conclusions

A general method has been proposed for the construction of a multilevel stochastic reduced-order computational model devoted to the robust prediction of the frequency response functions of complex linear dynamical systems. The proposed multilevel ROM is based on the nonparametric probabilistic approach. The presence of several structural scales, characterized by the presence of more or less local displacements intertwined with the usual global displacements, and associated with the distinct low-, medium-, and high-frequency bands, induces a heterogeneous variability. Using several orthogonal subspaces each one composed of a particular type of displacements, the multilevel stochastic ROM allows for constructing a finer modeling of uncertainties. We have demonstrated the capability of the method proposed to adapt the stochastic modeling to the level of uncertainties as a function of the frequency bands that can be correlated to the scales of the global and of the local displacements.

Abstract. *A stochastic load identification approach is proposed based on a beam structure. The dynamic force is assumed as a non-stationary Gaussian random field varying with both time and space. The mode shape functions are selected as orthogonal basis for the projection of the distribution function of the stochastic dynamic force which enables the excitation force can be estimate from limit measurement response data. The statistics of the stochastic distributed force are estimated by the Mode Superposition Method (MSM) combined with the Monte Carlo Approach (MCA). A numerical example is studied. A trapezium-shaped function is assumed for the distribution of the stochastic dynamic force. The stochastic time history of the excitation forces at each location on beam is assumed to be Gaussian and have a time-varying mean value and power density function. Numerical simulations are conducted to verify the load identification algorithm. Results show that the proposed method is effective to identify the stochastic distributed load on the structure.*

1 INTRODUCTION

Dynamic load is one of the key factors in the design and condition assessment of various engineering structures. In the cases when the load information is difficult to be obtained by direct measurement, indirect approaches which noted as force identification techniques, are often adopted.

Numerous force identification approaches have been proposed in the past decades which can successfully estimate the dynamic excitation forces on engineering structure from measurement dynamic response. These methods can mainly be classified into two categories: frequency-domain method [1, 2] and time-domain method [3, 4], etc. Just as their name imply, the relationship between the measurement response and the dynamic force to be estimated are formulated in frequency domain and time domain respectively in the two kinds of method. Most of the aforementioned approaches are deterministic and focusing on the identification of concentrated force.

It is noted that various kinds of the dynamic load are spatially distributed along the structure. Two approaches namely the finite difference method and the modal method were proposed by Pezerat and Guyader [5] to estimate the spatially distributed dynamic force on structure and the regularization approach was adopted to solve the ill-posed problem [6]. In the modal method, when the force to be identified only spans over the contact region, a prohibitively large number of basis functions is often needed. An improved method was proposed by Liu and Shepard [7] in which new basis functions are introduced to overcome the drawback. A mode-selection method for distributed dynamic force was proposed by Jiang and Hu [8] and the optimal range of frequency and spatial modes was studied; to improve the accuracy on the identified force at fix boundary, the Legendre polynomials are used as the consistent orthogonal base functions to describe the distributed dynamic loads instead of the mode shape function, similar work was done by Li et al. [9] with the Chebyshev orthogonal polynomials. The temporal-dependent external forces for the cutting tools were estimated by Huang et al. [10] based on the conjugate gradient method. The acoustic holography and the force analysis technique were adopted by Pezerat et al. [11] to identify vibration sources from radiated noise measurements. The Virtual Fields Method was adopted by Berry et al. [12] to identify both mechanical point load excitation and distributed acoustic excitation of a bending panel.

Since randomness often exists in excitation forces due to the random nature, e.g. wind load, earthquake, excitation due to the road surface roughness, excitation from the ocean waves, etc. Stochastic force identification techniques have been developed. To identify the concentrated stochastic force on structure, the system uncertainty is not included at first, which can be divided into two kinds: frequency domain method [13] and time domain method [14, 15]; later, both the uncertainty in system parameters and excitation forces have been included [16, 17, 18]. These research work provide statistical estimations on the stochastic excitation forces on structure, however, stochastic excitation forces such as the wind load, load due to ocean waves, etc. are spatially distributed, new techniques should be developed to deal with the distributed stochastic dynamic force identification. A frequency domain method was proposed by Granger and Perotin [19] to identify the distributed random excitation acting on a vibrating structure and this method was further be adopted to a fluid-induced vibration problem [20]. The distributed random excitation is assumed as a stationary Gaussian random field and the mode method was adopted to identify the distribution and power spectrum density (PSD) function of the excitation force from the PSD of the measurement random response.

In this paper, a time domain approach is proposed in which a non-stationary stochastic distributed dynamical force is identified from the response sample sets from limit number of sensors under a beam structure. The mode shape functions are selected as orthogonal basis for the

projection of the stochastic distributed force. The statistics of the stochastic distributed force are estimated by the mode superposition technique combined with the MCA.

2 STOCHASTIC RESPONSE ANALYSIS OF A DYNAMICAL SYSTEM

2.1 Description of the dynamical system

A uniform simply supported Euler-Bernoulli beam subjected to a stochastic distributed dynamic force is shown in Figure 1 and this dynamic system will be adopted to demonstrate the new identification algorithm in this paper. It is noted that the proposed method may also be effective on other kinds of structure with different boundary conditions as long as the vibration modes are available.

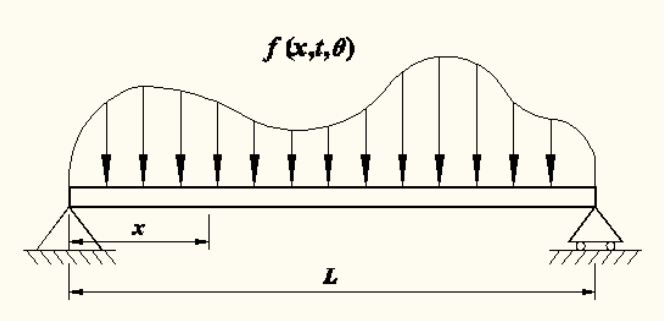

Figure 1: A simply supported beam subjected a stochastic distributed force

The equation of motion of the dynamical system is

$$\rho A\frac{\partial^2 w(x,t,\theta)}{\partial t^2}+c\frac{\partial w(x,t,\theta)}{\partial t}+EI\frac{\partial^4 w(x,t,\theta)}{\partial x^4}=f(x,t,\theta) \tag{1}$$

where ρ is the mass density and A is the cross-sectional area, therefore, ρA represents the mass per unit length. Symbols c and EI are the damping and the flexural rigidity of the beam, respectively. All the system parameters are assumed to be deterministic. $f(x,t,\theta)$ is a non-stationary Gaussian random field represents the stochastic distributed dynamic force; $w(x,t,\theta)$ is the stochastic displacement under the beam at location x and time t, and θ represents the random dimension.

2.2 Equation of motion in modal space

Though correlations may exist among the time, space and random dimension in stochastic excitations and random responses, in this research work, the distributed dynamic force is assumed as a non-stationary Gaussian random field and the distribution of the excitation is assumed to be independent of the other two dimensions and. With the ith mode shape function $\varphi_i(x)$, the stochastic distributed excitation $f(x,t,\theta)$ and the stochastic displacement under the beam $w(x,t,\theta)$ can respectively be expressed as

$$f(x,t,\theta)=\sum_{i=1}^{m}\varphi_i(x)F_i(t,\theta) \tag{2}$$

$$w(x,t,\theta)=\sum_{i=1}^{m}\varphi_i(x)q_i(t,\theta) \tag{3}$$

where the random processes $F_i(t,\theta)$ and $q_i(t,\theta)$ are the stochastic modal coordinates of the excitation and the displacement, respectively and m represents the number of modes adopted after truncation. When a simply supported Euler-Bernoulli beam is considered, the ith natural circular frequency ω_i and the mode shape $\varphi_i(x)$ have the following expressions respectively,

$$\omega_i=\left(\frac{i\pi}{L}\right)^2\sqrt{\frac{EI}{\rho A}} \quad i=1,2,\cdots,m$$
$$\varphi_i(x)=\sin\frac{i\pi x}{L} \tag{4}$$

where L is the length of the beam.

Substituting Eqs.(2) and (3) into Eq.(1), by employing the orthogonal property between the mode shape functions,

$$\int_0^L \rho A\varphi_i(x)\varphi_j(x)\mathrm{d}x=m_i\delta_{ij} \tag{5}$$

where δ_{ij} is the Kronecker delta and m_i represents the ith modal mass. In this case $m_i=\rho AL/2$. Then Eq.(1) can be rewritten as

$$\ddot{q}_i(t,\theta)+2\zeta_i\omega_i\dot{q}_i(t,\theta)+\omega_i^2q_i(t,\theta)=\frac{F_{mi}(t,\theta)}{m_i},\quad i=1,2,\cdots,m \tag{6}$$

where the over-dot represents the differentiation respect to time t. The symbol ζ_i denotes the damping ratio of the ith mode; $F_{mi}(t,\theta)$ is the ith modal force and

$$F_{mi}(t,\theta)=\int_0^L f(x,t,\theta)\varphi_i(x)\mathrm{d}x \tag{7}$$

The stochastic modal coordinates of excitation $F_i(t,\theta)$ can be calculated by

$$F_i(t,\theta)=\frac{F_{mi}(t,\theta)}{\int_0^L\varphi_i^2(x)\mathrm{d}x} \tag{8}$$

Eq.(6) is a set of stochastic ordinary differential equations which can be solved by numerical methods combined with statistical analysis tools such as the Monte Carlo simulation, the KL method, etc. and then the statistics of the random dynamical response under the beam can be obtained.

3 IDENTIFICATION OF THE DISTRIBUTED STOCHASTIC DYNAMIC FORCE

3.1 Projection scheme of the distributed excitation

When the distribution of the excitation is assumed to be independent of the other two dimensions, the stochastic distributed force $f(x,t,\theta)$ can be expressed in the follow form:

$$f(x,t,\theta)=T(x)\cdot P(t,\theta) \tag{9}$$

where $T(x)$ is a function represents the distribution pattern of the force and $P(t,\theta)$ is a random process represents the stochastic time history at each location x.

It is more difficult to estimate a distributed dynamic force $f(x,t)$ than a concentrate one since the unknown time histories of the force at each location x should be identified from limited measurement response data. The number of the unknowns tends to be infinite. In order to

reduce the unknowns in the identification process, a projection scheme is often adopted, e.g. to represent the distribution function $T(x)$ by a set of orthogonal bases $T_i(x)$,

$$f(x,t)=\sum_i T_i(x)d_i(t) \tag{10}$$

According to Eq.(10), once the coefficients $d_i(t)$ are estimated from limited measurement response data, the distributed dynamic force can be identified, which will significantly simplified the identification. With the projection scheme in Eq.(10), the ith modal force of a distributed dynamic force $f(x,t)$ gives,

$$F_{mi}(t)=\int_0^L f(x,t)\varphi_i(x)\mathrm{d}x=d_i(t)\int_0^L\sum_{ij}T_j(x)\varphi_i(x)\mathrm{d}x \tag{11}$$

When orthogonal property exists between $T_j(x)$ and $\varphi_i(x)$, the integration in Eq.(11) can be significantly simplified. Therefore, the mode shape function $\varphi_j(x)$ are adopted to replace $T_j(x)$ in Eq.(11) in this research work, according to Eq.(5), the expression of the ith modal force can be written as

$$F_{mi}(t)=d_i(t)\int_0^L\sum_{ij}\varphi_i(x)\varphi_j(x)\mathrm{d}x=\frac{m_i}{\rho A}d_i(t) \tag{12}$$

where

$$d_i(t)=\frac{\rho AF_{mi}(t)}{m_i} \tag{13}$$

Substituting Eq.(13) in to Eq.(10), according to Eqs.(5) and (8), the distributed dynamic force $f(x,t)$ can be represented by the mode shape functions as follows:

$$f(x,t)=\sum_i\varphi_i(x)d_i(t)=\sum_{i=1}^m\varphi_i(x)F_i(t) \tag{14}$$

It is noted that Eq.(14) will share the same expression with Eq.(2) when the random dimension θ is considered. To consider the random dimension θ in Eq.(12) and by substituting Eq.(12) into Eq.(6), we have

$$\ddot{q}_i(t,\theta)+2\zeta_i\omega_i\dot{q}_i(t,\theta)+\omega_i^2q_i(t,\theta)=\frac{1}{\rho A}d_i(t,\theta),\quad i=1,2,\cdots,m \tag{15}$$

Eq.(15) shows the relationship between the stochastic modal coordinates of the structural response and the stochastic coefficients of the distributed dynamic excitation force. The stochastic force identification algorithm can be formulated based on Eq.(15) with Monte Carlo approach.

3.2 Statistical force identification with MCA in modal space

Uncertainty in structural responses may originate from uncertainty in both the system parameters and excitation forces, in this research work, the system uncertainty is not addressed. The displacement measured at each location under the beam structure form a set of response sample and these sample sets belong to the population of the random displacement field $w(x,t,\theta)$. When the displacements at location $(x_1,x_2,\ldots x_n)$ are obtained from the rth measurement, these displacement data will form a vector as

$$\mathbf{W}_r = \begin{Bmatrix} w_r(x_1,t) & w_r(x_2,t) & \cdots & w_r(x_n,t) \end{Bmatrix}^{\mathrm{T}}, r = 1,\cdots,N_r \tag{16}$$

where N_r is the total number of the sample sets.

With the mode shape functions, the modal coordinates of each set of the dynamic response sample can be obtained from the following Equation,

$$\begin{Bmatrix} w_r(x_1,t) \\ w_r(x_2,t) \\ \vdots \\ w_r(x_n,t) \end{Bmatrix} = \begin{bmatrix} \varphi_1(x_1) & \varphi_2(x_1) & \cdots & \varphi_m(x_1) \\ \varphi_1(x_2) & \varphi_2(x_2) & \cdots & \varphi_m(x_2) \\ \vdots & \vdots & \ddots & \vdots \\ \varphi_1(x_n) & \varphi_2(x_2) & \cdots & \varphi_m(x_n) \end{bmatrix} \begin{Bmatrix} q_{1,r}(t) \\ q_{2,r}(t) \\ \vdots \\ q_{m,r}(t) \end{Bmatrix} + \begin{Bmatrix} \varepsilon_{1,r}(t) \\ \varepsilon_{2,r}(t) \\ \vdots \\ \varepsilon_{n,r}(t) \end{Bmatrix} \tag{17}$$

where $q_{i,r}(t)$ (i=1,⋯,m) is the modal coordinate of the ith mode and rth measurement and $\varepsilon_{j,r}(t)$ (j=1,⋯,n) is the error term of the jth location and rth measurement. The error term may include the measurement noise, model error, truncation of the higher order of modes and so on. Generally, the number of the modes m after truncation should be smaller than the number of the measurement locations n to avoid solving a set of underdetermined system of equations as shown in Eq.(17). When the rth sample of the coordinate of displacement $q_{i,r}(t)$ corresponding to the ith mode is obtained, the first and second derivatives of $q_{i,r}(t)$, which represent the coordinate of the velocity $\dot{q}_{i,r}(t)$ and acceleration $\ddot{q}_{i,r}(t)$, respectively, can be derived with differentiation. Therefore, the samples of the coefficient $d_{i,r}(t)$ for the distributed force can be calculated as

$$d_{i,r}(t) = \rho A\left[\ddot{q}_{i,r}(t) + 2\zeta_i\omega_i\dot{q}_{i,r}(t) + \omega_i^2 q_{i,r}(t)\right], \quad r = 1,2,\cdots,N_r \tag{18}$$

Finally, the statistics of the identified stochastic distributed force, i.e. the mean value $\mu_f(x,t)$ and the variance $Var_f(x,t)$ can respectively be derived as

$$\mu_f(x,t) = \frac{1}{N_r}\sum_{r=1}^{N_r}\sum_{i=1}^{m}\varphi_i(x)\,d_{i.r}(t) \tag{19}$$

$$Var_f(x,t) = \frac{1}{N_r - 1}\sum_{r=1}^{N_r}\left(\sum_{i=1}^{m}\varphi_i(x)\,d_{i.r}(t) - \mu_f(x,t)\right)^2 \tag{20}$$

4 NUMERICAL SIMULATIONS

To verify the effectiveness of the proposed method and investigate different factors which may influence the accuracy of this stochastic distributed dynamic force identification algorithm, numerical simulations are conducted. The following parameters of the beam structure are adopted.

Length of the beam L=40 m; Cross-sectional area A=4.8 m^2; Second moment of inertia of cross-section I=2.5498 m^4; Rayleigh damping is assumed for the structure with damping ratio ξ=0.02 for all vibration modes; Young's modulus E and mass density ρ of material are 5×10^{10} N/m^2 and 2.5×10^3 kg/m^3 respectively. The first five natural frequencies of the beam are 3.9, 15.6, 35.1, 62.5 and 97.6 Hz, respectively.

A trapezium-shaped distribution function of the stochastic dynamic force is assumed in this study which has the following expression,

$$T(x)=\begin{cases}4x/L & 0\le x<L/4\\ 1 & L/4\le x\le 3L/4\\ -4x/L+4 & 3L/4<x\le L\end{cases} \tag{21}$$

It should be noted that the selection of distribution function is arbitrary unless it is periodic. Theoretically, any periodical distribution functions $T(x)$ can be represented by the orthogonal modal shape function bases; therefore, it will not affect the investigation on the proposed method.

The stochastic time history of the excitation forces at each location x denoted by $P(t,\theta)$ is assumed with the following mean values,

$$P_{\mathrm{d}}(t)=20000\left(1+0.1\sin(2\pi t)\right)\ \mathrm{N} \tag{22}$$

where the subscript 'd' denotes the deterministic part. The random part of $P(t,\theta)$ is assumed as a zero-mean non-stationary Gaussian random process with a time-varying PSD function $S(\omega,t)$ as

$$S\left(\omega,t\right)=C_f P_{\mathrm{d}}(t)\Phi\left(\omega\right) \tag{23}$$

where C_f is a coefficient represents the level of randomness and $\Phi(\omega)$ is a two-sided PSD function of a zero-mean stationary Gaussian random process,

$$\Phi\left(\omega\right)=\frac{1}{2\pi}\frac{2}{\omega^2+1} \tag{24}$$

According to the spectral representation[21] for a Gaussian process, the rth sample of the stochastic distributed force $f(x,t,\theta)$ at location x can be simulated by the following series,

$$f_{\mathrm{r}}(x,t)=T\left(x\right)\left[P_{\mathrm{d}}(t)+C_f P_{\mathrm{d}}(t)\sum_{k=1}^{N_k}\sqrt{4\Delta\omega\Phi\left(\omega_k\right)}\cos(\omega_k t+\varphi_k)\right] \tag{25}$$

where

$$\omega_k=\omega_{\min}+\Delta\omega\left(k-1\right) \tag{26}$$

$$N_k=\left(\omega_{\max}-\omega_{\min}\right)/\Delta\omega \tag{27}$$

It should be noted that Eq. (25) is not unique and other forms of expansion can be adopted. The variable φ_k is a random phase angle uniformly distributed in the interval $[0, 2\pi]$. The constant $\Delta\omega$ denotes the frequency increment and N_k is the total number of frequency divisions in the interval $[\omega_{\min}, \omega_{\max}]$. In this study, $\omega_{\min}$=0 Hz, $\omega_{\max}$=200π Hz, N_k=512, therefore, $\Delta\omega$=1.227 Hz and the sampling frequency in all the simulations is 200Hz, the total time is 1s.

The relative errors between the referenced and calculated results, *RE*, is defined as

$$RE=\frac{\left\|R_{calculated}-R_{referenced}\right\|_2}{\left\|R_{referenced}\right\|_2}\times 100\% \tag{28}$$

where $\left\|\bullet\right\|_2$ denotes the 2-norm.

4.1 Verification of the Forward Problem

To verify the forward problem of the proposed algorithm, the response samples of the beam structure under a stochastic distributed dynamic force are calculated with two methods: Modal superposition method with MCA (MMA) and FEM with MCA (FMA).

The samples of the stochastic distributed dynamic force are calculated from Eq. (25) in which the random phase angle φ_k is generated by "rand" in MATLAB software. C_f which represents the level of randomness is set to 0.2. When the number of response samples is sufficient, accuracy of the proposed algorithm will not be affected by the level of randomness due to the characteristic of MCA. In MMA, the samples of the ith modal force $F_{mi}(t,\theta)$ is calculated according to Eq. (7) in which the integration is conducted using "trapz" in MATLAB software with a step of 0.4m. 30 vibrational modes are adopted and the samples of the modal coordinates of the structural response are calculated by solving Eq. (6) using Newmark-β method. Response statistics of both 5000 samples and 10000 samples from MCS are obtained. In FMA, the samples of the nodal forces are calculated by integrations between the samples of the stochastic distributed dynamic force and the Hermitian cubic interpolation shape functions and. eight beam elements are adopted in the finite element model. The response samples of the beam structure obtained in FMA is similar to that in MMA and the response statistics of 5000 samples from MCS are obtained.

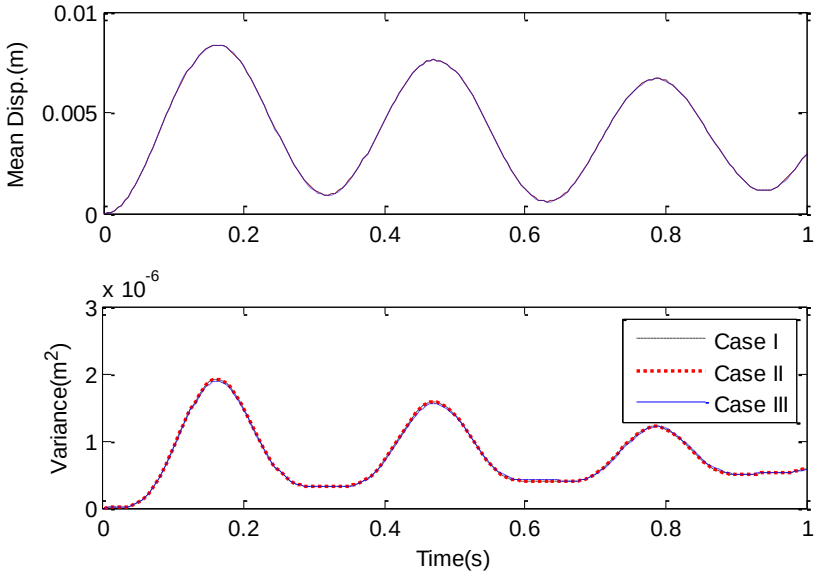

Figure 2. Response statistics of the mid-span displacement

Three sets of statistics of the mid-span displacement of the beam structure are demonstrated in Figure 2. They are from 5000 samples in MMA (Case I), 5000 samples in FMA (Case II) and 10000 samples in MMA (Case III), respectively. Results show that the time histories of mean value and covariance of the mid-span displacement from different simulations agree well with each other. If the response statistics of 10000 samples from MMA (Case III) is assumed as the "referenced" result, the relative errors of the mean value and variance between Case I and Case III according to Eq. (28) are 0.27% and 2.74%, respectively; the relative errors of the mean value and variance between Case II and Case III also equal to 2.85% and 5.82%, respectively. Results indicate that: (1) the time histories of response statistics in all Cases are agree well with each other; (2) 5000 runs in MCA are sufficient for obtaining accu-

rate response statistics; (3) Response statistics from FMA in this case is sightly smaller than that from MMA.

4.2 Verifications of the Inverse Problem

To verify the inverse problem of the proposed algorithm, i.e. to identify the statistics of the non-stationary stochastic distributed dynamic force from measurement response samples, 5000 sets of 19 displacements evenly distributed underneath the beam structure are adopted, i.e. N_r=5000 and n=19, the distance between two sensors in this case is 2m. It is noted that strain signals can also be adopted in the force identification, since strains have the following relationship with displacement for a beam structure,

$$\varepsilon(x,t) = -z\frac{\partial^2 w(x,t)}{\partial x^2} \tag{29}$$

where z represents the distance from the neutral axis of the beam to the strain gauge.

Nineteen modes are adopted in the inverse problem, i.e. m=19. When the number of the measurement locations n is not less than the number of the modes m, the modal coordinates for each set of displacement sample are calculated according to Eq. (17). The cubic spline interpolation is applied on the modal coordinates for each set of displacement sample $q_{i,r}(t)$, then the first and second derivatives of $q_{i,r}(t)$ are calculated which represent the modal coordinate of the velocity and acceleration, respectively. Therefore, the samples of the coefficient $d_{i,r}(t)$ for the distributed force can be calculated according to Eq.(18). Finally, the statistics of the identified stochastic distributed dynamic force can respectively be obtained from Eqs. (19) and (20). The "referenced" mean value and variance of the stochastic distributed dynamic force can respectively be estimated from the following Equations,

$$\tilde{\mu}_f(x,t) = \frac{1}{N_r}\sum_{r=1}^{N_r} f_r(x,t) \tag{30}$$

$$\tilde{Var}_f(x,t) = \frac{1}{N_r - 1}\sum_{r=1}^{N_r}\left(f_r(x,t) - \mu_f(x,t)\right)^2 \tag{31}$$

The identified and referenced statistics of the stochastic distributed dynamic force at the mid-span are shown in Figure 3. Results show that the time histories of two statistics agree well with each other, which indicates the statistics of the distributed non-stationary stochastic dynamic force can successfully be identified from response sample sets. The relative errors between the identified and the referenced mean value and variance are 4.55% and 7.08%, respectively.

Since the stochastic force is non-stationary, the distribution of the force will vary with respect to time. In order to demonstrate the accuracy on the identified distribution of the force, the identified distributions at different moments, e.g. at 0.25s, 0.5s and 0.75s, are normalized and compared with the referenced distribution function $T(x)$ in Eq. (21). Results are shown in Figure 4 in which the identified distributions of the mean force and the variance of the force at each moment are compared with $T(x)$ and $T(x)^2$, respectively. The distribution at each moment of the distributed non-stationary stochastic force can be successfully identified from limit number of measurement points. The relative errors between the identified and the referenced distribution for the mean value and variance of force at 0.5s are 0.57% and 0.92%, respectively. The relative errors among the identified distribution for the mean value and variance of force at different moments are smaller than 0.5%, i.e. the identification error is small and stable during the time history of the force.

5 CONCLUSIONS AND DISCUSSIONS

In order to estimate a distributed non-stationary random excitation on a vibrating structure, a time domain method is proposed and demonstrated on a beam structure. The dynamic force is assumed as a non-stationary Gaussian random field varying with both time and space. A trapezium-shaped distribution function is selected for the stochastic dynamic force in the numerical simulation. With a combination of MSM and MCA, both the distribution and the

time-varying statistics of the random excitation can be estimated from response sample sets with good accuracy.

Different factors such as the number of vibration modes, the installation of sensors, the noise pollution in the response samples, etc. which may affect the accuracy of the proposed method are need to be further investigated and since the mode shape function is adopted as the orthogonal basis, when the random excitation only applied on part of the structure, numerous mode shape function should be included to achieve accurate results, which will further require more measurement sensors to be installed to acquire response samples. For this statistical identification approach in time domain, sufficient number of sample sets is assumed to avoid the unexpected errors in variance identification, when the number of samples sets reduce, the errors in the identified statistics of the random forces will increase and tend to be unstable. Investigation on aspects mentioned above will improve this primary work and will be conducted in the future work.

Keywords: Corrosion, Polynomial Chaos, Reinforced Concrete, Service Life prediction

Abstract. *A main reason behind reinforced concrete structural deterioration is chloride-induced corrosion. Once the critical chloride concentration is exceeded at the rebar level, the structure becomes susceptible to corrosion initiation. Corrosion propagates progressively, degrades the resistance capacity of the structure and decreases the design safety margin. To mitigate this risk, a stochastic sequential data assimilation technique based on chloride concentration measurements and the Polynomial Chaos Kalman Filter (PCKF) is presented.*
The Power of PCKF lies in its sampling free scheme and polynomial structure to represent uncertainty. In modeling chloride ingress mechanism, different independent sources of uncertainty should be incorporated in the system including, mathematical model simplification errors, parametric errors, boundary condition errors, and time independent sensors errors. In such circumstances, the curse of dimensionality hinders the efficiency and the applicability of PCKF, due to the exponential growth of the required bases to account for the added uncertainties. This study presents a practical framework to maintain an acceptable accuracy of PCKF without scarifying the computational efficiency of the filter. A one dimensional synthetic numerical example is presented to verify the efficiency of the proposed implementation scheme.

1 INTRODUCTION

Reinforced concrete (RC) structures, like buildings, bridges, dams, tunnels, pipelines, among others, are complex engineering systems, with long life expectancy, that serve society's industrial needs and guarantee economic prosperity. Labor force and financial assets are extensively invested in the design and construction stages of RC projects to achiever two-primer concerns, safety and serviceability through their lifetime. Research efforts and gained experience, influence design codes and governmental regulations to improve current practices in order minimize the risk of failure and loss of serviceability. However, structures might be exposed to different environmental conditions and severe loading that can lead to structural deterioration. Therefore, continuous monitoring of the changing environmental conditions and accurate prediction of response of structures under real conditions are becoming highly recommended in practice [1]. In technical terms, this process is known as Structural Health Monitoring (SHM). SHM relies on real time measurements, damage detection algorithm and data assimilation technique for early detection of risks and better assessment of the operating conditions. Consequently, early risk alerts are set and maintenance schedules and repair mechanisms are optimized for proactive measures.

Among these damage mechanisms, corrosion in reinforcement bars is recognized as a serious deterioration phenomenon that threatens structural integrity. It is usually referred to as the most common cause for structural deterioration, and it leads to major problems in maintenance and rehabilitation of RC structures. In practice, corrosion of RC can be understood as a two-stage process: the corrosion initiation stage and the propagation stage [2]. During the first stage, the pH of the pore solution is reduced, leading to the de-passivation of the protective film, and exposing the rebar to corrosion initiation. The most common cause of corrosion initiation is typically attributed to the presence of chloride ions; the de-passivation of the protective films occurs when their concentration at rebar level exceed a certain threshold. The source of chlorides may be admixtures, contaminants, marine environments, industrial brine and deicing salts. Once the corrosion is initiated, the steel starts to corrode generating iron oxides, which remarks the starting of the second stage. Corrosion then progressively propagates causing cracking, delamination and spalling of the concrete cover, thus threatening the structure and alerts serviceability failure.

Once the damage occurs, the process becomes irreversible and needs detailed inspections and may required complex repair strategies. This shifts the attention to proactive maintenance measures that includes treatment before any considerable damage. The application of this strategy needs adequate knowledge about the state of the structure and close monitoring of the corrosive species. Condition assessment of such structures is typically based on comparing the chloride content at steel level to the critical threshold chloride concentration.

For accurate prediction of corrosion initiation, Polynomial Chaos Kalman filter (PCKF) will be employed, in this study, for parametric identification of the quantities of interest in a probabilistic framework. Based on real time measurements and dynamic model predictions, the PCKF calibrates the chloride profile and model parameters to improve the prediction of the remaining corrosion free service life and to initiate proactive maintenance alert. This study will also suggest a practical implementation of PCKF, when time independent sources of uncertainties are incorporated in the system. The computational cost efficiency and the accuracy of the implementation will be compared to its closest descendent in the Kalman Filter family, the Ensemble Kalman filter (EnKF).

2 CHLORIDE INGRESS

Different phenomena govern the ingress of chloride ions into concrete pores depending on the state of the structure and the depths of concrete cover. In unsaturated medium, diffusion is the governing mechanism beyond the convection zone. However, in saturated and fully submerged concrete structures, the diffusion process is the governing mechanism after initial wetting [3, 4]. Since the principle objective is to estimate, the chloride concentration at rebar level, chloride ingress is typically modeled as a diffusion process according to Fick's second law and assuming constant boundary conditions. The general diffusion equation relates the diffusion coefficient and the gradient of the concentration as follows:

$$\frac{\partial C}{\partial t} = \nabla.(D(t)\nabla C) \tag{1}$$

where $C\ (kg/m^3)$ is the spatial chloride content at a certain location and time t. $D(t)$ is the diffusivity coefficient at t generally represented as a time decaying function:

$$D(t) = D_R\left(\frac{t_R}{t}\right)^m \tag{2}$$

where D_R is the reference diffusion coefficient at time t_R (usually$t_R = 28$ days) and m is a constant depending on concrete mix proportions. $D(t)$ should also account for the effects temperature and relative humidity [5].

An analytical solution, eq. 3, is derived from eq. 1 under several assumptions: 1-D diffusion process, constant surface chloride content, constant diffusion coefficient and infinite medium.

$$C(x,t) = C_s[1 - \mathrm{erf}\left(\frac{x}{2\sqrt{Dt}}\right)] \tag{3}$$

where C_s is the chloride surface concentration, x is the location away from the surface, and t is the time period.

To maintain generality and robustness, a numerical discrete solution for eq.1 will be implemented based on finite element/finite difference scheme rather than the solution presented in eq. 3 since the latter tends to lose its accuracy for varying environmental and parametric conditions. Moreover, using a numerical discretization scheme, spatial variability in the chloride profile can be updated and incorporated in the state vector for more accurate dynamic model propagation.

3 SOURCES OF UNCERTAINTY

Many sources of uncertainty are identified once developing an accurate mathematical model to simulate the chloride ingress process. First, the model input parameters have a wide margin of variability: the diffusion coefficient depends on the concrete mix and heterogeneous aging of concrete, concrete cover depends on the workmanship skills and on-site quality control, chloride surface concentration depends on type and severity of exposure, chloride concentration threshold values depend on steel bars and cementing material types and admixtures and method of measurement etc. [4]. Additional uncertainties can also be attributed to simplifications associated with the adopted mathematical model, measurement and human errors. To account for the effect of these uncertainties in modeling corrosion, probabilistic models can be used to estimate the probability of corrosion initiation, yet the quantification of

statistical input is usually very difficult and unfavorable in practice due to limited data and wide discrepancy [6].

Therefore, to identify accurately the corrosion initiation time, engineers are resorting to structural health monitoring (SHM). The process of monitoring the corrosion initiation time is theoretically tied to monitoring the free chloride ions in concrete and sometimes to total chloride content [7].

4 SERVICE LIFE PREDICTION

To guarantee safety and integrity of the structure, adequate maintenance is an essence. In the case of corrosion deterioration, the typical forms of repair are removing the concrete cover to clean the corroded steel and restoring the integrity of the formed cracks by certain injections. In some cases, additional structural support is necessary to rehabilitate the loss in designed structural capacity. This reactive maintenance practice is usually unfavorable for two main reasons: First, it pushes the structure to an extreme limit before interfering, which might lead to serviceability failure or even structural failure. Second, in case of corrosive deterioration, the later the maintenance is scheduled the more cost is associated with the repair mechanism. Therefore, pro-active maintenance is highly desirable in practice. The main strategy is to provide protection to reinforced concrete structures to either prevent or halt the problem of corrosion of the reinforcement before any considerable damage.

The probability of corrosion of the structure is computed as the probability of the chloride concentration exceeding the threshold value at the steel bar location. Typically, a reliability tolerance is selected based on the significance of the monitored structure, and accordingly, a maintenance plan is set and recurrently updated to prevent the structure from exceeding the designated probability of corrosion.

To represent the probability corrosion initiation, a limit state function relating the chloride threshold to chloride concentration at cover location is presented in equation 4. The limit state, g, is evaluated as the algebraic difference of the chloride critical threshold concentration and the predicted concentration at rebar level. A negative limit state indicates that corrosion has initiated while a positive outcome represents a safe un-corroded structure.

$$\mathrm{g}(\mathrm{C_{th}}, \mathrm{C_s}, \mathrm{D_R}, \mathrm{m}, \mathrm{x_r}) = \mathrm{C_{th}} - \mathrm{C}(\mathrm{C_s}, \mathrm{D_R}, \mathrm{m}, \mathrm{x_r}) \tag{4}$$

To quantify the uncertainties associated with modeling, parametric and boundary condition errors,C_{th},C_s,D_R, and x_r are modeled as lognormal random variables representing the chloride threshold concentration, chloride surface concentration, diffusion coefficient, and cover location respectively. The age factor m is best modeled as beta distribution between 0 and 1, to abide by the constraining physical behavior. The random process C is the numerical solution of the stochastic diffusion equation approximated using a finite elements/ finite difference scheme.

Thus, the probability of corrosion is theoretically represented as the integral of the joint probability density function, $\mathrm{f_x}$, of the outcome of g, over the negative domain or corrosion domain as shown in equation 5:

$$\mathrm{P_f} = \int_{\mathrm{g(C_{th},C_s,D_R,d,m)<0}} \mathrm{f_x}(\mathrm{C_{th}}, \mathrm{C_s}, \mathrm{D_R}, \mathrm{m}, \mathrm{x_r})\mathrm{dx} \tag{5}$$

The solution of the above integral is estimated using Monte Carlo simulation, which is simple and easy to implement; it consists of simulating the outcome using random samples of

the input parameter and repeating the process sufficiently enough times to represent the pdf of the outcome

5 SEQUENTIAL DATA ASSIMILATION

Sequential data assimilation techniques typically utilize the dynamics of a known process and set of observations of the outcome for improving the knowledge of unknown state model parameters and dynamic variables. A well-known sequential filter, in estimation theory, is Kalman filter, which gives unbiased estimate with a minimum error variance when the system has linear dynamics and Gaussian measurement errors. However, in a non-linear modeling framework and in non-Gaussian framework, the Kalman filter loses many of its pros. Extensions of Kalman filter have been suggested in literature for approximating the posterior measures in complex systems. To address this issue, this study proposes the use of polynomial chaos based Kalman filter for data assimilation purposes. PCKF was suggested as a sampling free alternative [8, 9, 10, 11]. A detailed explanation of its theoretical background and implementation is discussed below.

5.1 Polynomial Chaos Expansion (PCE)

PCE is a non sampling approach to represent uncertainty using deterministic orthogonal polynomials. Let $\xi(\theta)$ be a vector containing random independent variables, where θ is used as an index of the probabilistic character of the components of the vector (ξi). Each component of the vector denotes an independent source of uncertainty, where it's considered as a modeling decision to choose the length of the random variables vector or the contributing sources of uncertainty. Non-linear functional of ξ are expanded with respect to a basis in space of square integrable random variables. A suitable set of these bases is utilized by multidimensional polynomials, such that they are orthogonal to the joint probability measure of the random variables vector ξ. Therefore, in accordance with this formulation, if the random variable used is Gaussian, the orthogonal multidimensional basis is Hermite polynomials. Then accordingly, the deterministic coefficients of each basis are determined to parameterize the probabilistic distribution of the expanded function that uniquely represents its distribution and in an L2 sense. To elaborate the PCE more, consider a random process $u(x,\theta)$ that is expanded with respect to the vector ξ, with a finite covariance. Thus, its polynomial expansion is written with respect to multidimensional Hermite polynomials in Gaussian random variables arguments ($\xi i1, \xi i2 \dots \xi in$) as follows [12]:

$$u(x,\theta) = a_0(x)\Gamma_0 + \sum_{i_{1=1}}^{\infty} a_{i_1}(x)\Gamma_1\left(\xi_{i_1}(\theta)\right) + \sum_{i_{1=1}}^{\infty}\sum_{i_{2=1}}^{\infty} a_{i_1 i_2}(x)\Gamma_2\left(\xi_{i_1}(\theta)\xi_{i_2}(\theta)\right) + \cdots \quad (6)$$

Where Γ_n is the nth multidimensional Hermite polynomial, and a_{i_n} is its corresponding deterministic coefficient. The above series could be truncated by choosing a finite length independent random variable vector and an upper limit for the degree of the Hermite polynomial. By introducing a one to one mapping to a set of ordered indices, and truncating the series after the P^{th} term, the above expansion is rewritten as follow:

$$u(x,\theta) = \sum_{j=0}^{P} u_j(x)\psi_j(\theta) \tag{7}$$

The accuracy of the polynomial expansion is usually refined by increasing the M random dimension and/or the maximum order p of the expansion. The total number of terms, P+1, can be calculated as following:

$$P + 1 = \frac{(p + M)!}{M!\, p!} \tag{8}$$

5.2 Polynomial Chaos Kalman Filter (PCKF)

The PCKF consists of two stages: (1) a forecast stage and (2) an analysis stage if a measurement is present. The order and dimension of PC expansion are fixed from the beginning and throughout the processing for simplicity and computational purposes.

5.2.1. Forecast stage

Let A be the state matrix, which contains the vectors representing the deterministic coefficients of the PCE corresponding to model state and parameters at time t*:*

$$A = (u_0, u_1 \dots, u_p)\ \ u_i \in R^n, A \in R^{n\times(P+1)} \tag{9}$$

where u_i corresponds to the i^{th} component of the PCE expansion of the state vector u containing the chloride concentration at nodes, D, m and Cs. In the forecast stage, the uncertainty of the parameters and the dynamic state is propagated forward in time using stochastic Galerkin scheme. A process noise is added after forecast to represent the modeling error.

5.2.2. Analysis stage

This is a learning stage, where parameters and uncertainties are updated when a measurement is available. The measurement probabilistic representation, which is in this case the free chloride concentration at certain locations, is also expanded in a polynomial chaos form,

$$D = \sum_{j=0}^{P} d_j\psi_j \tag{10}$$

where dj is the deterministic coefficient of the jth basis. D is stored in a matrix form,

$$B = (d_0, d_1 \dots, d_p) \tag{11}$$

The filtering step relies on a minimum square error estimator of the coefficient of the polynomial chaos expansion. To evaluate the coefficient of the analysis step, the filtering step equation is projected on an approximating space by the basis of polynomial chaos $\{\psi_j\}_{j=0}^{P}$, this results in:

$$u_j^a = u_j^f + P^f H^T (H P^f H^T + R)^{-1} . (d_j - H u_j^f) \quad (12)$$

where f and a denote the forecast and analysis variables respectively, H acts as a linear measurement operator, to relate the true model state, to the measurements d and P ,with f or a indices, and R are the covariance error matrices of the forecast state and the measurements respectively

In a matrix form, it becomes [8],

$$A^a = A^f + P^f H^T (H P^f H^T + R)^{-1} . (B - H A^f) \quad (13)$$

5.3 Curse of Dimensionality and Suggested Implementation

When the process noises and measurement errors are considered in PCKF application as time independent variables, the PCE terms could increase beyond computational applicability. PCKF has gained a noticeable popularity since it was first used in 2007 [10], however, it was rarely applied with time independent process noises and model errors. Moreover, time independent measurements are usually approximated with a finite memory dimension with no clear methodology or error analysis for this representation. The theoretical necessity to add independent dimensions for every independent source of error discouraged researchers from applying polynomial chaos based filters to problems with high independent sources of errors. This issue could be the reason behind limiting the application of polynomial chaos based filters to problems with initial value errors and made the use of sampling filters advantageous for other applications.

Theoretically, each independent source of error will cost an increase in the dimensionality of the problem. However, this study will focus on keeping the computational cost minimal yet without scarifying the accuracy. The suggested approach to deal with increasing dimensionality of the PCE, due to incorporation of time independent errors, relies on limiting the PCE bases to finite terms, yet keeping an approximate same covariance. This strategy can be achieved by projecting the covariance matrix on a pre-specified number of first order terms when an additional basis is required beyond the fixed expansion length (P+1). This methodology maintains a good approximate propagation of the covariance and the mean of the parameters, and maintains a low-dimensional PCE. Thus, the unbearable cost of curse of dimensionality is shifted to the cost of projection the covariance matrix on first order terms, which is the solution of a system of non-linear equations, with, in most cases, a close initial guess. This approach is influenced by the characteristics of PCKF as being suited as an identification filter rather than inference method, since PCKF provides a good approximation of the posterior mean in Bayesian setting with a random priori estimation error [13]. In addition, it relies on the covariance matrices of the forecasted state vector and the covariance of the measurements, for an optimal identification of the state vector, i.e. maintaining a good estimate of the first two moments is the pillar for a successful implementation of PCKF.

6 NUMERICAL APPLICATION

The efficiency of the presented health-monitoring scheme is illustrated on 1-D diffusion example. The problem represents the chloride ingress in a near shore wall or an interior column exposed to a corrosive environment. A 50x25 cm reinforced concrete column with a 5 cm cover depth is used to demonstrate the efficacy of the presented framework. The sensors

are put in two locations in the zone of interest, near the rebar location, as shown in Table 1, and only one surface is assumed fully saturated.

Sensors	Location (m)
1	0.05 from surface
2	0.03 from surface

Table 1 Sensors' Locations

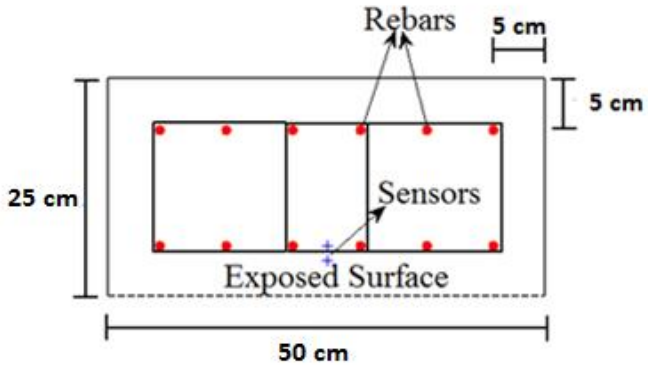

Figure 1 Schematic Drawing

6.1 Input Parameters

Table 2 presents the input parameters assumed for the base model. These parameters are used to simulate the measured chloride concentrations.

Parameter	Value	Comments
Surface Chloride Concentration, C_s	5 kg/m^3	High exposure
Reference Diffusion Rate, D_R	0.00015 $m^2/year$	At 28 days
Age factor, m	0.07	

Table 2 Base Model Input Parameters

The Crank solution eq. 3, with an average time varying diffusion rate Dm (t) [14], is used to generate the sensors' synthetic data. To represent measurement errors, an additive Gaussian white noise perturbation having a standard deviation equal to 2% of the actual data is added to the simulated chloride concentrations.

Starting with an initial assumption for the state of each parameter, the perturbed synthetic measurements are used to calibrate them as time progress. Table 3 presents the assumed initial probabilistic characteristics for the model parameters. Furthermore, it is assumed that the structures in both problems are chloride free at the beginning of the simulation time.

Parameter	Mean Value	cov	Distribution
Surface Chloride Concentration, C_s	4 kg/m^3	0.07	Lognormal
Reference Diffusion Rate, D_R	0.0001 $m^2/year$	0.07	Lognormal
Age factor, m	0.05	0.07	Beta

Table 3 Initial Model Parameters

Within the framework of the PCKF, a set of orthogonal polynomials are used to represent the uncertainty within the system. The initial PCE is propagated forward in time using finite element analysis with 0.025 years increment. The model error and parametric errors are represented via an additive Gaussian white noise with a standard deviation equals to 1.5% and 2.5% respectively of the forecasted mean. To represent the spatial variability in concrete, a spatial de-correlation length of 4 cm is assumed; thus a 6 i.d.d random variables are assigned to represent the uncertainty in the concentration profile grid each time model error is incorporated in the system. Whenever measurements are available, the model state vectors are updated using the analysis stage equations. With a real time sensor system, data availability is not a limitation since sensors typically give instantaneous measurements. However, due to the relatively slow nature of the chloride ingress, a one-year measurement interval is adopted.

6.2 Results

6.2.1. PCKF implementation

The benchmark for comparing the results of the suggested implementation will be an EnKF approach using theoretically sufficient ensembles representation, to eliminate sampling errors, that is in this case $5x10^5$ ensembles. To assess the effect of number of random variables and maximum order used in the PCE, the methodology will be applied to four independent formulations of PCE with: (1) 37 dimensions and order 1, (2) 37 dimensions and order 2 and (3) 37 dimensions and order 3 and (4) 45 dimensions and order 2. Note that the only constraint for applying the projection on the first order basis is that the number of first order basis (dimension) is at least equal to the length of the state vector, to be able to solve the non-linear system of equations. In addition, two EnKF formulations with $0.25\ x10^5$ and $1\ x10^5$ ensembles will be simulated for comparative purposes. The computational cost will be assessed based on the time (sec) needed to run the simulations for 20 years, or 800 time steps. However to assess the accuracy of the suggested scheme the average deviation, eq. 14, and the maximum deviation, eq. 15, of the first two order moments, from benchmark problem, of chloride concentration at rebar level and the time varying diffusion rate will be calculated for the simulated period, as follows:

Average deviation:

$$\%Ad = \sum_{n=0}^{800} \frac{|(\mathrm{u}^n - u^n_{benchmark})|}{800 \times u^n_{benchmark}} \times 100 \tag{14}$$

$$\%Maxd = Maximum\ (\frac{|(\mathrm{u}^n - u^n_{benchmark})|}{u^n_{benchmark}} \times 100)_0^{800} \tag{15}$$

Where u and $u_{bechmark}$ are first or second order moments of the studied sequential formulation and benchmark problem formulation respectively. The $\%Maxd$ of the studied parameters and the $\%Ad$, for the simulation period are presented in Tables 4 and 5 respectively. Table 6 presents the computational time, in seconds, required for the different sequential filters' formulations, to perform the forecast steps and the analysis steps for the 20 years. These tables reflect the power of the suggested scheme, where the PCKF with dimension 37 and order 2 rendered accurate results, with less than 0.35 $\%Maxd$ and less than 0.094 $\%Ad$ and with better accuracy and computational cost compared to EnKF formulations. Moreover, no significant improvement is shown in the PCE formulation beyond 37 dimensions and second

order. This can be attributed to the emphasize of the lower order terms due to the projection on the first order bases and to conservation of first two moments in all PCE expansions.

6.2.2. Parametric identification

PCKF with 37 dimensions and second order PCE is used for health monitoring of chloride ingress in concrete. Figure 2 shows the mean prediction of chloride concentration at rebar level using PCKF calibration technique compared to using initial value parameters, and Figure 3 shows the mean and 1 std error bars of the calibrated time varying diffusion coefficient as compared to the base case model assumptions. A significant improvement in identifying the chloride concentration at rebar level and the diffusion parameter is reflected in these two figures. Consequently, a more accurate reliability assessment for corrosion initiation can be performed using the updated state vector parameters.

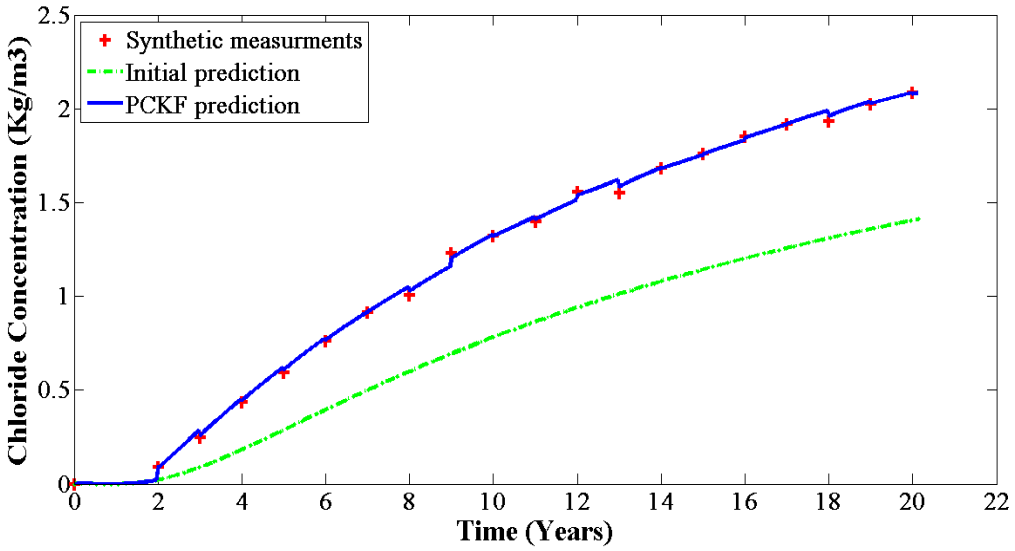

Figure 2 Measured Vs. Predicted chloride concentration chloride concentration using PCKF and initial parameters at rebar level

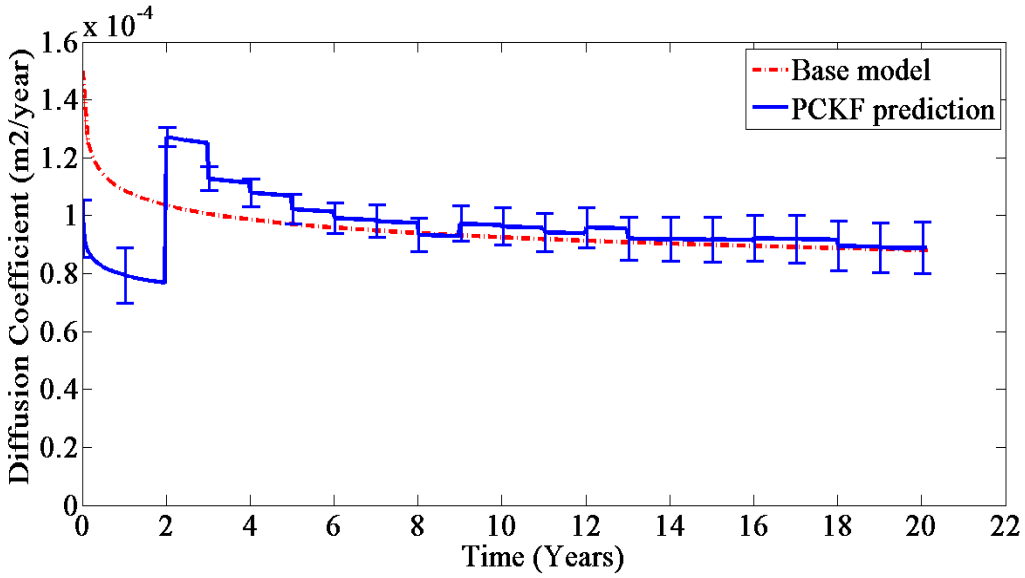

Figure 3 Base Case Vs. Mean calibrated time varying diffusion coefficient with 1 std error bars

7 CONCLUSIONS

In this study, PCKF was employed as a parametric identification tool using a suggested practical framework to mitigate the curse of the dimensionality. The power of the suggested scheme was reflected by comparing its accuracy and computational efficiency to the well - known EnKF. The suggested methodology was used for calibration of dynamic variables and model parameters of 1-D diffusion problem for better assessment of corrosion initiation time.

Keywords: Dynamic soil-structure interaction, stochastic analysis, perfectly matched layers, functionally graded finite elements.

Abstract. *This paper presents a probabilistic computational model for the dynamic soil-structure interaction problem. Specifically, the structure and a limited bounded volume of subsoil in its vicinity are modeled with functionally graded finite elements, allowing to consider heterogeneous local subsoil conditions. This part of subsoil is modeled as a three-dimensional constrained stochastic field. The unboundedness of the surrounding soil is accounted for by coupling the finite element model with perfectly matched layers. An incident wave field is incorporated in the finite element-perfectly matched layers model without explicitly including the source in the computational domain by decomposing the displacement field of the soil in accordance with the subdomain formulation developed for the soil-structure interaction problem. The proposed methodology is illustrated with a case study in which the overall uncertainty is propagated by means of Monte Carlo simulation. The analysis shows that the uncertainty of the structural response increases at specific frequency bands and generally for higher frequencies. These results illustrate how the stochastic variability of the subsoil properties affect both the incident wave field and the structural response in a wide frequency range, and sets the base for future investigations.*

1 INTRODUCTION

Dynamic soil-structure interaction (SSI) refers to the dynamic behavior of the coupled soil-structure system. This problem occurs in several applications from earthquake engineering to the prediction of traffic induced vibrations in the built environment. Pioneering work on the subject started in the nuclear industry for the design and construction of earthquake resistant nuclear reactors. More recently, the development of high-speed railway lines in Europe, east Asia and USA turned research interest also in the field of railway induced vibrations. Railway induced vibrations may lead to malfunctioning of sensitive equipment, discomfort to people and, at high vibration levels, damage to structures. The development of computational models that efficiently and effectively predict the dynamic response of structures excited by ground born vibrations is a matter of ongoing research.

When the knowledge of the subsoil properties is incomplete, the dynamic soil-structure interaction problem should be cast into a stochastic form. This can be done by considering parametric [14] and/or non-parametric uncertainty [3]. Most of the previously conducted work on the subject is mainly focused on earthquake engineering applications considering the very low frequency range (< 10 Hz). The present study considers parametric uncertainty and focuses on the prediction of vibrations in the built environment which makes the frequency range of interest much broader.

The remainder paper is organized as follows. First, the stochastic dynamic soil-structure interaction problem is introduced and the available modeling techniques are briefly discussed. Next, the particularities of modeling the stochastic subsoil are addressed. Finally, the results of a case study are presented, and conclusions are drawn.

2 THE STOCHASTIC DYNAMIC SSI

The soil immediately below the structure plays a dominant role in the structural response. In many cases, this soil is imperfectly known as it may have been perturbed during construction and its characteristics are likely to be different from those identified by geophysical tests on virgin land next to the structure. As discussed in the following, the use of finite elements (FE) provides a great flexibility that allows to incorporate heterogeneous properties in the modeling of this bounded volume of soil. The structure of interest and the limited bounded volume of soil in its vicinity will be denoted for convenience as the generalized structure (Figure 1).

The main difficulty in the modeling of dynamic soil-structure interaction stems from the semi-infinite extent of the soil surrounding the generalized structure, for which the radiation conditions of the elastodynamic waves to infinity should be satisfied. Generally, the dynamic soil-structure interaction problem can be formulated either directly or by following a domain decomposition technique [18]. In the direct approach, the unboundedness of the surrounding soil is accounted for by using appropriate absorbing boundaries in the limits of the regular domain (i.e. generalized structure). The use of perfectly matched layers (PML) [2] is a quite versatile solution to impose these boundary conditions. In the subdomain approach [1], the system is decomposed into two subsystems: the generalized structure and the soil. Both subsystems are analyzed separately and usually by a different computational method. The boundary element method can be used to simulate the unbounded soil domain of infinite extent, where the radiation conditions to infinity are implicitly satisfied, while the finite element method is typically used for the generalized structure.

Although the use of boundary elements entails the benefit of rendering three-dimensional problems in two-dimensional ones, the resulting boundary element system matrices are fully

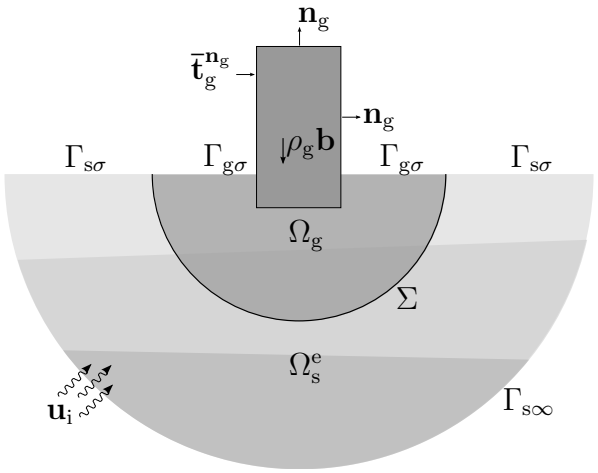

Figure 1: Dynamic soil-structure interaction problem. The interface Σ defines the physical boundary between the unbounded soil $\Omega_\mathrm{s}^\mathrm{e}$ and the generalized structure Ω_g.

populated as opposed to the sparse finite element matrices, leading to increased memory requirements and longer computer time for processing. This aggravates in the case of embedded or extended foundations where a large soil-foundation interface has to be considered. For these reasons, the direct formulation of the problem by means of FE-PML is advocated in this study.

The PML are non-physical absorbing layers that are placed at the exterior limits of the computational domain (Figure 2). Ideally, the waves that are outwardly propagating from the regular domain are fully attenuated inside the PML without any spurious reflections emerging [2]. The effectiveness of the PML strongly depends on the choice and parameterization of their stretch functions [8]. The bounded soil domain is modeled with finite elements: a distinction is made between heterogeneous functionally graded finite elements [13] with continuously varying properties and deterministic homogeneous finite elements. The former are used for the stochastic soil subdomain while the latter are used to enforce the perfectly matched conditions between the PML and the functionally graded FE. The resulting finite element system of equations of the total system is written in the frequency domain as:

$$\hat{\mathbf{K}}\hat{\mathbf{u}} = \hat{\mathbf{f}} \tag{1}$$

where $\hat{\mathbf{f}}$ is the load vector, $\hat{\mathbf{u}}$ is the displacement vector and $\hat{\mathbf{K}}$ is the dynamic stiffness matrix. The dynamic stiffness matrix $\hat{\mathbf{K}}$ can be subdivided into block matrices according to the degrees of freedom: $\hat{\mathbf{u}}_\mathrm{b}$ of the structure, $\hat{\mathbf{u}}_\mathrm{t}$ of the stochastic-heterogeneous soil, $\hat{\mathbf{u}}_\Sigma$ of the interface Σ delimiting the limits of the regular domain, $\hat{\mathbf{u}}_\mathrm{q}$ of the deterministic-homogeneous soil and $\hat{\mathbf{u}}_\mathrm{p}$ the non-physical degrees of freedom of the PML (Figure 2):

$$\begin{bmatrix} \hat{\mathbf{K}}_{\mathrm{bb}} & \hat{\mathbf{K}}_{\mathrm{bt}} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \hat{\mathbf{K}}_{\mathrm{tb}} & \hat{\mathbf{K}}_{\mathrm{tt}} & \hat{\mathbf{K}}_{\mathrm{t}\Sigma} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \hat{\mathbf{K}}_{\Sigma\mathrm{t}} & \hat{\mathbf{K}}_{\Sigma\Sigma} & \hat{\mathbf{K}}_{\Sigma\mathrm{q}} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \hat{\mathbf{K}}_{\mathrm{q}\Sigma} & \hat{\mathbf{K}}_{\mathrm{qq}} & \hat{\mathbf{K}}_{\mathrm{qp}} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \hat{\mathbf{K}}_{\mathrm{pq}} & \hat{\mathbf{K}}_{\mathrm{pp}} \end{bmatrix} \begin{bmatrix} \hat{\mathbf{u}}_\mathrm{b} \\ \hat{\mathbf{u}}_\mathrm{t} \\ \hat{\mathbf{u}}_\Sigma \\ \hat{\mathbf{u}}_\mathrm{q} \\ \hat{\mathbf{u}}_\mathrm{p} \end{bmatrix} = \begin{bmatrix} \hat{\mathbf{f}}_\mathrm{b} \\ \hat{\mathbf{f}}_\mathrm{t} \\ \hat{\mathbf{f}}_\Sigma \\ \mathbf{0} \\ \mathbf{0} \end{bmatrix} \tag{2}$$

Excitation sources can be located either close to the receiver like in the case of railway induced vibrations or far from the receiver like in case of an earthquake. If the interest of the analysis is limited only in the neighborhood of the receiver, a remote excitation source S

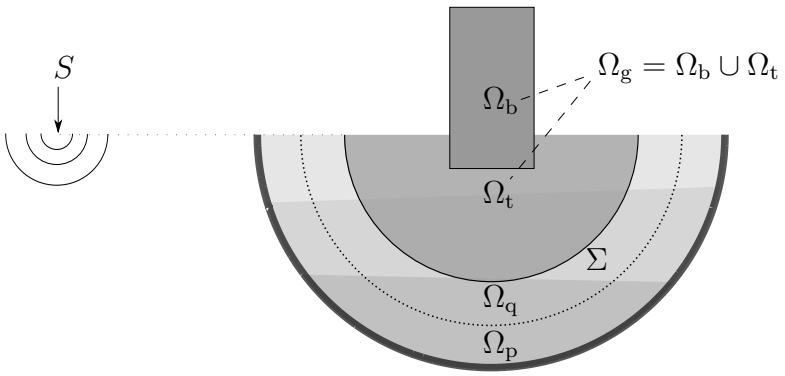

Figure 2: Formulation of the stochastic dynamic soil-structure interaction problem by means of FE-PML. The computational domain is subdivided into the structural Ω_{b}, stochastic soil Ω_{t}, deterministc soil Ω_{q} and PML Ω_{p} subdomains respectively. All but the last are modeled with finite elements. The interface Σ defines the limits of the regular computational domain.

(Figure 2) can be implicitly taken into account by decomposing the displacement field of the soil in accordance with the subdomain formulation developed for the soil-structure interaction problem [1]. This way, the computational cost decreases significantly as only the generalized structure has to be included in the regular domain. Specifically, the displacement field of the soil is decomposed as (Figure 3):

$$\hat{\mathbf{u}}_{\mathrm{s}} = \hat{\mathbf{u}}_{\mathrm{i}} + \hat{\mathbf{u}}_{\mathrm{d0}} + \hat{\mathbf{u}}_{\mathrm{d}} \tag{3}$$

where $\hat{\mathbf{u}}_{\mathrm{i}}$ are the free field displacements generated by the remote source S (Figure 3b). Generally, the free field displacements $\hat{\mathbf{u}}_{\mathrm{i}}$ (and tractions $\hat{\mathbf{t}}_{\mathrm{i}}$) can be computed by using the appropriate source model. The locally diffracted wave field $\hat{\mathbf{u}}_{\mathrm{d0}}$ is defined as the displacement field that is radiated in the soil with excavated the generalized structure for which applies $\hat{\mathbf{u}}_{\mathrm{d0}} = -\hat{\mathbf{u}}_{\mathrm{i}}$ on the interface Σ (Figure 3c). The wave field $\hat{\mathbf{u}}_{\mathrm{d}}$ corresponds to the displacement field radiated in the soil due to the generalized structure displacements $\hat{\mathbf{u}}_{\mathrm{g}}$ on the interface Σ (Figure 3d). Only the first and the second of the aforementioned displacement fields contribute to the equivalent loading vector $\hat{\mathbf{f}}_{\Sigma}$ on the interface Σ of the FE-PML model which represents excitation by a remote source.

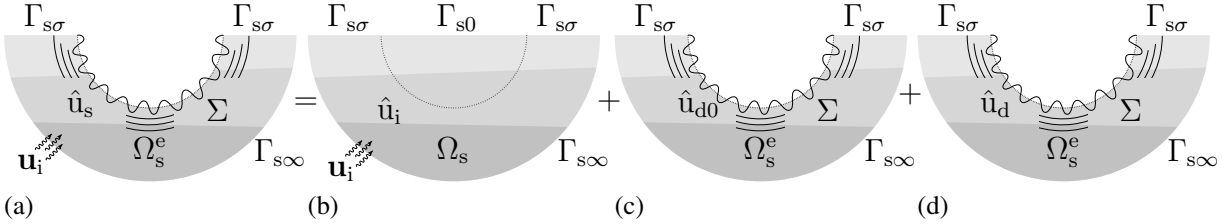

Figure 3: Decomposition of soil displacement field in accordance with the subdomain formulation of the dynamic soil-structure interaction problem. (a) The displacement field in the soil $\hat{\mathbf{u}}_{\mathrm{s}}$ is decomposed into: (b) free field $\hat{\mathbf{u}}_{\mathrm{i}}$, (c) locally diffracted $\hat{\mathbf{u}}_{\mathrm{d0}}$ (with $\hat{\mathbf{u}}_{\mathrm{d0}} = -\hat{\mathbf{u}}_{\mathrm{i}}$ on Σ) and (d) structurally radiated $\hat{\mathbf{u}}_{\mathrm{d}}$ (with $\hat{\mathbf{u}}_{\mathrm{d}} = \hat{\mathbf{u}}_{\mathrm{g}}$ on Σ).

Once the free field displacements $\hat{\mathbf{u}}_{\mathrm{i}}$ and tractions $\hat{\mathbf{t}}_{\mathrm{i}}$ have been evaluated on the interface Σ, the loading $\hat{\mathbf{f}}_{\Sigma}$ can be computed as:

$$\hat{\mathbf{f}}_{\Sigma} = -\int_{\Sigma} \mathbf{N}_{\boldsymbol{\Sigma}}^{\mathbf{T}} \hat{\mathbf{t}}_{\mathbf{i}}^{\mathbf{n_s^e}} d\Sigma - \hat{\mathbf{r}}_{\boldsymbol{\Sigma}}\left(\hat{\mathbf{u}}_{\mathbf{d0}}\right) = -\int_{\Sigma} \mathbf{N}_{\boldsymbol{\Sigma}}^{\mathbf{T}} \hat{\mathbf{t}}_{\mathbf{i}}^{\mathbf{n_s^e}} d\Sigma - \hat{\mathbf{r}}_{\boldsymbol{\Sigma}}\left(-\hat{\mathbf{u}}_{\mathbf{i}}\right) \tag{4}$$

where $\mathbf{N}_\Sigma$ is a matrix containing the shape functions of the finite element faces located on the interface Σ, $\hat{t}_i^{\mathbf{n_s^e}}$ are the free field tractions and $\hat{\mathbf{r}}_{\mathbf{\Sigma}}\left(-\hat{\mathbf{u}}_{\mathbf{i}}\right)$ is a vector of the reaction forces on the interface Σ of the FE-PML model with excavated the generalized structure due to the imposed displacements $-\hat{\mathbf{u}}_{\mathbf{i}}$ (figure 4). The reaction forces $\hat{\mathbf{r}}_{\mathbf{\Sigma}}\left(-\hat{\mathbf{u}}_{\mathbf{i}}\right)$ are computed as follows:

$$\hat{\mathbf{r}}_{\mathbf{\Sigma}}\left(-\hat{\mathbf{u}}_{\mathbf{i}}\right) = \left(\hat{\mathbf{K}}_{\Sigma \mathrm{r}} \hat{\mathbf{K}}_{\mathrm{rr}}^{-1} \hat{\mathbf{K}}_{\mathrm{r}\Sigma} - \hat{\mathbf{K}}_{\Sigma\Sigma}\right) \hat{\mathbf{u}}_{\mathbf{i}} \tag{5}$$

where the degrees of freedom of the deterministic soil $\hat{\mathbf{u}}_{\mathrm{q}}$ and the PML $\hat{\mathbf{u}}_{\mathrm{p}}$ have been grouped for clarity as $\hat{\mathbf{u}}_{\mathrm{r}} = \hat{\mathbf{u}}_{\mathrm{q}} \cup \hat{\mathbf{u}}_{\mathrm{p}}$. The stochastic variation of the soil properties inside the generalized structure does not affect the loading vector $\hat{\mathbf{f}}_\Sigma$ and as a result, in a Monte Carlo analysis it has to be computed only once.

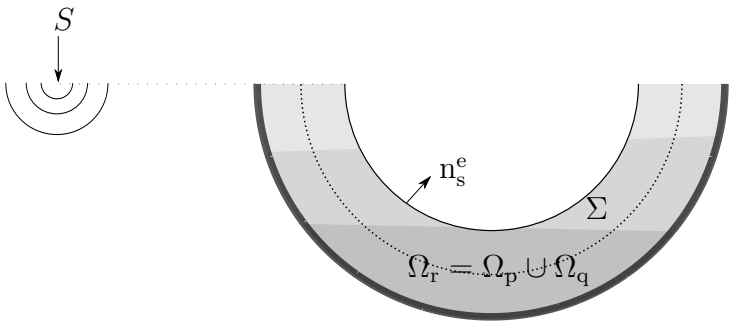

Figure 4: FE-PML model with excavated the stochastic soil subdomain. Auxiliary model for the incorporation of an incident wave field.

3 THE STOCHASTIC SUBSOIL MODELING

The imperfectly known subsoil is modeled as a stochastic field with given marginal probability distribution function (PDF) and correlation structure [17]. Usually, the mean value and the standard deviation are the only available information for the probabilistic characterization of the subsoil properties. In the absence of more detailed experimental results, a covariance function is assumed for the stochastic field. The covariance function is usually defined by the standard deviation function $\sigma_{\mathrm{G}}(s)$ and a correlation structure $\kappa_{\mathrm{G}}(s, s')$:

$$C_{\mathrm{G}}(s, s') = \sigma_{\mathrm{G}}(s)\sigma_{\mathrm{G}}(s')\kappa_{\mathrm{G}}(s, s') \tag{6}$$

This information is sufficient to generate realizations of Gaussian stochastic fields. In this study, non-Gaussian stochastic field realizations are generated by non-linear transformation of the underlying Gaussian. This is referred as translation process [7, 10]:

$$G(\theta, \boldsymbol{s}) = F_{\mathrm{G}}^{-1}\left(F_{\mathrm{Z}}\left(Z(\theta, \boldsymbol{s})\right)\right) \tag{7}$$

where F_{G}^{-1} is the inverse of the target non-Gaussian marginal cumulative probability distribution and Z is the standard normal cumulative probability distribution.

Furthermore, in order to avoid non-physical dynamic impedance contrasts, a conforming coupling between the stochastic and the deterministic subdomains of the soil is desirable. This is achieved by modeling a conditional (or constrained) stochastic field [17]. Conditional stochastic fields are necessarily heterogeneous as the mean value and standard deviation vary from location to location [11].

The Karhunen-Loève expansion can be employed to straightforwardly generate realizations of a heterogeneous Gaussian stochastic field [16]. Nevertheless, the computation of the Karhunen-Loève modes entails the solution of a Fredholm eigenvalue problem [6], which is computationally rather expensive and not trivial to implement in this case. Instead, the approach that is followed in this study is to directly discretize the stochastic field and its covariance matrix into a random vector and a covariance matrix respectively [9]. Subsequently, the random vector describing the Gaussian stochastic field is decorrelated by performing eigenvalue analysis to its covariance matrix:

$$\mathbf{\Lambda} = \mathbf{\Phi}^{\mathbf{T}} \mathbf{C}_{\mathrm{Z}} \mathbf{\Phi} \tag{8}$$

where $\mathbf{\Lambda}$ and $\mathbf{\Phi}$ are matrices containing the eigenvalues λ_{i} and the eigenvectors ϕ_{i} of the covariance matrix $\mathbf{C}_{\mathrm{Z}}$ respectively. The Gaussian realizations are computed as the superposition of the deterministic eigenvectors ϕ_{i} of the covariance matrix multiplied by random numbers ξ_{i} from the standard normal distribution. This corresponds to an equivalent discrete Karhunen-Loève expansion:

$$\mathbf{Z} = \mathbf{Z}_0 + \sum_{i=1}^{n_{\mathrm{m}}} \phi_{\mathrm{i}} Y_{\mathrm{i}} \quad = \mathbf{Z}_0 + \sum_{\mathbf{i}=1}^{\mathbf{n_m}} \phi_{\mathrm{i}} \sqrt{\lambda_{\mathrm{i}}} \xi_{\mathrm{i}} \tag{9}$$

Having generated the Gaussian realizations, the non-Gaussian are generated by following the translation process outlined previously. In Equation 9, the number of eigenvalues considered in the summation should be sufficiently large in order to capture the relevant information that is encoded in the covariance matrix. The first n_{m} largest magnitude eigenvalues, that result in normalized accumulated sum larger than a threshold value ϵ_{min} can be used as a selection criterion:

$$\epsilon(n_{\mathrm{m}}) = \frac{\sum_{i=1}^{n_{\mathrm{m}}} \lambda_i}{\mathrm{tr}(\mathbf{C}_{\mathrm{Z}})} \geq \epsilon_{\mathrm{min}} \tag{10}$$

where $\mathrm{tr}(\mathbf{C}_{\mathrm{Z}})$ is the trace of the covariance matrix.

In a Monte Carlo simulation, when random realizations are generated from the entire sampling space, clusters of realizations may form and as a result the space might not be equally explored. In order to improve the representativeness of the sampled pool of realizations, more sophisticated sampling techniques can be employed. Latin hypercube sampling with artificial correlation reduction is used in the present investigation [12].

4 CASE STUDY

The methodology is illustrated with a case study. A three story R/C office building with regular layout and slab foundation resting at the surface of a visco-elastic halfspace is studied (Figure 5). The characteristics of the building are summarized in Table 1, while the mean properties of the visco-elastic halfspace are shown in Table 2.

Figure 6 shows the FE-PML computational model. The subsoil domain is modeled with three-dimensional twenty-node finite elements. An element size of maximum 2.6 m is used for the mesh at the exterior limits of the computational domain, corresponding to 2.5 quadratic finite elements per shear wavelength λ_s at a frequency of 50 Hz, which is the upper limit considered in this work. The building is modeled with frame and eight-node shell elements. Standard

Story height h_s	3 m
Columns	0.35 m $\times$ 0.35 m
Beams	0.20 m $\times$ 0.50 m
x direction walls	0.20 m $\times$ 4 m
y direction walls	0.20 m $\times$ 2 m
Slab thickness t_s	0.15 m
Raft foundation thickness t_f	0.60 m
Young's modulus E_s	30 GPa
Material density ρ_s	2500 $\mathrm{kg/m^3}$

Table 1: R/C building characteristics.

h	C_s	C_p	G	ν	ρ	β
[m]	[m/s]	[m/s]	[MPa]	[$-$]	[kg/m^3]	[$-$]
∞	300	600	162	1/3	1800	0.01

Table 2: Mean properties of the visco-elastic halfspace.

stretch functions are used for the formulation of the PML [8]. Because of the specifically employed FE discretization and PML parameterization, the model is appropiate for analysis in the frequency range between 10 Hz and 50 Hz. As the analysis is performed in the frequency domain, hysteretic damping is assumed for the R/C building with $\eta = 2\xi = 5\%$ [4].

First, the methodology for the incorporation of an incident wave field in the FE-PML model is verified. The homogeneous visco-elastic halfspace with the properties of Table 2 is used for this purpose. The visco-elastic halfspace is excited by a remote source S of unit amplitude located at (-34 m,-26 m,0 m) with respect to the origin of the reference system (Figure 6). The analysis is performed for the computation of the free field displacements without the presence of the R/C building. Figure 7 shows both the solutions obtained with the FE-PML model and the direct stiffness method [15]. The obtained results match perfectly for the frequencies at 10 Hz and 30 Hz, while small differences ($< 5\%$) are observed for the frequency at 50 Hz. This

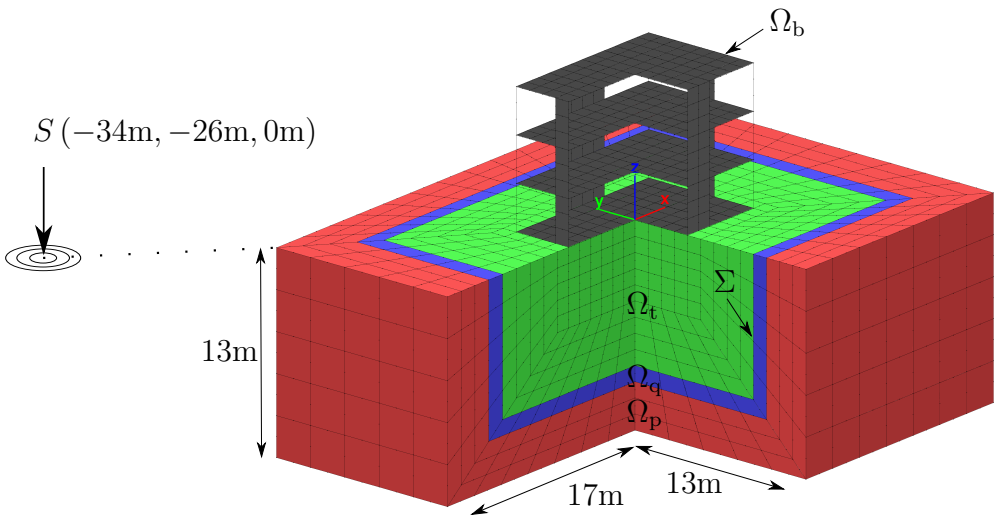

Figure 6: FE-PML model. Regular domain: heterogeneous functionally graded FE (green color) and homogeneous deterministic FE (grey and blue colors). PML domain (red color). Remote excitation source S located outside the limits of the computational domain.

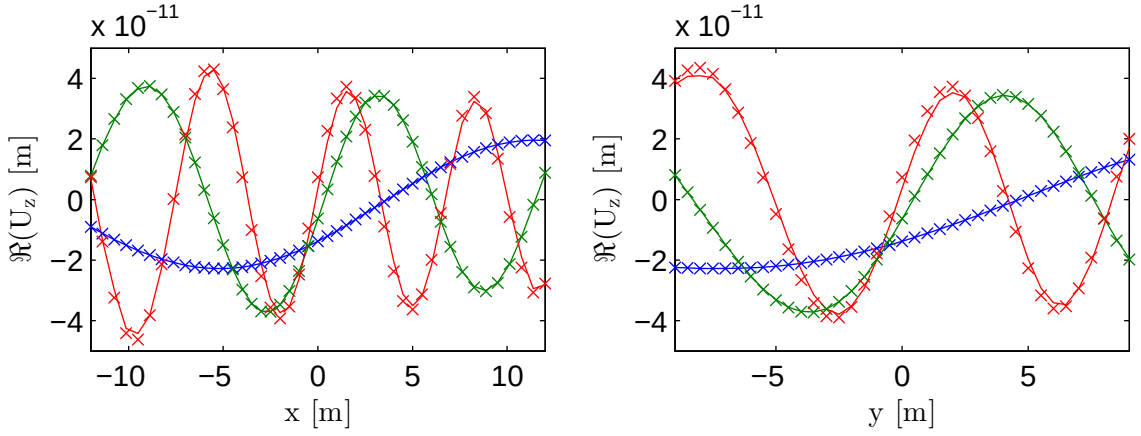
difference can be mostly attributed to discretization error.



(a) (b)

Figure 7: Real part of vertical free field displacements along the (a) x and (b) y axes (z=0) of the FE-PML model. FE-PML model (solid lines) versus EDT solutions (x marks) [15]. Responses for 10 Hz (blue), 30 Hz (green) and 50 Hz (red).

Next, the R/C building is added at the surface of the stochastic soil. The soil has the mean properties of Table 2 and only the shear modulus is considered to be stochastic. The Gamma PDF is adopted for the shear modulus with a coefficient of variation of $\text{CoV} = 0.3$ (Figure 8). An exponential correlation structure with a correlation length of $l_c = 1.5$ is assumed for the

covariance function of the univariate stochastic field:

$$C_{\mathrm{G}}(s,s') = \sigma_{\mathrm{G}}^2 \exp\left(-\frac{|s-s'|^2}{l_{\mathrm{c}}^2}\right) \tag{11}$$

A threshold value $\epsilon_{\min} = 0.95$ (Equation 9) is used in the present work for the generation of the stochastic field realizations, resulting in $n_{\mathrm{m}} = 1000$ eigenvalues (figure 9). A large number of eigenvalues (and therefore random numbers) is generally required for an adequate representation of weakly correlated stochastic fields. Figure 10 shows a realization of the stochastic shear modulus of the soil mapped onto the finite element mesh. The stochastic shear modulus is constrained to take the deterministic value of the surrounding soil on the interface Σ.

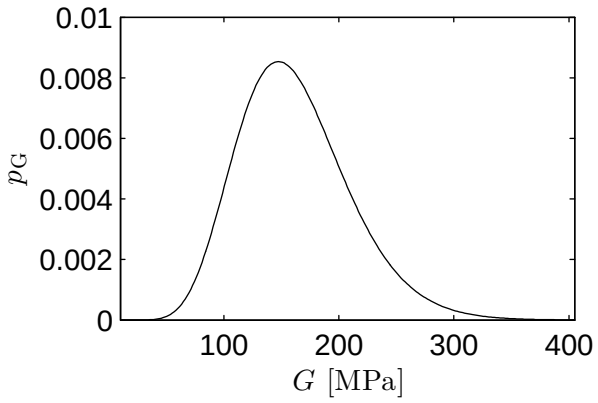


Figure 8: Marginal probability distribution function of soil's shrear modulus.

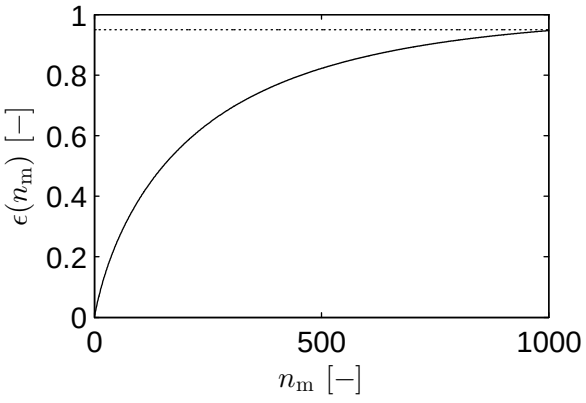

Figure 9: Normalized accumulated sum of Karhunen-Loève eigenvalues.

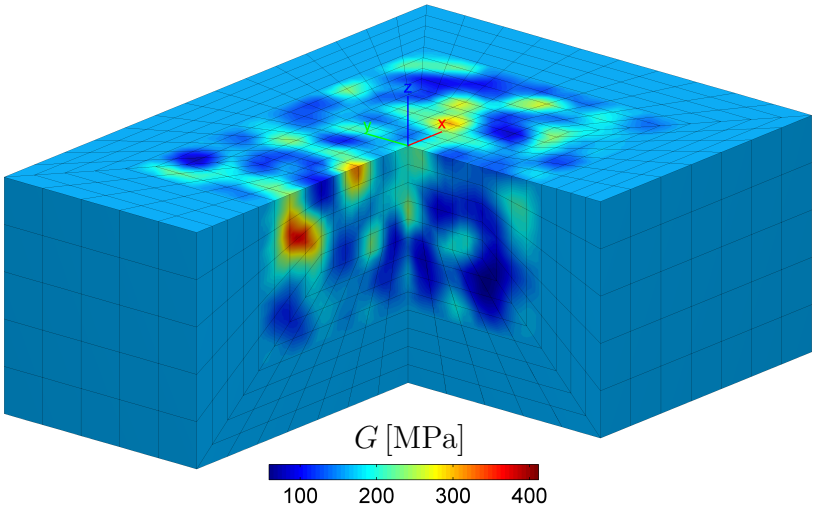

Figure 10: Realization of the stochastic shear modulus of the soil mapped onto the finite element mesh.

The uncertainty is propagated from the stochastic subsoil properties to the structural response quantities by means of Monte Carlo simulation. In total, $n_{\mathrm{R}} = 1001$ realizations are used for the

statistical estimation of the structural response quantities. Moreover, the quality of the estimated statistics is quantified by utilizing the bootstrap method [5]. The degree of uncertainty on the structural response is assessed by means of coefficients of variation and confidence regions. The former are defined as:

$$\mathrm{CoV}_{|\mathrm{U}|} = \frac{\sigma_{|\mathrm{U}|}}{\mu_{|\mathrm{U}|}} \tag{12}$$

where $|U|$ is the modulus of the response quantity U, and $\sigma_{|\mathrm{U}|}$ and $\mu_{|\mathrm{U}|}$ are the standard deviation and the mean value of $|U|$ respectively. Alternatively, a confidence region with a confidence level of $p_c = 90\%$ for the modulus of a response quantity $|U|$ can be defined such that:

$$P(|U_b| \leq |U| \leq |U_t|) \geq p_c \tag{13}$$

where the lower $|U_b|$ and the upper $|U_t|$ bounds can be obtained as the 5% and 95% percentiles of $|U|$ respectively from the Monte Carlo simulation results.

The (stochastic) spatial variability of the subsoil properties affects the structural response in two ways. First, the actual load that excites the structure is altered. Figure 11 shows the free field incident wave field that excites the R/C building in case of homogeneous subsoil conditions, and subsoil conditions as those depicted in Figure 10. Although the same excitation source S (Figure 6) is considered in both cases, the actual free field load that excites the building is different. This happens because, in the latter case, the spatial variability of the subsoil properties, with its inherent subsoil impedance contrasts (Equation 2), may give rise to constructive/destructive inference mechanisms that perturb the incident wave field.

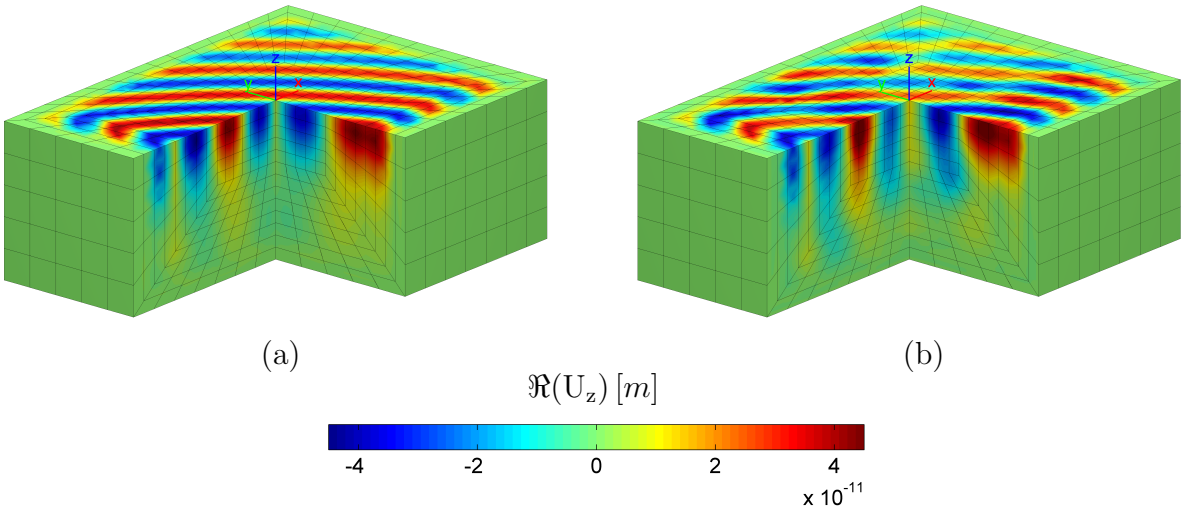

Figure 11: Free field displacements generated by the remote source S at 50 Hz. (a) Homogeneous subsoil conditions and (b) Stochastic realization with heterogeneous subsoil conditions.

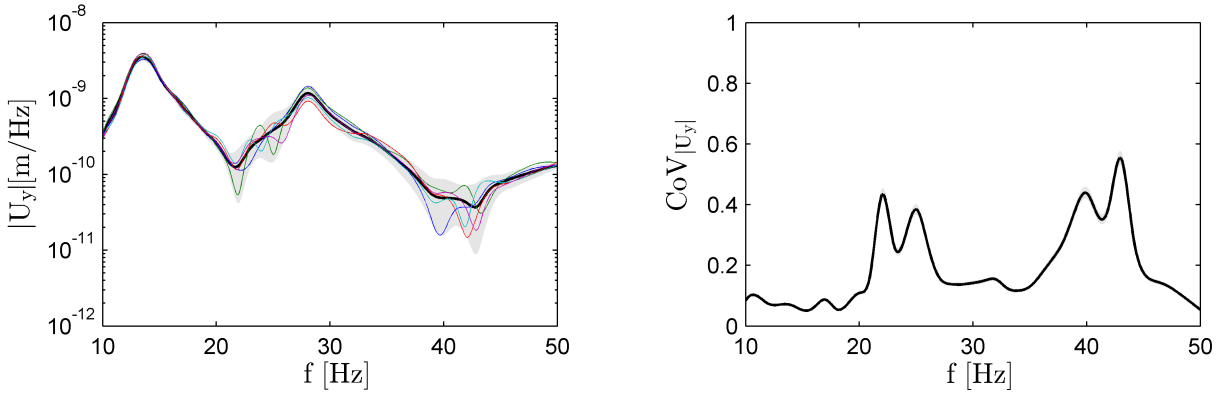
Second, the modal characteristics of the coupled structure-soil system are modified. In the case where the loading on the structure is exactly the same for all stochastic subsoil realizations, any difference between the corresponding responses should be solely attributed to the influence that the spatial variability of the subsoil properties has on the modal characteristics of the system. This is demonstrated in Figure 12 which shows the response of node A_1 (Figure 5) in the

y direction in the case where the excitation is directly applied on the R/C building. Specifically, unit amplitude forces are simultaneously imposed on nodes A_1, A_2 and A_3 in the x, y and z directions (the subscripts of A stand for floor number). The mean value of $|U_{\mathrm{y}}|$ is plotted with the corresponding 90% confidence region as function of frequency. The response for five different stochastic subsoil realizations is also plotted. Figure 12b shows the CoV of $|U_{\mathrm{y}}|$ and the corresponding confidence 95% interval for this estimated statistics.



(a) (b)

Figure 12: Modulus of response of node A_1 in the y direction due to applied loading in the x, y and z directions on the nodes A_1, A_2 and A_3. (a) Mean value of response (solid line), the corresponding 90% confidence region of response (shaded area) and five realizations of response (colored lines). (b) Coefficient of variation of response (solid line) and 95% confidence interval for this statistical measure (shaded area).

In case the structure is excited by ground born vibrations, both of the aforementioned effects take place. Figures 13a and 14a show the responses of node A_1 (Figure 5) in the x and z direction, respectively, when the structure is excited by the remote source S (Figure 6). The mean value of $|U_{\mathrm{x}}|$ and $|U_{\mathrm{z}}|$ are plotted with the corresponding 90% confidence regions of response as functions of frequency. Additionally, Figures 13b and 14b show the CoV of $|U_{\mathrm{x}}|$ and $|U_{\mathrm{z}}|$ and the corresponding 95% confidence intervals for these estimated statistics.

A general trend observed in all figures, is that the structural response uncertainty increases at higher frequencies. However, there are certain frequency bands where the response of the coupled soil-structure system is found to be more sensitive to the subsoil properties. Similarly, there are other frequency bands in which the structural response is less sensitive. These frequency bands are not the same for every structural degree of freedom. From the mean response lines (Figures 13a, 14a and 12a), the uncertainty seems to increase at what looks to be the anti-resonance frequencies of the coupled structure-soil system. This can be misleading as these frequencies may correspond to eigenmodes of the coupled soil-structure system which are sensitive to the stochastic subsoil properties. This is demonstrated in Figure 12a, in which individual realization responses are plotted. Frequencies around 24Hz and 40Hz, which seem to be anti-resonance frequencies of the system in the mean response, are actually frequencies where the response of the coupled system is extremely sensitive to the subsoil properties.

5 CONCLUSIONS

- A methodology is outlined for the direct formulation of the stochastic soil-structure interaction problem by means of coupled finite elements-perfectly matched layers. The model is suitable for analysis in a wide frequency range.
- The methodology is illustrated with a case study, the results of which set the base for future investigations. The two ways in which the stochastic spatial variability of the subsoil properties affects the structural response are, also, discussed.

- Generally, the structural response uncertainty increases at higher frequencies. However, the structural response sensitivity to the subsoil properties varies considerably over frequency bands.

Keywords: multiscale homogenization, micro- meso- and macro-scales, stochastic assimilation, uncertainty propagation, NCF composite materials, polynomial chaos expansion.

Abstract. *A multiscale framework to construct stochastic macroscopic constitutive material models is proposed. A spectral projection approach, specifically polynomial chaos expansion, has been used to construct explicit functional relationships between the homogenized properties and input parameters from finer scales. A homogenization engine embedded in Multiscale Designer, software for composite materials, has been used for the upscaling process. The framework is demonstrated using non-crimp fabric composite materials by constructing probabilistic models of the homogenized properties of a non-crimp fabric laminate in terms of the input parameters together with the homogenized properties from finer scales.*

1 INTRODUCTION

Conventional approaches to perform multiscale designs have been to average over the fluctuations of the material properties throughout the scales. In these approaches it is possible to deduce the constitutive material properties at the macroscopic scale from information available at finer scales [1], where the properties are computed by averaging over fluctuations in the stress response of the material. For instance, to deduce the material properties of continuous non-crimp fabric (NCF) composite materials, the averaged homogenized properties of a unit cell of a unidirectional lamina (consisting of a tow surrounded by resin within a bounded volumetric unit), at the so-called meso-scale are required. These meso-scale properties of the tow are in turn homogenized properties from its constituents at a finer scale, i.e., micro- scale.

Robust designs for such complex systems, where properties across scales matter, require reliable accounting of the material features as well as the fluctuations and uncertainties associated with the description and the performance of the constitutive representations at the various scales of interest. The main objective of this work is to propose a multiscale framework that is able to account for uncertainties associated with finer scales explicitly. The multiscale framework is demonstrated by performing stochastic modeling of an NCF composite material across multiple scales. Specifically, the uncertainties associated with three hierarchical scales have been assimilated from available measurements and propagated throughout the scales. A Polynomial Chaos (PC) spectral projection approach [2] has been used to construct the hierarchical functional relationships throughout the scales. The hierarchy of the scales starts at the scale of the fibers and resin within the tows and goes upward to construct stochastic constitutive models of a laminate or a structure composed of composite laminates. A homogenization engine embedded in Multiscale Designer [3], software for composite materials, has been used for the upscaling process. The proposed framework (i) is suitable for the modeling and analysis of composite materials, (ii) can be generalized to account for the behavior of physical systems containing composite parts, and (iii) can be incorporated in inverse calibration frameworks.

2 DEFINITION OF THE COMPOSITE MATERIALS

The proposed multiscale framework is used to construct probabilistic models of composite laminates that are up-scaled across multiple scales. The composite laminates consist of eight laminae made of continuous non-crimp fabric (NCF). That is, each lamina is composed of continuous unidirectional tows and resin. The carbon fiber tows are made of 12K fibers (T700SC 12000 50C). The laminate is designed to be symmetric such that the laminae are oriented as $[0/45/-45/90/90/-45/45/0]$.

3 DEFINITION OF THE SCALES AND THE RESPECTIVE ASSOCIATED PARAMETERS

The NCF laminate, used in this study, is composed of 8 laminae. Each lamina is composed of unidirectional tows and resin. The tows are composed of fibers with resin filling the space between the fibers. Thus, the properties of the fibers and resin are required to predict the constitutive properties of the tows. Then, the properties of the composite tows and those of the resin again are required to predict the constitutive properties of the NCF unidirectional lamina, which in turn together with other laminae, being oriented according to a certain layout, are required to predict the constitutive properties of the eight-layer laminate. The chart depicted in Figure 1 defines the multiple scales involved in the aforementioned upscaling process.

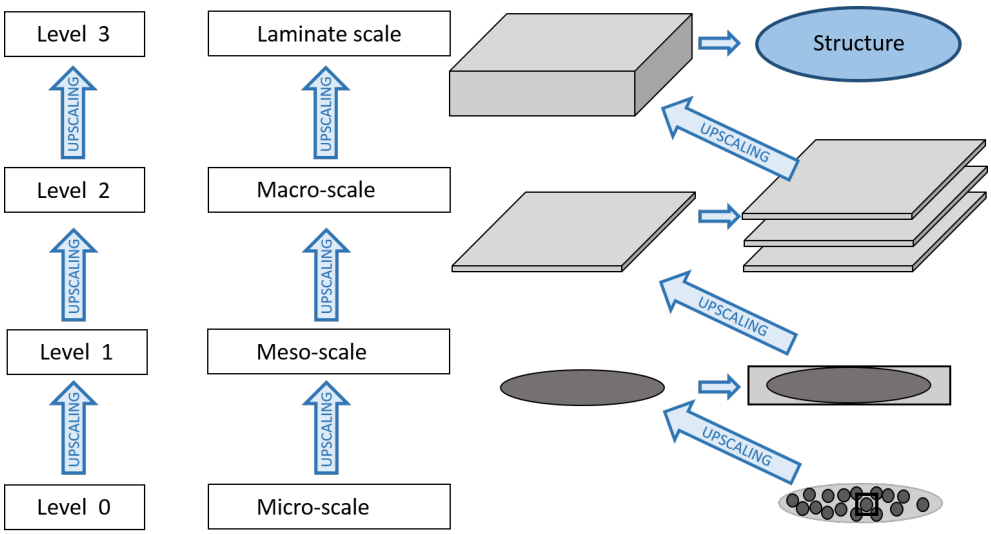

Figure 1: Schematic definition of the multiple scales.

The input parameters at each scale are grouped as (a) the parameters introduced at the scale (l) and which are characterized from available data at this scale, and (b) the parameters that are up-scaled from level ($l-1$). The parameters belonging to the first group are denoted by $\mathbf{P}^l$, where l refers to the respective scale. These groups are specific inputs to each level l; i.e., $\mathbf{P}^0$ is a group of inputs at level 0, and so on. The parameters belonging to the second group are denoted by $\mathbf{Q}^l$. The parameters from this group are input parameters at level l that have been obtained via an upscaling process from level $l-1$ to level l. The parameters from both groups are defined in the following subsections at each level.

3.1 Input parameters associated with level $l = 0$

The set of input parameters at level $l = 0$, $\mathbf{P}^0$, consists of three groups $\mathbf{P}^0_g$, $\mathbf{P}^0_f$,and $\mathbf{P}^0_m$ representing the parameters associated with the geometry of the unit cell, the material properties of transverse isotropic fibers, and the material properties of isotropic matrix, respectively.

Group	Parameter	Description
$\mathbf{P}^0_g$	$V_f^{F,T}$ %	Volume fraction of fiber within the tow
$\mathbf{P}^0_f$	$E_{f,A}$	Axial Young's modulus of fibers
	$E_{f,T}$	Transverse Young's modulus of fibers
	$G_{f,A}$	Axial shear modulus of fibers
	$\nu_{f,A}$	Axial Poisson's ratio of fibers
	$\nu_{f,T}$	Transverse Poisson's ratio of fibers
$\mathbf{P}^0_m$	E_m	Young's modulus of the matrix
	ν_m	Poisson's ratio of the matrix

Table 1: Input parameters $\mathbf{P}^0$ at level $l = 0$.

These parameters are modeled by uniform random variables. The volume fraction of fibers within the tow is denoted by $V_f^{F,T}$. The subscripts A and T, used with the tow material properties, denote the axial and transverse properties, respectively.

3.2 Input parameters associated with level $l = 1$

The set of input parameters at level $l = 1$, $\mathbf{P}^1$, consists of two groups $\mathbf{P}^1_g$ and $\mathbf{P}^1_m$ representing the parameters associated with the geometry of the unit cell in a NCF lamina and the material properties of an isotropic matrix, respectively. These parameters are modeled by uniform random variables.

Group	Parameter	Description
$\mathbf{P}^1_m$	E_m	Young's modulus of the matrix
	ν_m	Poisson's ratio of the matrix
$\mathbf{P}^1_g$	D_a	Major diameter of the tow
	d_a	Free distance along the major axis
	D_b	Minor diameter of the tow

Table 2: Input parameters $\mathbf{P}^1$ at level $l = 1$.

The geometry parameters define the dimensions of the unit cell of a NCF unidirectional lamina and are listed in Table 2. These are illustrated by the drawing in Figure 2, where D_a and D_b refer to the diameters of the tow along the major and minor directions, d_a and d_b refer to the gap between the tows along the major and minor directions, which are filled in by the matrix. Here, d_b is assumed to be constant and equal to $0.1\ mm$. The dimensions of the unit cell are denoted by $S_a = D_a + d_a$ and $S_b = D_b + d_b$.

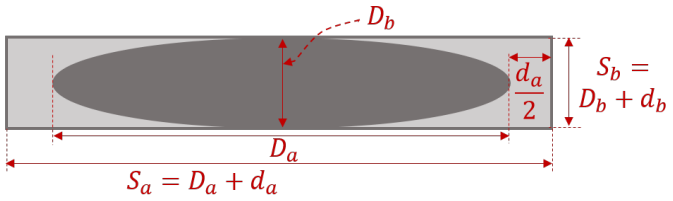

Figure 2: A schematic drawing of a unit cell in a NCF unidirectional lamina.

In addition, another set of input parameters at this scale is $\mathbf{Q}^1$, the set of homogenized material properties of the tow. These are the outcome of the homogenization H_1 associated with the upscaling process from level $l = 0$ to level $l = 1$.

Group	Parameter	Description
$\mathbf{Q}^1$	$E_{t,A}$	Axial Young's modulus of tow
	$E_{t,T}$	Transverse Young's modulus of tow
	$G_{t,A}$	Axial shear modulus of tow
	$\nu_{t,A}$	Axial Poisson's ratio of tow
	$\nu_{t,T}$	Transverse Poisson's ratio of tow

Table 3: Input parameters $\mathbf{Q}^1$ at level $l = 1$.

The material properties of the homogenized tow, which manifest a transverse isotropic symmetry, are denoted by $\mathbf{Q}^1 = (E_{t,A},\ E_{t,T},\ G_{t,A},\ \nu_{t,T},\ \nu_{t,A})$; where the subscript t refers to the tow and the subscripts A and T refer to the axial and transverse properties, respectively.

3.3 Input parameters associated with level $l = 2$

The input parameters at level $l = 2$, $\mathbf{P}^2$, consists of the geometry layout of the laminae within the eight-layer laminate, $\mathbf{P}^1_g$. The orientation of the unidirectional laminae is defined as $[0/45/-45/90]_s$, where the upper and lower laminae are oriented along the 0^o axis. The number of laminae is fixed for the laminate analyzed in this paper. The orientation of each lamina is also considered constant at this stage.

Moreover, the other set of input parameters at this scale, $\mathbf{Q}^2$, is the set of homogenized material properties of a unidirectional NCF lamina. These are the outcome of the homogenization H_2 associated with the upscaling process from level $l = 1$ to level $l = 2$. The material properties of the homogenized lamina, which are expected to manifest a transverse isotropic symmetry, are denoted by $\mathbf{Q}^2 = (E_{l,A},\ E_{l,T},\ G_{l,A},\ \nu_{l,T},\ \nu_{l,A})$; where the subscript l refers to the lamina and the subscripts A and T refer to the local axial and transverse properties, respectively.

Group	Parameter	Description
$\mathbf{Q}^2$	$E_{l,A}$	Axial Young's modulus of NCF lamina
	$E_{l,T}$	Transverse Young's modulus of NCF lamina
	$G_{l,A}$	Axial shear modulus of NCF lamina
	$\nu_{l,A}$	Axial Poisson's ratio of NCF lamina
	$\nu_{l,T}$	Transverse Poisson's ratio of NCF lamina

Table 4: Input parameters $\mathbf{Q}^2$ at level $l = 2$.

3.4 Output parameters associated with level 3

The layout of the laminate, $[0/45/-45/90]_s$, is designed to have quasi-isotropic material properties. These are grouped in $\mathbf{Q}^3$ and are: (1) $E_{xx} = E_{yy}$, (2) E_{zz} , (3) $G_{yz} = G_{xz}$, (4) G_{xy}, (5) $\nu_{xy} = \nu_{yx}$, (6) $\nu_{xz} = \nu_{yz}$, and (7) $\nu_{zx} = \nu_{zy}$.

4 HOMOGENIZATION APPROACH

A homogenization engine embedded in Multiscale Designer, software for composite materials, has been used for the upscaling process [3]. The multiscale design system enables the analysis and design of material systems, such as composite materials given their microstructure. An appropriate unit cell morphology is selected for each of the tow homogenization and the lamina homogenization, respectively.

5 MULTI-SCALE STOCHASTIC ASSIMILATION USING A SPECTRAL PROJECTION APPROACH

The homogenized properties of the laminate are obtained by upscaling the material and geometry parameters of the ordered laminae. The material properties of a lamina are obtained using a homogenization protocol that upscales the material and geometry parameters of a unit cell representing a lamina and consisting of a unidirectional tow. The homogenized material

properties of a tow are also obtained using a similar homogenization protocol that upscales the geometry and material properties of a unit cell of fibers and resin.

This hierarchy of upscaling processes is addressed in this current work by propagating uncertainties associated with parameters from each scale to construct probabilistic models of the homogenized material properties of the laminate. It is worth noting that the proposed hierarchical framework is not confined to the eight-layer laminate addressed in this paper. It is a general framework that can be applied to other composite materials or any heterogeneous material where fluctuations observed at coarse scales are influenced by fluctuations present at multiple finer scales.

The propagation of uncertainties across the scales has been carried out using a Non-Intrusive Spectral Projection (NISP) approach [4]. The NISP approach enables probabilistic models of the engineering constants representing the homogenized material properties of a laminate as well as the homogenized properties at lower levels. In other words, stochastic surrogate models could be constructed to approximate the functional relationship of the parameters $\mathbf{Q}^l$, l denotes the corresponding level, in terms of the input parameters at the finer scales (lower levels); i.e., $\mathbf{Q}^3$ can be expressed in terms of $\mathbf{P}^0$, $\mathbf{P}^1$, and $\mathbf{P}^2$ instead of $\mathbf{P}^2$ and $\mathbf{Q}^2$. This is achieved by projecting the stochastic properties $\mathbf{Q}^l$ on a finite-dimensional stochastic space, Θ, through an orthogonal projection. The dimension of this stochastic space equals the dimension of the grouped input variables $\mathbf{P} = \{\mathbf{P}^0,\ \mathbf{P}^1,\ \cdots,\ \mathbf{P}^{l-1}\}$. To do so, a mapping of $\mathbf{Q}^l$ to a probability space, Θ, can be expressed in terms of a truncated polynomial chaos (PC) expansion [2] as,

$$\mathbf{Q}^l\left(\xi\right) = \sum_{j=0}^{N_{pc}} \mathbf{q}_j^l\ \Psi_j(\xi), \tag{1}$$

where, $l = 1,\ 2,\ or\ 3$ refers to the level of upscaled parameters $\mathbf{Q}^l$, and $\Psi_j(\xi)$ is the PC basis which consists of a set of normalized multi-dimensional orthogonal polynomials in ξ; ξ is a vector grouping normalized standard variables. The mapping between ξ and the independently-assumed random variables $\mathbf{P}^i$, introduced in the previous sections at the finer scales i, is defined such that $\Phi^{\xi}\left(\boldsymbol{\xi}\right) = \Phi^{P}\left(\mathbf{P}\right)$. The parameters $\mathbf{q}_j^l$ are the projection coefficients and $N_{pc}+1$ is the dimension of the PC terms, which can be defined in terms of the PC order q and the stochastic dimension N_{rv} denoting the size of vector ξ.

The orthogonality condition can be expressed in terms of the inner product, defined on the stochastic space Θ, as,

$$\langle \Psi_i(\xi), \Psi_j(\xi) \rangle = \langle \Psi_j(\xi), \Psi_j(\xi) \rangle\ \delta_{ij}, \tag{2}$$

where,

$$\langle u, v \rangle = \int_{\Theta} u(\xi)\ v(\xi)\ p_{\xi}(\xi)\ d\xi, \tag{3}$$

The projection coefficients $\mathbf{q}_j^l$ at level l can be expressed, given the orthogonality of the basis, in terms of the following inner products,

$$\mathbf{q}_j^l = \frac{\left\langle \mathbf{Q}^l(\xi), \Psi_j(\xi) \right\rangle}{\left\langle \Psi_j(\xi), \Psi_j(\xi) \right\rangle},\ j = 0, 1, ..., N_{pc}. \tag{4}$$

To estimate $\left\langle \mathbf{Q}^l(\xi), \Psi_j(\xi) \right\rangle$, a sparse grid cubatures (SGC) approach could be used [4]. According to this approach, N_{sgc} sets of ξ realizations and associated weights are generated; $\xi^{(i)}$ and $w_i,\ i = 1,\ \cdots,\ N_{sgc}$ [5]. The dimension of each set N_{sgc} is a function of the stochastic dimension N_{rv} and the level of the sparse grid cubatures L. Thus,

$$q_j^l = \sum_{i=1}^{N_{sgc}} w_i\ \mathbf{Q}^l(\xi^{(i)})\ \Psi_j(\xi^{(i)})\ ,\ j = 1,\ \cdots,\ N_{pc}. \tag{5}$$

The spectral representation defined in eqation 1 is then fully identified in terms of the PC coefficients. The mean values, $\overline{\mathbf{Q}}^l$, and variances, $Var\left[\mathbf{Q}^l\left(\xi\right)\right]$, of the projected quantities of interest can be estimated, given the orthogonality of the basis, respectively, as,

$$\overline{\mathbf{Q}}^l = \mathbf{q}_j^0. \tag{6}$$

$$Var\left[\mathbf{Q}^l\left(\xi\right)\right] = \sum_{j=1}^{N_{pc}} {\mathbf{q}_j^l}^2. \tag{7}$$

6 EXAMPLE AND DISCUSSION

As explained in the previous section, it is possible to express the homogenization output at multiple scales ($\mathbf{Q}^l$, $\mathbf{Q}^2$, and $\mathbf{Q}^3$) using the same set of SGC nodes. First, the quantities of interest are computed at a set of SGC nodes, each of which consists of a combination of input parameters reported earlier for each scale. The process is repeated for increasing values of the SGC level in order to determine the appropriate SGC level. Second, at each of the given SGC levels, a set of respective polynomial chaos coefficients are estimated using equation 5. The estimated coefficients of (i) the axial modulus of a homogenized tow, $E_{t,A}$ from level $l = 1$, (ii) the axial modulus of a homogenized NCF lamina, $E_{l,A}$ from level $l = 2$, and (iii) the axial modulus of a homogenized NCF laminate E_{xx} from level $l = 3$ are plotted in Figures 3 to 5, respectively. The x-axis represents the index of the terms in the polynomial chaos expansion while the y-axis represents the value of the coefficients. The axial indices 1 to 11 correspond to the coefficients of the linear terms in the polynomial chaos representation. The coefficients are plotted for a set of polynomial chaos orders ranging from 1 to 3.

It is clearly shown that the nodes associated with SGC level 3 are sufficient to identify the coefficients $\mathbf{q}_j^l$. It can also be concluded that the contributions of some second order terms and possibly third order terms in the expansion are important for accurate representation of some homogenized properties at the different scales. To corroborate this conclusion, the probability density functions (PDFs) of the homogenized axial moduli at homogenization levels $l = 1$, $l = 2$, and $l = 3$ are plotted in Figure 6. The Figures show that the axial modulus of the homogenized tow at level $l = 1$ could be expressed as a linear combination of some of the input variables since the PDF curves associated with orders 1 to 3 are converged. However, the PDF curves of the axial moduli of the lamina, $l = 2$, and the laminate, $l = 3$, show that a second order polynomial chaos representation is appropriate, which indicates that some second order terms in the expansion contribute to these homogenized properties.

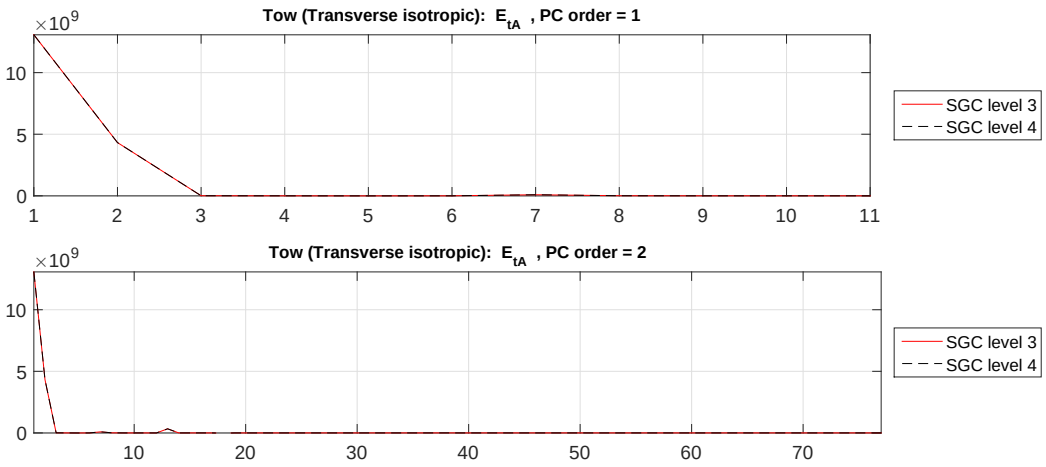

Figure 3: The PC coefficients q_j^1 for $E_{t,A}$.

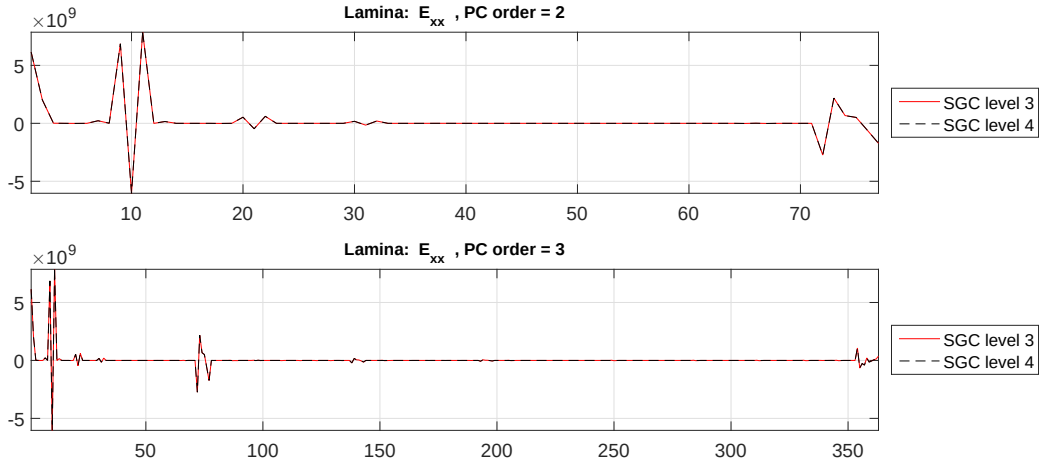

Figure 4: The PC coefficients q_j^2 for $E_{l,A}$.

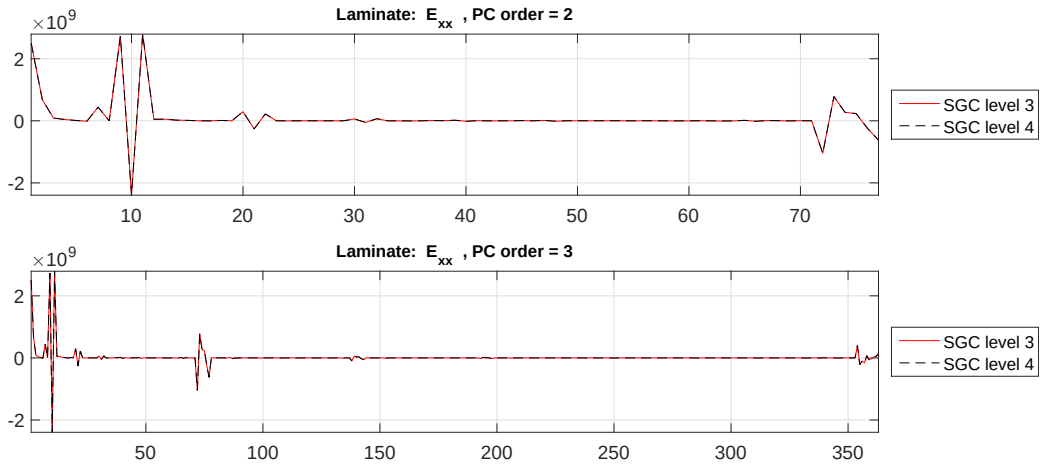

Figure 5: The PC coefficients q_j^3 for $E_{xx} = E_{yy}$.

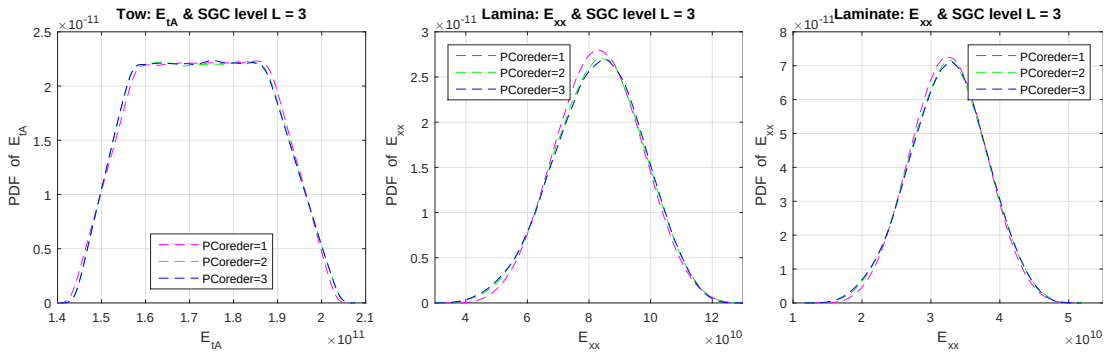

Figure 6: PDF curves for the axial elastic moduli: (left) $E_{tA} \in \mathbf{Q}^1$ (middle) $E_{lA} = E_{xx} \in \mathbf{Q}^2$ (right) $E_{xx} \in \mathbf{Q}^3$

7 CONCLUSIONS

It is shown that polynomial chaos expansion is able to characterize properties at a coarse scale in terms of fluctuations associated with properties from one or more finer scales. This characterization is achieved in terms of an analytical form of functional relationships with the underlying variables at the finer scales.

It is worth noting that the proposed hierarchical framework is not confined to the eight-layer laminate addressed in this paper. It is a general framework that can be applied to other composite materials or any heterogeneous material where fluctuations observed at coarse scales are influenced by fluctuations present at multiple finer scales.

The proposed framework (i) is suitable for the modeling and analysis of composite materials, (ii) can be generalized to account for the behavior of physical systems containing composite parts, (iii) enables analytical forms that can be readily used in sensitivity analyses, and (iv) can be incorporated in inverse calibration frameworks.

Abstract. *A multi-fidelity global metamodel is presented for uncertainty quantification of computationally expensive simulations. The multi-fidelity approximation is built as the sum of a low-fidelity-trained metamodel and the metamodel of the difference (error) between high- and low-fidelity simulations. The metamodel is based on dynamic stochastic radial basis functions, which provide the prediction along with the associated uncertainty. New training points are added where the prediction uncertainty is largest, according to an adaptive sampling procedure. The prediction uncertainty of both the low-fidelity and the error metamodel are considered for the adaptive training of the low- and high-fidelity metamodels, respectively. The method is applied to a steady fluid-structure interaction (FSI) problem of a 3D NACA 0009 stainless steel hydrofoil. Two functions are considered simultaneously, namely lift and drag coefficients, versus angle of attack and Reynolds number. Two problems are presented: in the first problem the high-fidelity evaluations are obtained through steady FSI computer simulations, whereas in the second problem they are given by available experimental data from literature. Low-fidelity evaluations are provided in both cases by steady hydrodynamic simulations. The overall uncertainty of the multi-fidelity metamodel is used as a convergence criterion.*

1 INTRODUCTION

The simulation-based design (SBD) process of complex engineering systems (such as aerial, ground or maritime vehicles) requires computationally expensive physics-based solvers, in order to achieve accurate solutions. When dealing with real-world applications, most of the relevant inputs and outputs are affected by uncertainty, which stems from operational and environmental conditions, geometrical tolerances, numerical and/or modelling errors. Therefore, uncertainty quantification (UQ) methods are required, in order to assess the effects of uncertain parameters on the relevant outputs. Earlier uncertainty studies addressed deterministic uncertainty analysis (UA) for numerical and modelling errors [1, 2, 3]. More recently, the research moved to stochastic UQ for environmental and operating conditions. Stochastic UQ studies using high-fidelity simulations for ship hydrodynamic problems have been presented in [4, 5, 6, 7].

In design optimization, high-fidelity solvers and UQ methods are integrated with single/multi-objective local/global minimization/maximization algorithms, which may require a large number of computer simulations (and high computational cost) in order to converge to the final solution [7, 8, 9]. UQ and design optimization with high-fidelity solvers still represent a technological challenge and require efficient methods and implementations.

In order to reduce the computational cost, metamodelling methods have been developed and successfully applied in several engineering fields [10, 11, 12]. In addition to metamodels, multi-fidelity approximation methods have been developed with the aim of combining to some extent the accuracy of high-fidelity solvers with the computational cost of low-fidelity solvers [13, 14, 15], or the accuracy of experiments (high-fidelity data) and computer simulations (low-fidelity) [16]. Multi-fidelity approximations for uncertainty quantification have been successfully investigated in [17] and applied in maritime [18] and industrial problems [19]. Furthermore, multi-fidelity metamodels have been successfully used for design optimization [20, 21, 22].

The objective of the present work is to present a multi-fidelity global metamodel, which manages high- and low-fidelity solvers through a multi-fidelity adaptive sampling procedure. The method is developed as an essential part of efficient uncertainty quantification of computationally expensive computer simulations. The current method is an extension to multiple functions [23] of the work presented in [24].

The multi-fidelity approximation is built as the sum of a low-fidelity-trained metamodel and the metamodel of the difference (error) between high- and low-fidelity evaluations. The metamodel is based on the dynamic stochastic radial basis function (RBF) method, presented in [23] for uncertainty quantification and extended to design optimization in [25]. The method provides the prediction and the associated uncertainty. The adaptive sampling procedure is driven by the maximum absolute value of the uncertainty, evaluated for each multi-fidelity metamodel. The prediction uncertainty of both the low-fidelity and the error metamodel is used for the adaptive refinement of the low- and high-fidelity training sets. High- or low-fidelity simulations are computed, depending on the relative uncertainty of error and low-fidelity metamodels.

The method is applied to a steady fluid-structure interaction (FSI) problem, used as a benchmark both for experimental [26] and simulation-based shape design optimization studies, using high-fidelity solvers [27]. Herein, the performances of the 3D NACA 0009 stainless steel hydrofoil are addressed in terms of lift and drag coefficients versus the angle of attack (AoA) and the Reynolds number (Re). Two problems are presented. The first problem addresses lift and drag coefficients using high- and low-fidelity simulations. Specifically, high-fidelity evaluations are provided by steady FSI simulations and low-fidelity evaluations are given by

steady hydrodynamic simulations with fixed geometry. The second problem addresses the same functions using available experimental data [26] as high-fidelity evaluations. Both high- and low-fidelity simulations are performed by finite element method (FEM) using the commercial code COMSOL Multiphysics^{TM}. A preliminary structural and hydrodynamic characterization of the current hydrofoil has been provided in [28].

2 MULTI-FIDELITY ADAPTIVE METAMODEL

Considering n functions (relevant outputs), the multi-fidelity metamodel is defined as

$$\begin{aligned} \hat{f}_i(\mathbf{x}) &= \tilde{f}_{i,L}(\mathbf{x}) + \tilde{\delta}_i(\mathbf{x}),\ i = 1, \ldots, n \\ \delta_i(\mathbf{x}) &= f_{i,H}(\mathbf{x}) - f_{i,L}(\mathbf{x}),\ i = 1, \ldots, n \end{aligned} \tag{1}$$

where $\mathbf{x} \in \mathbb{R}^n$ is the independent variable (uncertain parameter), superscript $\sim$ denotes the RBF prediction, and δ_i is the difference (error) between high- and low-fidelity simulations (respectively, $f_{i,H}$ and $f_{i,L}$ with $i = 1, \ldots, n$).

The uncertainty associated with the prediction provided by the multi-fidelity metamodel of the i-th function is defined as

$$U_{\hat{f}_i}(\mathbf{x}) = \sqrt{U^2_{\tilde{f}_{i,L}}(\mathbf{x}) + U^2_{\tilde{\delta}_i}(\mathbf{x})} \tag{2}$$

where $U_{\tilde{f}_{i,L}}$ and $U_{\tilde{\delta}_i}$ are the uncertainties associated to the prediction of the i-th function, provided by the low-fidelity and error metamodels ($\tilde{f}_{i,L}$ and $\tilde{\delta}_i$), respectively [23].

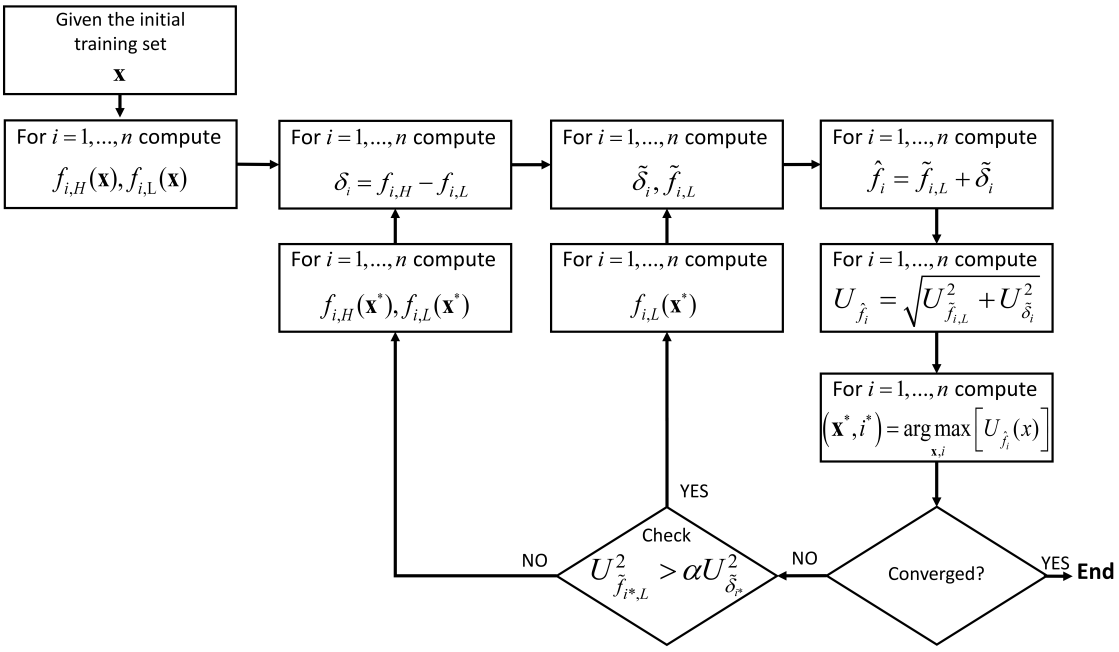

Figure 1: Multi-fidelity metamodel adaptive sampling procedure.

The multi-fidelity metamodel is trained using the adaptive procedure shown in Fig. 1. After initialization, a new sample is added to the training set at each iteration, solving the following

problem:

$$(\mathbf{x}^*, i^*) = \underset{\mathbf{x},i}{\operatorname{argmax}}[U_{\hat{f}_i}(\mathbf{x})] \tag{3}$$

Once $\mathbf{x}^*$ and i^* are evaluated, the training sets H and/or L (high- and low-fidelity, respectively) are updated as

$$\begin{cases} \text{If } U^2_{\tilde{f}_{i^*,L}}(\mathbf{x}^*) \geq \alpha U^2_{\tilde{\delta}_{i^*}}(\mathbf{x}^*), \text{ then add } \mathbf{x}^* \text{ to } L \\ \text{If } U^2_{\tilde{f}_{i^*,L}}(\mathbf{x}^*) < \alpha U^2_{\tilde{\delta}_{i^*}}(\mathbf{x}^*), \text{ then add } \mathbf{x}^* \text{ to } H \text{ and } L \end{cases} \tag{4}$$

where $\alpha \in$[0, 1] is an arbitrary tuning parameter, related to the ratio of the computational cost of the low- and high-fidelity simulations.

3 STOCHASTIC RADIAL BASIS FUNCTIONS

The prediction $\tilde{f}$ is evaluated as the expected value of a set of stochastic RBF predictions [23], which depend on the stochastic parameter $\epsilon \sim \text{unif}[1, 3]$:

$$\tilde{f}(\mathbf{x}) = E[g(\mathbf{x}, \epsilon)]_\epsilon \tag{5}$$

with

$$g(\mathbf{x}, \epsilon) = \sum_{i=1}^{m} w_i \, \varphi(\mathbf{x} - \mathbf{x}_i) \tag{6}$$

where m is the size of the training set, $\mathbf{x}_i$ are the training points, $\varphi(\cdot) = \|\cdot\|^\epsilon$, and $\|\cdot\|$ is the Euclidean norm. The coefficients w_i are obtained by the linear system $\mathbf{A}\mathbf{w} = \mathbf{y}$ with $\mathbf{w} = \{w_i\}$. The elements of the matrix $\mathbf{A}$ are $a_{ij} = \varphi(\mathbf{x}_i - \mathbf{x}_j)$ and the vector $\mathbf{y} = \{y_i\}$ collects the function evaluations at the training points, $y_i = f(\mathbf{x}_i)$.

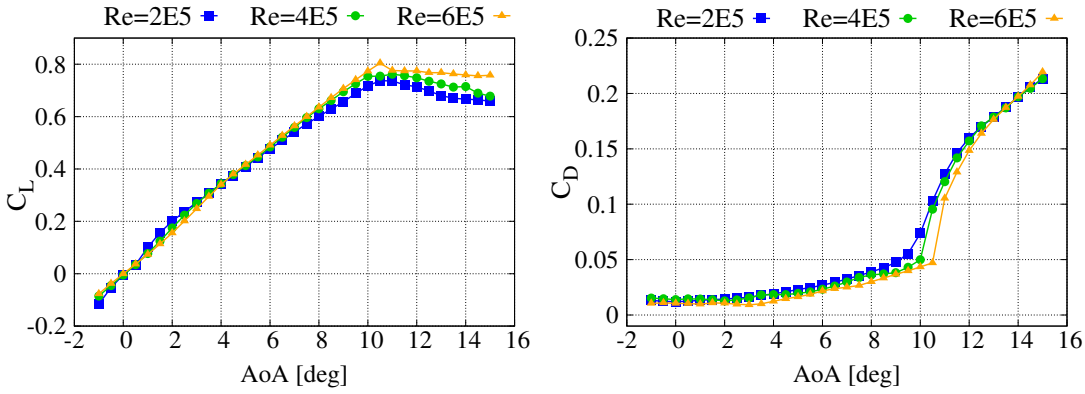
The uncertainty associated to the metamodel prediction, $U(\mathbf{x})$, is quantified at each $\mathbf{x}$ as the 95%-confidence interval of $g(\mathbf{x}, \epsilon)$. This may be evaluated using a Monte Carlo sampling over ϵ, as shown in [23].

4 APPLICATION: NACA 0009 STAINLESS STEEL HYDROFOIL

The FSI problem presented by [26] is used herein to demonstrate the method. Specifically, the performances of a 3D NACA 0009 stainless steel hydrofoil are addressed in terms of lift and drag coefficients (C_L, C_D). C_L, C_D are evaluated versus AoA and Re (2D problem), respectively varying within [-1, 15] deg and [2E5, 6E5], which represent a subdomain of experimental data provided by [26] (AoA $\in$ [-15, 15] deg and Re $\in$ [2E5, 1E6]). Both the range of variation have been selected according to the outcomes provided by [26]. Specifically, it was observed that pre-stall forces are Re dependent only for Re$\leq$8E5 (although the dependence is weak).

The model main particulars are: root, mid and tip chords respectively equal to 0.12 m, 0.09 m and 0.06 m, and span length equal to 0.3 m. The resulting aspect ratio is 3.33. According to [26], a stainless steel with a density of 7900 kg/m^3, a Young modulus of 193 GPa and a Poisson modulus of 0.3 is chosen for the hydrofoil. Water density and dynamic viscosity are set equal to 999 kg/m^3 and 1.1545E–3 Pa·s, whereas the absolute pressure and temperature are set to 201.13 kPa and 293.15 K.

Figures 2(a) and 2(b) respectively show the experimental values of lift and drag coefficients, provided by [26], versus AoA for Re=$\{$2E5;4E5;6E5$\}$. The peak of the lift coefficient falls within 10 and 11 deg, showing stall for AoA$>$11 deg.



(a) Lift coefficient versus AoA

(b) Drag coefficient versus AoA

Figure 2: Experimental lift and drag coefficients for several Reynolds numbers [26].

Two problems are solved. In the first problem (namely problem 1) high-fidelity evaluations are provided by FSI simulations, performed with a two-way stationary coupling between hydrodynamic (steady incompressible Reynolds Averaged Navier-Stokes Equations, RANSE) and structural simulations. The low-fidelity evaluations are obtained through steady incompressible RANSE hydrodynamic simulations, with rigid hydrofoil. Both high- and low-fidelity simulations are performed using the commercial FEM-based code COMSOL Multiphysics^{TM} and the ratio between the computational time of the low- and the high-fidelity simulations is approximately equal to 0.2, see Tab. 1.

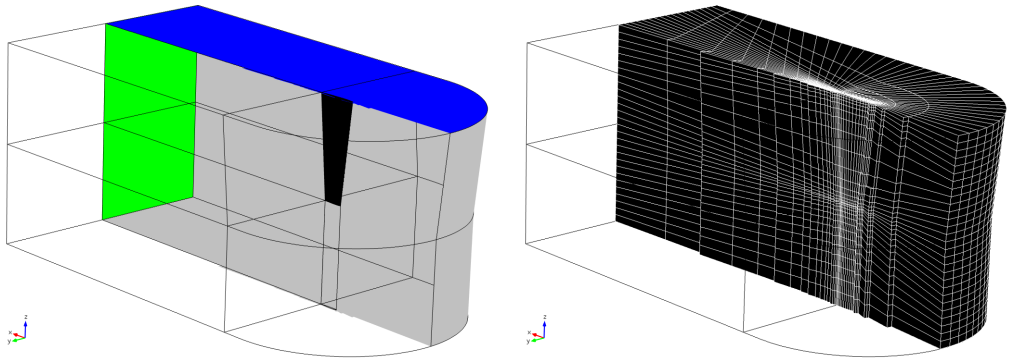
In the second problem (namely problem 2), the high-fidelity evaluations are provided by available experimental data from [26]. Therefore, the multi-fidelity metamodel is initially trained with experimental data and low-fidelity simulations. For this problem, the ratio between the computational time of the high-fidelity evaluations and the low-fidelity simulations is set to infinite, implying that only low-fidelity evaluations are used to update the multi-fidelity metamodel.

5 SIMULATION SETUP

FSI and hydrodynamic simulations share the same *C*-type domain for the hydrodynamics. A length equal to four mid-chords (C_m) is used as radius of the *C*, the total height of the domain is twice the span of the hydrofoil. Downstream, the domain extends ten times the mid-chord, see Fig. 3(a).

The domain is discretized with a structured mesh and the distribution of the elements in the downstream region is intentionally refined to guarantee the finest discretization of wake flow for each AoA of the hydrofoil. The grid is also refined in critical regions such as the root and the tip of the hydrofoil, Fig. 3(b). Parameters pertaining to the grid size used for high- and low-fidelity simulations are summarized in Tab. 1. Note that high-fidelity (FSI) simulations also include the structural grid (with coincident nodes) and associated degrees of freedom.

The $k-\epsilon$ turbulence model is used with standard coefficients [29] and wall function. The non-linear stationary problem is solved with a dumped Newton method through linear step [30]. A pseudo time-stepping is introduced to increase the simulation stability. The Courant-Friedrichs-Lewy (CFL) number adjusts the local time-step according to $\Delta t_{loc} = CFL_{loc}h/U$, where h is the longest cell edge, and U is the magnitude of the local fluid flow velocity. The



(a) Hydrodynamic domain and boundary conditions

(b) Meshed *C*-type domain

Figure 3: Hydrodynamic domain and grid.

Simulation	N. of elements	DoFs	Simulation time [h]
FSI	31.3k	2M	≈ 10
Hydrodynamic	29.7k	1.2M	≈ 2

Table 1: Summary of the simulation parameters.

CFL is decreased, proportionally with the increase of the AoA, starting from the value CFL=1.

Second order shape functions are used for the displacement vector, mesh deformation (if any), velocity, turbulent kinetic energy and turbulent dissipation rate. First order shape functions are used for the pressure.

The hydrodynamic boundary conditions are set considering an inlet/undisturbed flow on the gray face, a wall on the blue face and an outlet on the green face. The black faces represent the hydrofoil (elastic/rigid wall), see Fig. 3(a).

5.1 High-Fidelity Simulations: Fluid-Structure Interaction Solver

The structural boundary conditions include null displacement and rotation at the root section of the hydrofoil. The hydroelastic deformation of the hydrofoil implies the deformation of the mesh. In COMSOL Multiphysics^{TM} arbitrary Lagrangian-Euler (ALE) method is implemented. The Yeoh method is applied, with a stiffness factor equal to 150 [31].

A segregated iterative solver is applied in order to reduce the problem dimension. Specifically, three segregated groups are defined: the first for the displacement vector, the second for the spatial coordinates of the deformed mesh, and the third for the velocity, pressure, turbulent kinetic energy and turbulent dissipation rate.

The displacement vector is solved with a direct MUltifrontal Massively Parallel Solver (MUMPS) [31]. The others segregated groups are solved using the Flexible Generalized Minimal Residual Method (FGMRES) [32], preconditioned with Generalized Minimal Residual Method (GMRES) [33].

5.2 Low-Fidelity Simulations: Hydrodynamic Solver Only

Two segregated groups are solved: the first for velocity and pressure, and the second for turbulent kinetic energy and turbulent dissipation rate. Both segregated groups are solved using

the FGMRES, preconditioned with GMRES.

6 NUMERICAL RESULTS

The pressure contour on the hydrofoil and on the half-span plane are shown for both FSI and hydrodynamic-only simulations, for AoA=7 deg, Re=4E5, respectively in Figs. 4(a) and 4(b). In particular, the deflection of the tip of the hydrofoil is evident in Fig. 4(a).

Figure 5(a) shows for the FSI simulation the pressure contour on the hydrofoil and on the half-span plane, along with the streamlines deformed by the local velocity component (left color legend). Finally, Fig. 5(b) shows the pressure contour on the hydrofoil and the velocity contour on the half-span plane, along with the streamlines deformed by the local velocity component (left color legend).

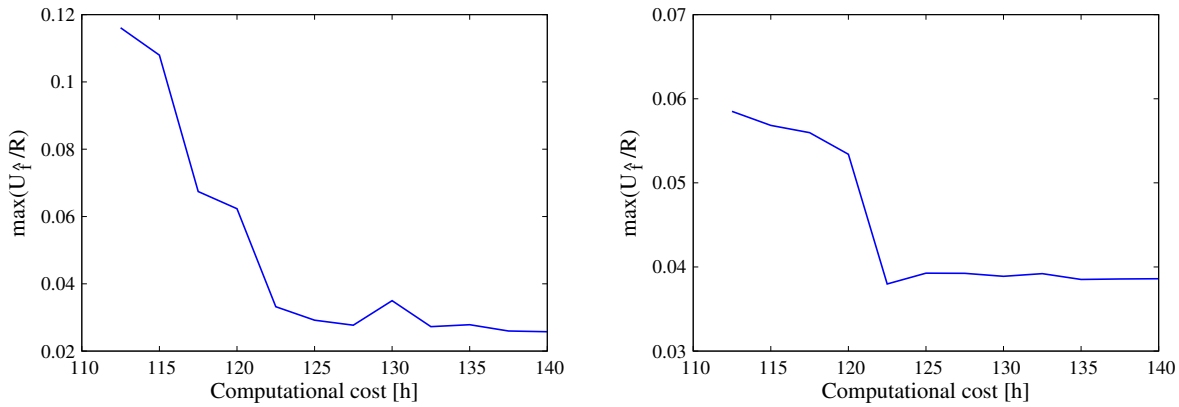
Figure 5: High-fidelity simulation, AoA=7 deg, Re=4E5.

The numerical results that follow are presented showing the maximum value of the uncertainty of the multi-fidelity metamodel, normalized with respect to the function range (R). The

adaptive sampling procedure is assumed at convergence when the maximum value of the uncertainty does not change significantly, if new simulations are added. Furthermore, the multi-fidelity metamodel, along with the uncertainty of the low-fidelity and error metamodels are shown at the initial and final iterations. Non-dimensional variables are used to build the metamodel. However, for the sake of clarity, dimensional results are shown. The initial training set is composed by the extreme values of the domain and the central point: AoA={-1;7;15} deg, permuted with Re={2E5;4E5;6E5}.

6.1 Problem 1

Figure 6 shows the maximum value of the normalized uncertainty of the multi-fidelity metamodel versus the computational cost. The maximum value of the uncertainty of the multi-fidelity metamodel of the lift coefficient shows a significant reduction during the iterative process, as shown in Fig. 6(a). The maximum value of the uncertainty of the multi-fidelity metamodel of the drag coefficient shows a quite sudden reduction after 4 iterations, as shown in Fig. 6(b). The convergence of the multi-fidelity metamodel is achieved after 13 iterations, corresponding to about 140 hours of simulation time (wall clock, using 1 Intel Xeon E5-1620 v2 3.9 GHz with 4 cores in parallel). A total of 9 high-fidelity and 20 low-fidelity simulations are used, as summarized in Tab. 2.



(a) Lift coefficient (b) Drag coefficient

Figure 6: Problem 1, maximum multi-fidelity metamodel uncertainty versus computational cost.

Figures 7(a)-(b), (c)-(d), and (e)-(f) show the initial multi-fidelity metamodel, the low-fidelity and error metamodel uncertainties, respectively for the lift and drag coefficients. The squares and triangles represent the points where the high- (H) and low-fidelity (L) simulations are computed.

Comparing Figs. 7(c) and 7(d) it is worth noting that the uncertainty associated to the low-fidelity metamodel of the lift coefficient is one order of magnitude greater than the uncertainty associated to the low-fidelity metamodel of the drag coefficient.

Figures 8(a)-(b), (c)-(d), and (e)-(f) show the multi-fidelity metamodel, the low-fidelity and error metamodel uncertainties, respectively for the lift and drag coefficients, corresponding to the final iteration (13-th iteration).

It should be noted that the uncertainty of the low-fidelity metamodel is significantly lower than in Figs. 7(c) and 7(d). Figures 8(e) and 8(f) show the uncertainty of the error metamodel, which is not changed, since high-fidelity simulations are not added to the original training set.

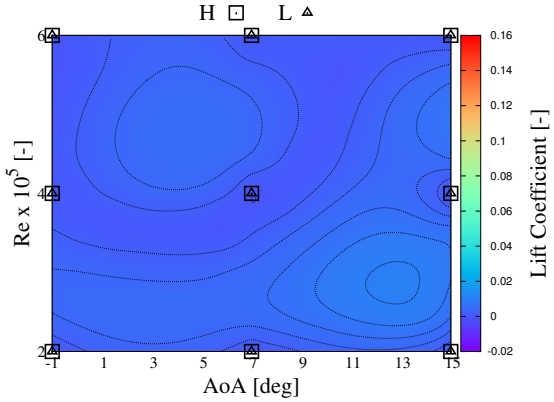
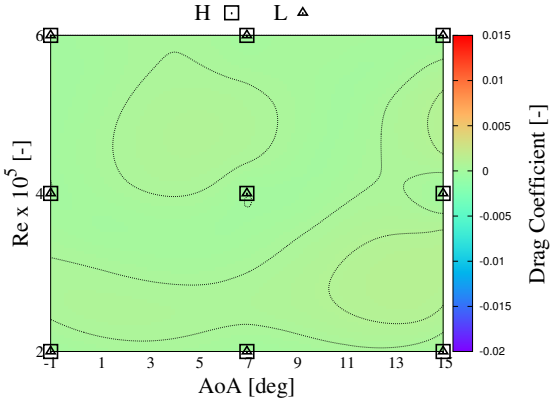
(d) Uncertainty of the low-fidelity metamodel of the drag coefficient



(e) Uncertainty of the error metamodel of the lift coefficient



(f) Uncertainty of the error metamodel of the drag coefficient

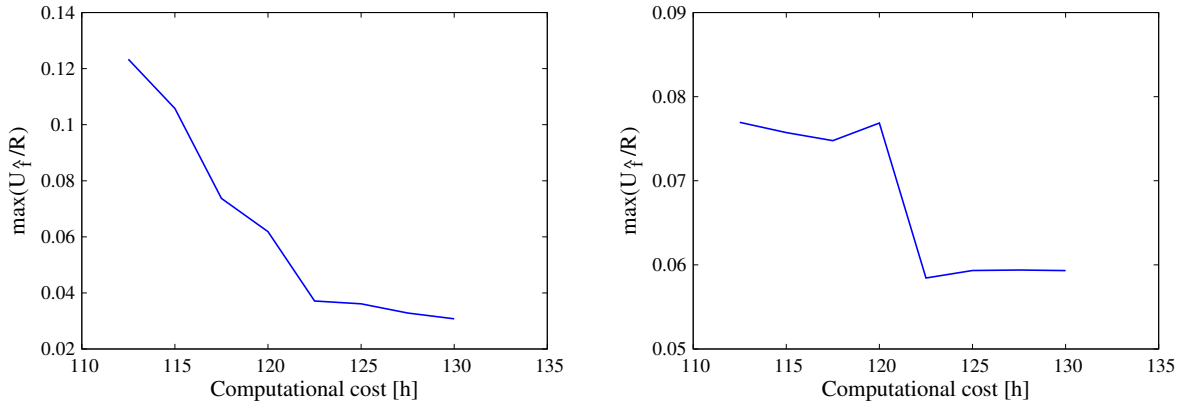
Figure 8: Problem 1, final iteration.

6.2 Problem 2

Figure 9 shows the maximum value of the uncertainty of the multi-fidelity metamodel versus the computational cost. Figure 9(a) shows the reduction of the maximum value of the uncertainty of the multi-fidelity metamodel of the lift coefficient. The maximum value of the uncertainty of the multi-fidelity metamodel of the drag coefficient shows a quite sudden reduction after 3 iterations, see Fig. 9(b). The convergence of the multi-fidelity metamodel is achieved after 7 iterations, corresponding to about 130 hours of simulation time (wall clock, using 1 Intel Xeon E5-1620 v2 3.9 GHz with 4 cores in parallel). A total of 9 high-fidelity experimental data and 16 low-fidelity simulations are used, as summarized in Tab. 2.



(a) Lift coefficient (b) Drag coefficient

Figure 9: Problem 2, maximum multi-fidelity metamodel uncertainty versus computational cost.

Figures 10(a)-(b), (c)-(d), and (e)-(f) show the initial multi-fidelity metamodel, the low-fidelity and error metamodel uncertainties, respectively for lift and drag coefficients. The squares represent high-fidelity experimental data (H) and the triangles represent the points where low-fidelity (L) simulations are computed.

Considering Figs. 10(c) and 10(d) it should be noted that the uncertainty associated to the low-fidelity metamodel of the lift coefficient is one order of magnitude greater than the uncertainty associated to the low-fidelity metamodel of the drag coefficient. Figures 10(e) and 10(f) show the uncertainty of the error metamodel, which is considerably greater than the corresponding uncertainties of Figs. 7(e) and 7(f). This effect is due to the difference between the simulations and the experiments, which is significantly greater than the difference between the high- and low-fidelity simulations.

Figures 11(a)-(b), (c)-(d), and (e)-(f) show the multi-fidelity metamodel, the low-fidelity and error metamodel uncertainties, respectively for lift and drag coefficients, at the final iteration (8-th iteration).

It is worth noting that the uncertainty of the low-fidelity metamodel, Figs. 11(c) and 11(d), is significantly lower than in Figs. 10(c) and 10(d), and that the uncertainty of the error metamodel is not changed, since no experimental data is added to the training set.

7 CONCLUSIONS

A multi-fidelity global metamodel has been presented for uncertainty quantification of computationally expensive computer simulations. High- and low-fidelity solvers are used for the metamodel training and managed through an adaptive sampling procedure. Multiple functions

have been considered, simultaneously. The multi-fidelity approximation is obtained as the sum of a low-fidelity-trained metamodel and the metamodel of the difference (error) between high- and low-fidelity evaluations. The metamodel is based on the dynamic stochastic RBF method, which provides the prediction and the associated uncertainty. The prediction uncertainty of both the low-fidelity and the error metamodel is used for the adaptive refinement of the low- and high-fidelity training sets, respectively.

The method has been applied to a steady FSI problem addressing the lift and drag coefficients of a 3D NACA 0009 stainless steel hydrofoil. Two problems have been presented: the first with high-fidelity evaluations provided by steady FSI simulations and the second with high-fidelity evaluations provided by experimental data. Low-fidelity evaluations have been provided by hydrodynamic simulations for both problems.

For problem 1, the overall uncertainty of the multi-fidelity metamodels has been reduced achieving 2.5% and 3.8% (of the function range) for the lift and drag coefficient, respectively. For problem 2, an uncertainty of 3% and 5.9% for the lift and drag coefficient has been achieved, respectively. Although the overall uncertainty in Problem 1 is lower than in problem 2, a better agreement with the experimental results is obtained using experimental data in the initial training set as in problem 2. Furthermore, less iterations have been used for problem 2. For both problems 1 and 2, the adaptive sampling method always required low-fidelity evaluations and no high-fidelity information was added to the model after the initialization. This is due to the high cost of high-fidelity evaluations (simulations or experiments) and the small uncertainty associated to the error between low- and high-fidelity functions.

Future work will extend the current study to different (and more flexible) materials, such as aluminum and/or composite materials, and will also include the application of the method to separate and combined problems of uncertainty quantification and design optimization.

Keywords: Uncertainty quantification, Sensitivity analysis, Adaptive ANOVA, Polynomial dimensional decomposition (PDD), Combustion.

Abstract. *We employ a new stochastic methodology for the construction of surrogate models for uncertainty quantification (UQ) and sensitivity analysis (SA). It is based on polynomial dimensional decomposition (PDD), as are widely used in solving high-dimensional stochastic problems that arise in various applications. In our approach, the coefficients of the PDD expansion are determined by using a least-squares regression (LSR). Compared to a projection approach, the use of LSR not only avoids the computation of high-dimensional integrals, but also affords an attractive flexibility in choosing the sampling points, which facilitates importance sampling using a calibrated posterior distribution based on a Bayesian approach. LSR can be particularly advantageous in cases where the asymptotic convergence properties of polynomial expansions cannot be realized due to computation expense, focusing effort on efficient finite-resolution sampling. To efficiently include parameter spaces with a moderate number of uncertain parameters (up to 7 in this work), the PDD is coupled with an adaptive ANOVA (analysis of variance) decomposition. This provides an accurate surrogate as the union of several low-dimensional spaces, avoiding the typical computational overhead cost of a high-dimensional expansion. In addition, the PDD representation of the ANOVA component functions is further simplified in an adaptive way according to the relative contribution of the different polynomials to the variance. The overall methodology is demonstrated on plasma-mediated ignition simulations as part of a large predictive science effort in the Center for Exascale Simulation of Plasma-Coupled Combustion (XPACC). The specific configuration we study includes model parameters arising from reaction rates in a global chemical kinetics description, and a laser-induced breakdown ignition seed.*

1 INTRODUCTION

It is well-understood that global sensitivity analysis (GSA) has the advantage of taking into account the broad influence of input parameters over the ranges and their interactions onto the output quantity of interest, by considering the entire input space rather than a specific nominal point (see for example [6]). However, the main difficulty encountered when employing global methods is the high cost of Monte Carlo (MC) or a quasi Monte Carlo (QMC) methods. These can be prohibitively expensive.

The objective of this work consists of building an efficient Uncertainty Quantification (UQ) and GSA method featuring a surrogate model representation that is affordable for complex numerical simulation problems. To address the so-called curse of dimensionality, we employ the polynomial dimensional decomposition (PDD) (introduced and developed by Rahman and coworkers in e.g. [12, 13, 15, 21, 14]) and combine it with the Analysis of Variance (ANOVA) decomposition due to their direct link with each other. The least-squares regression (LSR) approach is an efficient tool to determine the expansion coefficients, by minimizing the error of the surrogate model representation in the mean square sense (see e.g. [7, 18, 3]). Compared to the projection approach (see e.g. [9, 11, 2]) where each polynomial coefficient is obtained by computing a multi-dimensional integral, the regression approach is more flexible (in choosing sampling points) for problems involving a moderate number of uncertain parameters. It is known that the number of ANOVA component functions increases exponentially with respect to the uncertain parameter dimensionality, and meanwhile the imposed polynomial order for the PDD expansion involves a polynomial increase of the number of PDD terms for each component function. This phenomenon causes one main limitation of the regression approach even for a truncated low-order ANOVA expansion, namely the high number of deterministic model evaluations for problems characterized by a moderate to large number of uncertainties; indeed, for the regression problem to be well posed, the number of deterministic model evaluations is necessary to be larger than the total polynomial expansion size [3, 4]. In this respect, this paper employs the approach proposed in [20] to combine the *active dimension* strategy and the *stepwise regression* technique [3, 4] to obtain an efficient sparse surrogate model representation.

In Section 2, we review basic concepts of ANOVA, Sobol' sensitivity indices and outline main idea of variance-based dimension reduction techniques. A 2-D axisymmetric application case is investigated in Section 3. Conclusions follow.

2 ANOVA AND VARIANCE-BASED DIMENSION REDUCTION

Let us suppose that the response of a given system of interest can be represented by a N-dimensional function $y = f(\boldsymbol{\xi})$

$$y = f(\boldsymbol{\xi}) = f(\xi_1, \xi_2, \cdots, \xi_N), \tag{1}$$

where $\boldsymbol{\xi}$ are independent input uncertain parameters.

An Analysis of Variance (ANOVA) [16, 8, 1, 17] decomposes $f(\boldsymbol{\xi})$ into a series of lower-dimentional component functions as

$$y = f_0 + \sum_{1 \leqslant i \leqslant N}^{N} f_i(\xi_i) + \sum_{1 \leqslant i < j \leqslant N}^{N} f_{ij}(\xi_i, \xi_j) + \cdots + f_{1,2,\cdots,N}(\xi_1, \xi_2, \cdots, \xi_N), \tag{2}$$

or in compact form

$$y = f_0 + \sum_{T=1}^{N} \sum_{i_1<\cdots<i_T}^{N} f_{i_1,\cdots,i_T}(\xi_{i_1}, \cdots, \xi_{i_T}). \tag{3}$$

Note in ANOVA component functions have zero mean and are orthogonal. For notational convenience in this section, we write a general T-dimensional component function ($1 \leq T \leq N$) of the ANOVA decomposition as

$$f_{\mathbf{i}_T}(\boldsymbol{\xi}_T) = f_{i_1,i_2,\cdots,i_T}(\xi_{i_1}, \xi_{i_2}, \cdots, \xi_{i_T}). \tag{4}$$

Keeping in mind its zero-mean property, the component function (4) can be expanded by employing Polynomial Dimensional Decomposition (PDD) using an infinite number of orthogonal basis functions (as done in [12]) by a tensor product for multi-indices $\mathbf{j}_T$:

$$f_{\mathbf{i}_T}(\boldsymbol{\xi}_T) = \sum_{j_T,\cdots,j_1}^{\infty} C_{\mathbf{i}_T}^{\mathbf{j}_T} \Psi_{\mathbf{i}_T}^{\mathbf{j}_T}. \tag{5}$$

Here $C_{\mathbf{i}_T}^{\mathbf{j}_T}$ is a coefficient, and $\Psi_{\mathbf{i}_T}^{\mathbf{j}_T}$ is a T-dimensional basis polynomial function.

In practice, the expansion with an infinite number of terms in (5) must be truncated. Following previous work [12], we truncate (5) by m terms for each dimension:

$$f_{\mathbf{i}_T}(\boldsymbol{\xi}_T) = \sum_{j_T,\cdots,j_1 \leq m} C_{\mathbf{i}_T}^{\mathbf{j}_T} \Psi_{\mathbf{i}_T}^{\mathbf{j}_T}. \tag{6}$$

In particular, the first-order, second-order, and third-order component functions are expressed as

$$\begin{aligned} f_i(\xi_i) &= \sum_{j=1}^{m} C_i^j \psi^j(\xi_i), \\ f_{\mathbf{i}_2}(\boldsymbol{\xi}_{\mathbf{i}_2}) &= \sum_{j_2=1}^{m} \sum_{j_1=1}^{m} C_{\mathbf{i}_2}^{\mathbf{j}_2} \psi^{j_1}(\xi_{i_1}) \psi^{j_2}(\xi_{i_2}), \\ f_{\mathbf{i}_3}(\boldsymbol{\xi}_{\mathbf{i}_3}) &= \sum_{j_3=1}^{m} \sum_{j_2=1}^{m} \sum_{j_1=1}^{m} C_{\mathbf{i}_3}^{\mathbf{j}_3} \psi^{j_1}(\xi_{i_1}) \psi^{j_2}(\xi_{i_2}) \psi^{j_3}(\xi_{i_3}). \end{aligned} \tag{7}$$

Least-squares regression (LSR) [5, 20] can be employed to determine the coefficients $\mathbf{C}_\alpha$ of (vector-form) PDD expansion

$$f(\boldsymbol{\xi}) = \mathbf{C}_\alpha^T \Phi_\alpha(\boldsymbol{\xi})$$

by using a suitable set of training points (i.e. experimental design) and model outputs. The second-order moment and the global sensitivity indices can be obtained in a straightforward way by post-processing.

Indeed, keeping in mind

$$E(f(\boldsymbol{\xi})) = C_{\alpha_0},$$

the approximated variance of the model output is then

$$\mathrm{Var}(f(\boldsymbol{\xi})) = \sum_{j=1}^{P-1} C_{\alpha_j}^2 \gamma_{\alpha_j},$$

with the multivariate normalization constant determined by

$$\gamma_{\alpha_j} = E\left[\Phi^2_{\alpha_j}(\boldsymbol{\xi})\right],$$

where P is the expansion size.

It is straightforward to write the variance-based global sensitivity indices (SI) by using the PDD expansion. Indeed,

$$\mathcal{S}_{i_1,\cdots,i_T} = \frac{\mathrm{Var}(f_{i_1,\cdots,i_T})}{\mathrm{Var}(f(\boldsymbol{\xi}))} = \frac{1}{\mathrm{Var}(f(\boldsymbol{\xi}))} \sum_{\alpha_j \subseteq (i_1,\cdots,i_T)} C^2_{\alpha_j} \gamma_{\alpha_j}. \tag{8}$$

The total sensitivity index $\mathcal{S}_i^T$ can be obtained simply by adding all the measures $\mathcal{S}_{i_1,\cdots,i_T}$ whose index involves the variable ξ_i.

For practical problems, in particular for the ones with a large number of stochastic parameters, the size of the PDD representation must be reduced to make the uncertainty analysis feasible.

A stepwise regression method has been proposed in [4, 3] using a generalized Polynomial Chaos (gPC) approach to build sparse polynomial representation of the model output. In order to efficiently represent a moderate to large dimensional parameter space, in addition to the stepwise regression technique proposed in [4, 3], the PDD approach used in this work is further coupled with an adaptive ANOVA decomposition, which allows to model a given number of low-dimensional spaces instead of a single high-dimensional one. The overall adaptive technique, as a variant of the one used in [4, 3], has been proposed in [20]. We summarize this LSR strategy as a set of coupled adaptive strategies as follows.

1. Set a truncation dimension ν (the maximum interaction order) in the ANOVA expansion. This follows the assumption that low-order interactions are of dominant importance compared to their high-order counterparts.

2. Solve the LSR system including only the PDD terms of the first-order ANOVA component functions, and a rank of importances can then be established quantitatively for all the input parameters. Hence, we retain only so-called active dimensions (the most influential parameters) for the PDD terms of the second- and higher-order ANOVA components. Let us use D_T to represent the active dimension for interaction order T.

3. Enrich the surrogate model representation by adding one-by-one significant polynomials of second- and higher-order interaction terms by keeping only the corresponding active dimensions. A variance-based selection criterion is used to retain only polynomials of significant importance to the total variance, which allows to build a very sparse model representation. We emphasize that recursive resolutions of regression problems are required for this task.

In next section, this adaptive LSR ANOVA approach is applied to an application case featuring input uncertainties arising from chemical kinetics and laser-induced breakdown ignition seed.

3 APPLICATION TO A 2-D COMBUSTION SYSTEM

The combustion in this work is modeled by multi-species Navier–Stokes equations involving source terms including contributions from a reduced chemical mechanism, and

a simplified laser-induced breakdown (LIB) plasma model. Both thermal and vortical contributions are modeled for LIB ignition seed [10]. The model parameter uncertainties considered in this work mainly come from these source terms.

Note the system of Navier–Stokes equations is discretized by finite difference methods on structured grids using the software *PlasComCM*. For details on numerical techniques, we refer to [10].

3.1 Source of uncertainties

The present combustion model featuring a Laser Induced Breakdown (LIB) ignition seed includes seven uncertain parameters, which are calibrated against low-dimensional computations or estimated based on experiments or previous literature data. We summarize these uncertain parameters in Table 1. Note A_3, b_3, and E_3 are calibrated Arrhenius

Combustion kinetics	A_3, b_3, E_3	Joint pdf_{post} calibrated
Laser Induced Breakdown	$L_{TW} \sim \mathcal{U}(0.993, 2.979)$	[mm]
	$R_{TW}(= D_{TW}/2) \sim \mathcal{U}(0.168, 0.504)$	[mm]
	$M_e \sim \mathcal{U}(1, 3)$	
	$E_{abs} \sim \mathcal{N}(17.642, 3.1157)$	[mJ]

Table 1: Summary of uncertain model parameters.

coefficients of the following reaction,

$$2H_2 + O_2 + H \rightarrow 2H_2O + H. \tag{9}$$

L_{TW} (resp. R_{TW}) represents the length (resp. radius) of the luminosity region measured by experiments (we assume the laser energy is spatially distributed over the luminosity region). M_e is the Mach number of LIB vorticity model, and finally, E_{abs} is the absorbed laser energy. The reader is refered to [10] for detailed physical modeling of LIB. Among the four parameters of LIB, the Gaussian distribution of E_{abs} is approximated using experimental results (3160 trials). However, we know significantly less about other three parameters. Thus, L_{TW} and R_{TW} are simply taken to follow a uniform distribution using an error bar of 50 % of their norminal value. The upper-bound value of $M_e = 3$ is the threshold with which our current numerical model becomes significantly unstable.

3.2 Axisymmetric 2-D test problem and quantity of interest (QoI)

An ignition case is computed on a 2-D rectangular domain (as shown in Fig. 1) discretized as a structured grid of size 501×503. The initial condition over the 2-D domain

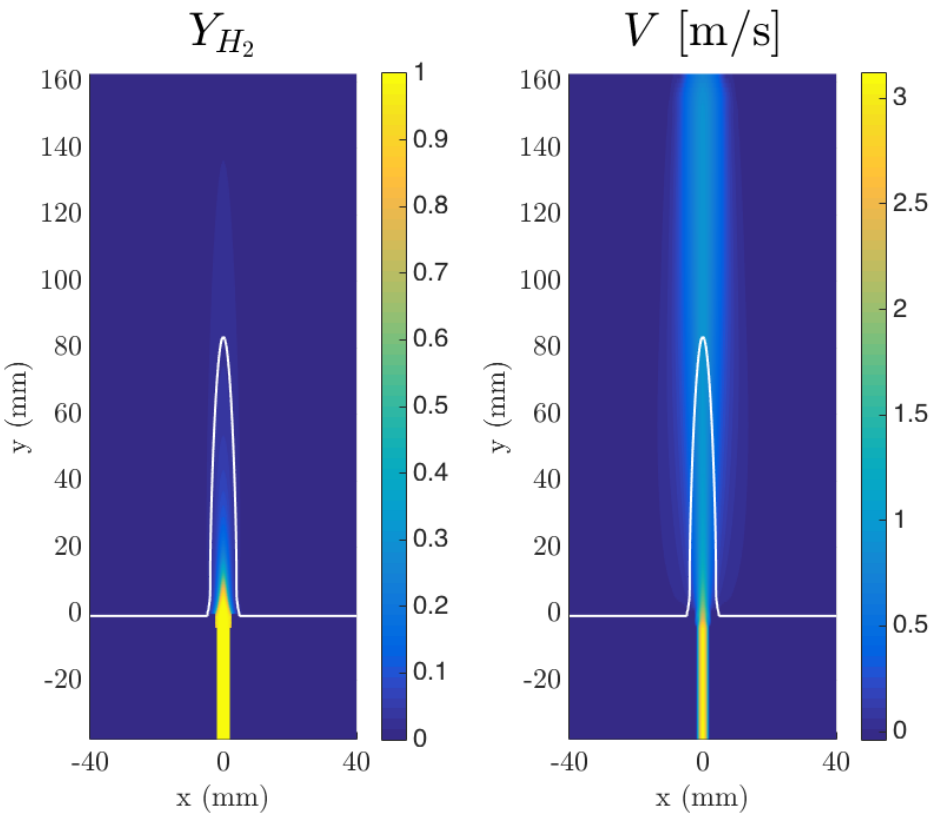

Figure 1: 2-D axisymmetric computational domain for the ignition case. Left: H_2 mass fraction at $t = 0$. Right: flow y velocity at $t = 0$.

is a stabilized cold hydrogen fuel jet (about 3 m/s) into a squared domain filled with air. The Fig. 1 illustrates this initial flow by showing the H_2 mass fraction and y-velocity.

Let

$$\boldsymbol{\zeta} = (\ln(A_3), b_3, \ln(E_3), L_{TW}, R_{TW}, M_e, E_{abs})^T$$

represent the random vector of uncertain model parameters, and $Q(\mathbf{x}, t; \boldsymbol{\zeta})$ be a quantity related to the solution of combustion system, and $Q_0(\mathbf{x})$ is its initial value. We can define the following quantity that links the mass fraction of fuel H_2 and oxidizer O_2 for the reaction (9),

$$\Phi(\mathbf{x}, t; \boldsymbol{\zeta}) = \frac{\nu'_{H_2,3} Y_{O_2}/W_{O_2}}{\nu'_{O_2,3} Y_{H_2}/W_{H_2}} = \frac{Y_{O_2}}{8 Y_{H_2}}.$$

Thus, the contour

$$\Phi(\mathbf{x}, t; \boldsymbol{\zeta}) = 1$$

defines the stoichiometric surface. E.g. the white contour in Fig. 1 represents the (stabilized) initial stoichiometric surface.

A spatial weighting function $w(\mathbf{x}, t; \boldsymbol{\zeta})$ can be defined following a Gaussian pdf with

respect to Φ,*

$$w(\mathbf{x}, t; \boldsymbol{\zeta}) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{(\Phi - 1)^2}{2\sigma^2}\right),$$

where σ is a predefined deviation parameter; we use $\sigma = 0.001$ in this work. The spatial integral of weighting function is denoted by

$$\Omega(t; \boldsymbol{\zeta}) = \int w(\mathbf{x}, t; \boldsymbol{\zeta})\, \mathrm{d}\mathbf{x}.$$

The QoI used in this work is defined as a dimensionless average as follows

$$\mathcal{J}_Q(t; \boldsymbol{\zeta}) = \frac{\frac{1}{\Omega(t;\boldsymbol{\zeta})} \int Q(\mathbf{x}, t; \boldsymbol{\zeta}) w(\mathbf{x}, t; \boldsymbol{\zeta})\, \mathrm{d}\mathbf{x}}{\frac{1}{\Omega_0} \int Q_0(\mathbf{x}) w_0(\mathbf{x})\, \mathrm{d}\mathbf{x}} = \frac{\langle Q(t; \boldsymbol{\zeta}) \rangle}{\langle Q_0 \rangle}.$$

If $\mathcal{J}_Q(t \gg t_0; \boldsymbol{\zeta})$ is close to unity for a quantity such as temperature, it is obvious no ignition has appeared. Fig. 2 illustrates the temperature field of an ignited example, in which case the stoichiometric surface is heated by combustion and thus we have a high $\mathcal{J}_T$.

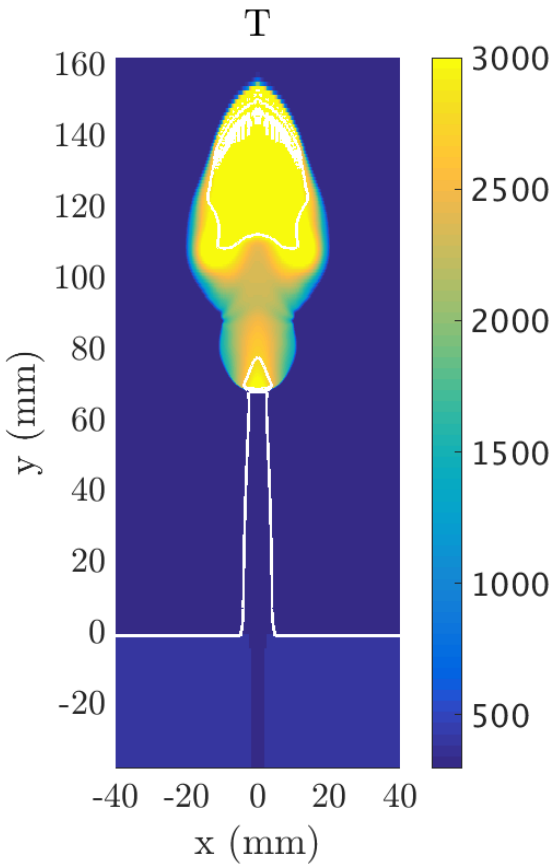

Figure 2: A successful ignition example. Compuational domain with a typical temperature field in [K]. Laser height: $y = 103.40$ mm.

*In present case where the stoichiometric surface under flame prpopagation does not change its form significantly in time, we can use a time-independent weighting function $w_0(\mathbf{x})$ for simplicity.

3.3 Uncertainty propagation and analysis

This section is devoted to the parameter sensitivity analysis for QoI $\mathcal{J}_T$. Let us analyze the case where the laser source is put at height $y = 103.40$ mm (with respect to experiments). We set the ANOVA interaction order $\nu = 3$ and size of experimental design $\mathcal{Q} = 100$.

The scatter plots of QoI with respect to each (tranformed) parameter are given in Fig. 3. Note here we employ the following isoprobabilistic tranform by using the cumulative distribution function (CDF) $\mathcal{F}$,

$$\xi_i = \mathcal{F}_{\zeta_i}(\zeta_i).$$

By definition $\mathcal{J}_T$ represents the dimensionless average temperature weighted on the initial-time stoichiometric surface. If we assume the raise of flame temperature in the vicinity of stoichiometric surface is mainly due to the release of enthalpy of formation of chemical reaction itself (not due to laser heat transfer), it is obvious that the greater the value of $\mathcal{J}_T$, the faster the flame propagates. Thus from Fig. 3 and as expected, we observe qualitatively

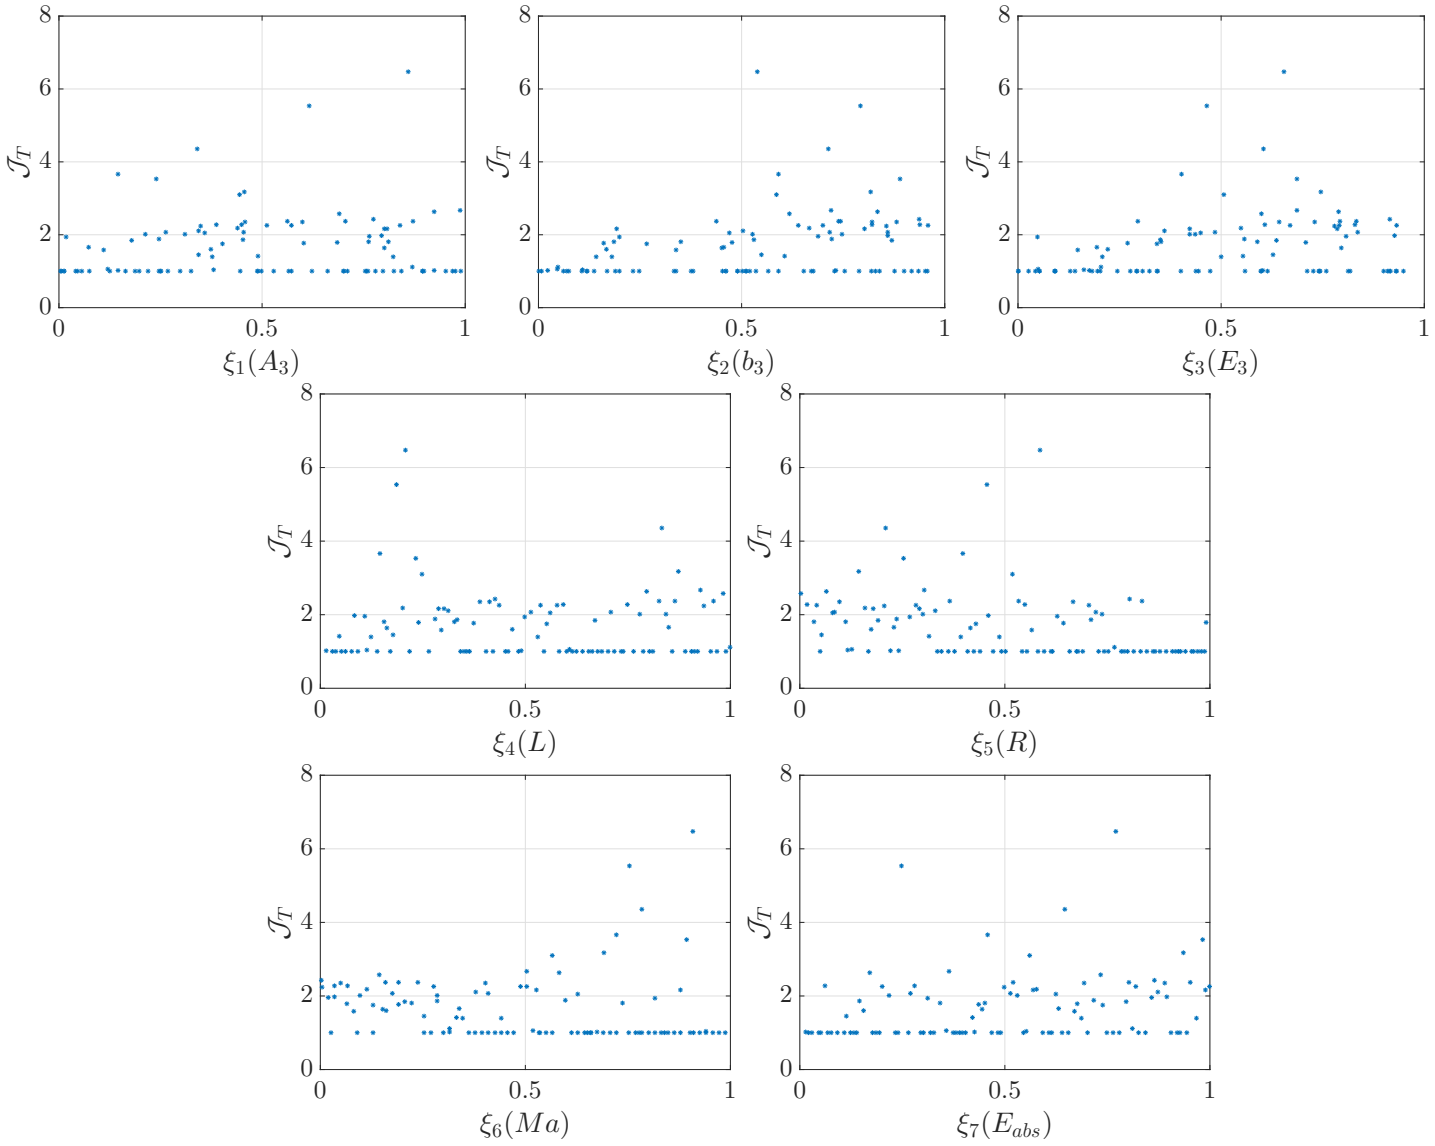

Figure 3: QoI vs. model parameters. Laser height: $y = 103.40$ mm.

with a stronger laser source (greater E_{abs} or smaller R_{TW} i.e. a more narrow region of high temperature), the more probably ignition occurs, and if this happens, the faster flame propagates. Also, a greater value of Mach number parameter M_e makes ignition more diffcult to happen because of the flow mixing; however, once ignited the flame is found to propagate considerably faster due to the vorticity. Concerning the remaining model parameters, we find it more difficult to draw a similar qualitative conclusion.

A procedure of parameter re-ordering is generally required (see end of Section 2) that depends upon their variance contribution of first-order ANOVA components.[†] Fig. 4 (top) presents the SI of input parameters, while the bottom figures illustrate the SI in the descending order together with the cumulated value. We denote the re-ordered input random vector for case $m = 4$ as,

$$\hat{\boldsymbol{\xi}}_{m=4} = (\xi_3, \xi_2, \xi_4, \xi_5, \xi_1, \xi_7, \xi_6)^T, \tag{10}$$

and for $m = 5$,

$$\hat{\boldsymbol{\xi}}_{m=5} = (\xi_2, \xi_3, \xi_4, \xi_5, \xi_1, \xi_7, \xi_6)^T. \tag{11}$$

Note they are slightly different about the relative importance of b_3 and E_3. In fact, the SI of b_3 and E_3 are very close in the case of $m = 5$.

Active dimension D_2 is evaluated using the sum of variances of first-order terms

$$\sum_{i=1}^{D_2} \mathrm{Var}(f_i) \geqslant p \sum_{i=1}^{N} \mathrm{Var}(f_i), \tag{12}$$

where p is a proportionality constant in $(0, 1)$, and is very close to 1. Thus we can conclude from Fig. 4 the following

$$\begin{aligned} D_2 &= 3, \quad \text{if } p = 0.7, \\ D_2 &= 4, \quad \text{if } p = 0.8, \\ D_2 &= 5, \quad \text{if } p = 0.9, \\ D_2 &= 6, \quad \text{if } p = 0.95, \\ D_2 &= 7, \quad \text{if } p = 0.999. \end{aligned}$$

We set $p = 0.999$ for this case, which results that all input parameters are taken into consideration for interaction calculations. In fact, the dimensionality of 7 is relatively low, and the proposed adaptive approach can handle this problem with an experimental design size $\mathcal{Q} = 100$ by setting this high active dimensionality at this stage. As a result, the ANOVA expansion has its size equal to

$$N + \binom{D_2}{2} + \binom{D_3}{3} = 63.$$

Fig. 5 illustrates the first-order SI together with total sensitivity indices (TSI). We observe that the kinetic parameters have a more significant variance contribution than their laser source counterparts in general. Meanwhile, both measures indicate the input parameter $\xi_3(E_3)$ is the most significant one, followed by $\xi_2(b_3)$. The TSI when setting $m = 5$ shows the variance contribution of the input $\xi_1(A_3)$ is more significant than all laser source parameters.

[†]We remind that this step involves a least-squares regression system that only contains polynomial bases of first-order.

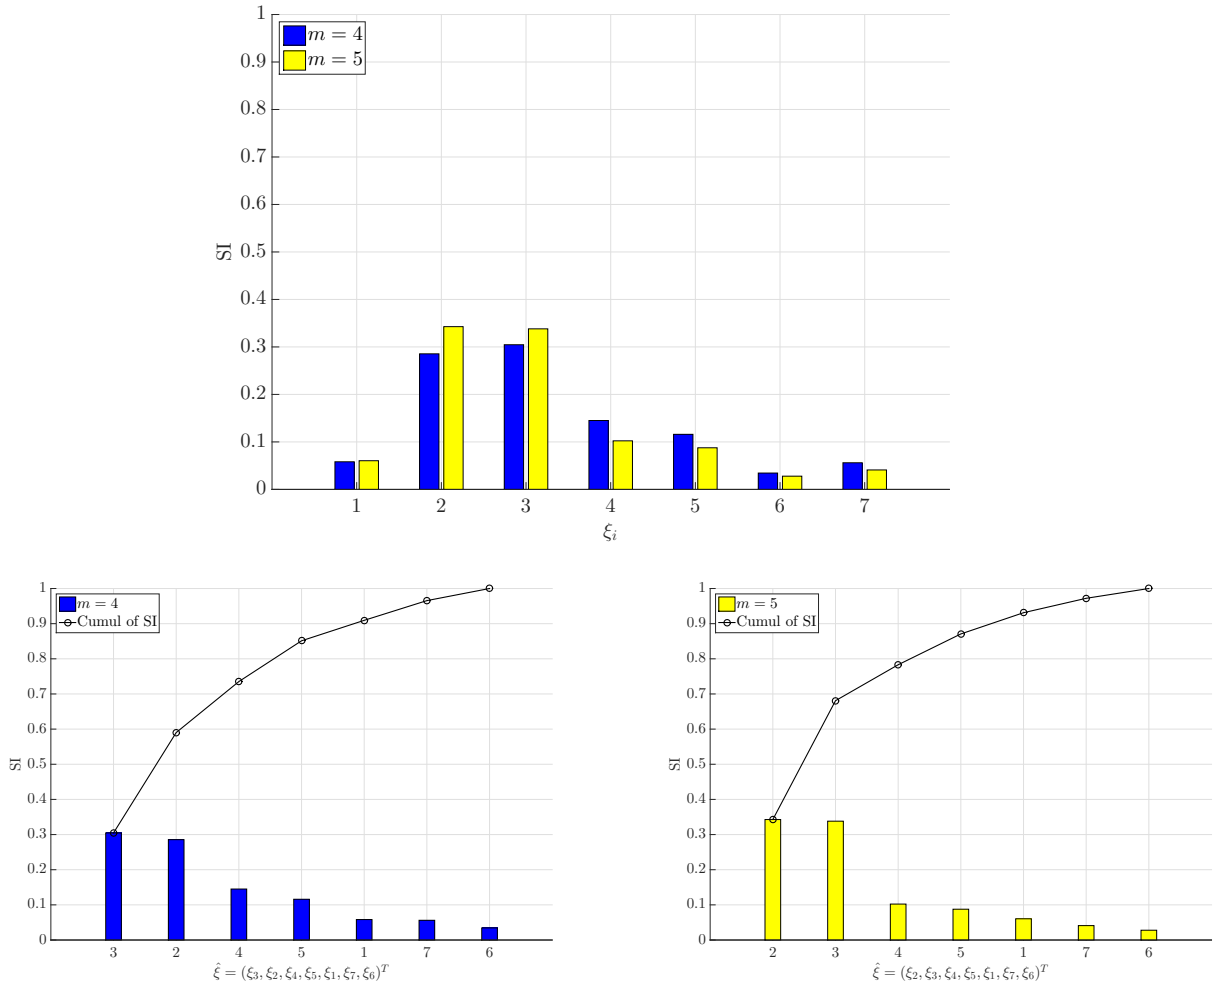

Figure 4: First-order SI for $m = 4$ and $m = 5$. x-axis indexing on the top figure is according to original random vector $\boldsymbol{\xi}$. $\hat{\boldsymbol{\xi}}$ on the bottom figures is the re-ordered input vector. $\nu = 3$. Experimental design size $\mathcal{Q} = 100$. $p = 0.999$. Laser height: $y = 103.40$ mm.

Fig. 6 illustrates the Sobol' sensitivity indices for both first- and higher-order ANOVA component functions. For the sake of clarity, we point out explicitly the following:

- $x-$axis indices $1-7$ represent first-order ANOVA components that are ordered according to the original random vector

$$\boldsymbol{\xi} \rightarrow \boldsymbol{\zeta} = (\ln(A_3), b_3, \ln(E_3), L_{TW}, R_{TW}, M_e, E_{abs})^T.$$

- $x-$axis indices $8-28$ represent second-order ANOVA components, while $29-63$ represent third-order ones. These indices are ordered following $\hat{\boldsymbol{\xi}}$ (10) or (11), and by using an ANOVA multi-index system presented in [19, page 1556].

We then mostly observe from Fig. 6 that the interaction between b_3 and $\ln(E_3)$ is significant compared to first-order and other interaction contributions. The third-order interactions are in general of less importance than second- and first-order components.

4 CONCLUSIONS AND FUTURE WORK

This paper aims to deal with Uncertainty Quantification of engineering and physical problems featuring a moderate to large number of uncertain input parameters. The purpose is to identify the relative importance of these uncertainties onto a given quantity of interest. This is achieved in this work by performing global sensitivity analysis, and in particular by combining the Analysis of Variance technique (ANOVA) and the polynomial dimensional decomposition approach (PDD). A set of coupled adaptivity strategies are futher employed and have been proved useful to identify important parameters in a simplified plasma-assisted combustion system.

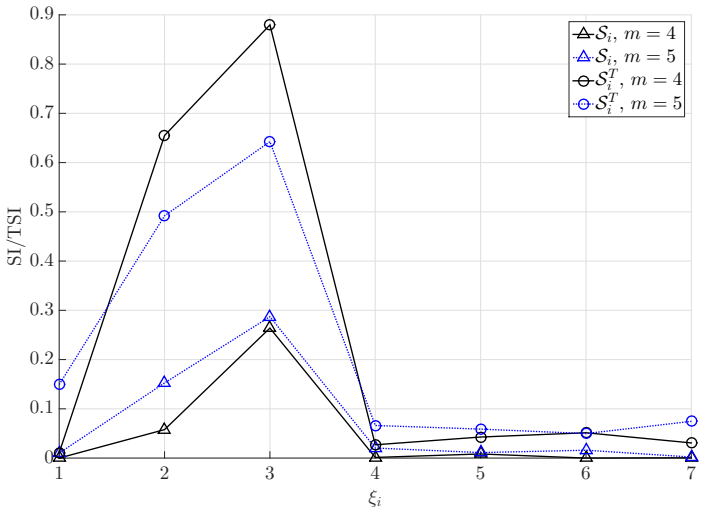

Figure 5: First-order Sobol' Sensitivity Indices (SI) and Total Sensitivity Indices (TSI). $\nu = 3$. $m = 4, 5$. Experimental design size $\mathcal{Q} = 100$. $p = 0.999$. All 7 parameters are considered in first- and higher-order ANOVA components. Laser height: $y = 103.40$ mm.

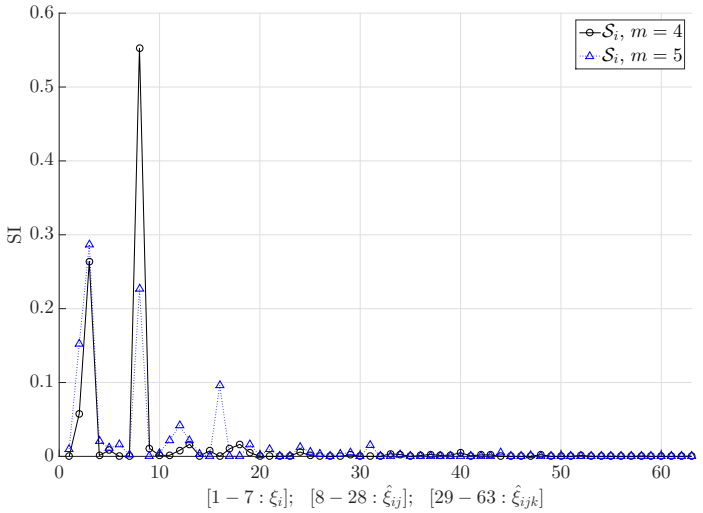

Figure 6: First-, second- and third-order Sobol' Sensitivity Indices (SI). The element indices of the original input vector $\boldsymbol{\xi}$ are used for first-order SI, while the ones of the re-ordered input vector $\hat{\boldsymbol{\xi}}$ are used for second- and third-order SI. $\nu = 3$. $m = 4, 5$. Experimental design size $\mathcal{Q} = 100$. $p = 0.999$. All 7 parameters are considered in first- and higher-order ANOVA components. Laser height: $y = 103.40$ mm.

The resulting surrogate polynomial approximation is a very sparse representation of the deterministic model. Since the surrogate model size is updated recursively in the stepwise regression procedure, the number of the required deterministic model evaluations is well controlled, and its final value is significantly smaller than when employing a standard Monte Carlo or quasi Monte Carlo method. Finally, the computation of the global sensitivity indices simply requires a post-processing of the polynomial coefficients.

More detailed models for Laser Induced Breakdown and Laser-Plasma Interaction are currently in development in XPACC, while we are also considering more detailed chemistry mechanism for future work. A dielectric-barrier discharge (DBD) force and radical generation model will also be included in our future parametric UQ study.

Keywords: Ascending thoracic aortic aneurysms, CFD simulations, uncertainty quantification, polynomial chaos.

Abstract. *Numerical simulations of the flow in thoracic aortic aneurysms are carried out by using the open-source tool SimVascular and considering patient-specific geometries, obtained through in-vivo imaging. One of the main issues in these simulations is the choice of suitable boundary conditions, modeling the organs and vessels not included in the computational domain. The current practice is to use outflow conditions based on proximal resistance, capacitance and distal resistance (three-element Windkessel model), whose values are tuned to obtain a physiological behavior of the patient pressure. However, it is not known a priori how this choice affects the results of the simulation. A quantification of the impact on the numerical simulation results of uncertainties in the values of the Windkessel model parameters is carried out by using the generalized Polynomial Chaos approach. Different patient-specific geometries are considered, characterized by a different size of the aneurysms, and the effect of wall compliance is also investigated. We analyze the impact of the uncertainties in the selected outflow parameters on the time-averaged wall shear stress and on the oscillatory shear index, which are commonly used as hemodynamic descriptors.*

1 INTRODUCTION

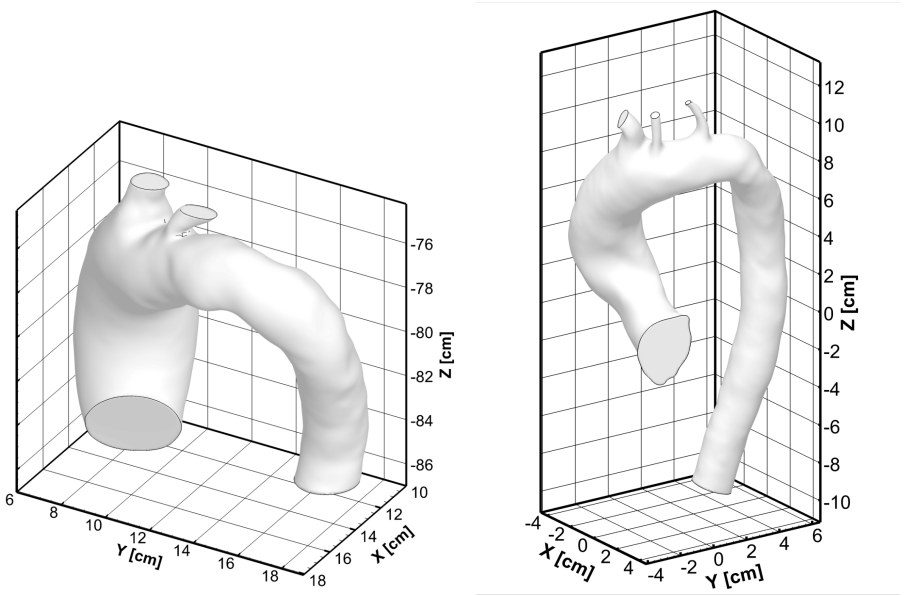
The Ascending Thoracic Aortic Aneurysm (ATAA) is a life-threatening cardiovascular disease with remarkable morbidity and mortality. It is defined as a permanent and localized dilatation of the aorta, resulting from an irreversible loss of structural integrity of the aortic wall ([1, 2]), triggered by genetic mutations and/or mechanobiological aspects. Conventionally, an increase in diameter greater than 50% may be considered as evidence of an aneurysm ([3]). At the state of the art, clinical decisions on treatment strategies are currently based on empiric criteria, like the aortic diameter value or its growth rate.

From a biomechanical point of view, the aneurysmatic pathology has been investigated considering the structural change of the artery wall and its effects on the wall stress distribution, as well as performing fluid dynamical analyses in order to obtain the distribution of the wall shear stress. Biomechanical studies (see e.g. [4]) demonstrated that the criterion most widely used to predict the pathological state of ascending thoracic aortic aneurysms, i.e. the maximum aortic diameter, fails to predict rupture or dissection, especially in case of small-sized ascending thoracic aortic aneurysms and this means that other predictors are needed to understand and estimate the state of the aneurysm. Indeed, ATAAs are characterized by the presence of a complex hemodynamics, which could contribute to the onset/progression of the disease.

Advances in medical images provide not only accurate morphological features but also the non-invasive quantification of blood flow. In this context, the Phase Contrast Magnetic Resonance (PC-MRI) technique has become the prevalent imaging technique for non-invasive and detailed information due to its good spatial resolution with respect to hemodynamic quantities and due to the possibility of acquiring time-dependent data sets of the three-directional components of the blood flow velocity ([5, 6]).

In this scenario, CFD-based techniques are being used to build complex computer representations of the cardiovascular system in health and disease. CFD modeling enables investigation of pressure and flow fields at a temporal and spatial resolution unachievable by any clinical methodology, therefore allowing to easily quantify variables and indicators difficult to be obtained from *in-vivo* measurements. The main difficulty is represented by the assumptions made in CFD models, concerning, for instance, boundary conditions or the modeling of wall compliance and wall properties, which may affect the accuracy of CFD predictions. Thus, the combination between CFD simulation techniques and *in-vivo* and ex-vivo measurements is a key ingredient to set up reliable predictive tools. For instance, phase velocity and anatomic data ([7]) from PC-MRI have been used to perform patient-specific computational hemodynamics in healthy ([8, 9]) and diseased subjects ([10, 11]), in order to provide evidence of a possible relation of local wall shear stress with disease ([12, 13]), but, despite all those investigations, reliable patient-specific models are usually not easy to be obtained.

As previously mentioned, the accuracy of CFD predictions depends on the adopted modeling, but also on the quality of input data. For CFD applications it is unclear how detailed the clinical data needs to be in terms of geometry (segmented from medical images) and parametrization (variability described by the model and the tuning of patient-specific boundary conditions). In the present work we want to determine the impact of the uncertainties in the input data. This will provide further understanding of the relative importance of physiological parameters, determining those which are most influential, and those which can be assumed or averaged. In particular, we focused on the choice of suitable boundary conditions, modeling the organs and vessels not included in the computational domain. The current practice is to use outflow conditions based on proximal resistance, capacitance and distal resistance (three-element Windkessel model), whose



(a) Geometry A ($D_{r1} = 1.7$) (b) Geometry B ($D_{r2} = 1.5$)

Figure 1: Sketch of the considered geometries.

values are tuned to obtain a physiological behavior of the patient pressure. However, it is not known a priori how this choice affects the results of the simulation. Since a preliminary analysis showed that the proximal resistance and the capacitance are the main parameters affecting the pressure profile obtained in the Windkessel model, these two quantities were selected as uncertain parameters for the uncertainty quantification analysis, while a fixed reference value of the distal resistance was maintained.

This sensitivity was carried out through a stochastic approach, i.e. by modeling the unknown parameters as input random variables with a given probability distribution and propagating the uncertainties through the computational model to statistically quantify their effect on the results. The stochastic quantification was carried out by using the generalized Polynomial Chaos approach. Different patient-specific geometries were considered, characterized by a different size of the aneurysms, and the effect of wall compliance was also investigated. The impact of the uncertainties in the selected outflow parameters was investigated on the different quantities of interest; in particular, we analyzed the stochastic mean and standard deviation of the time-averaged wall shear stress and oscillatory shear index.

2 DEFINITION OF THE PROBLEM

2.1 Geometry definition

Two patient-specific geometries of thoracic aortas subjected to aneurysm in their ascending region were considered. Both cases were acquired by means of *in-vivo* imaging. The geometry A was reconstructed from Computed Tomography (CT), the geometry B by using Magnetic Resonance Imaging (MRI).

The two geometries are sketched in Figure 1. They differ in the severity of the disease, property quantified by the maximum diameter ratio $D_r = D_{\max}/D_{\text{healthy}}$, where $D_{\max}$ is the maximum transverse diameter (thus, obtained in correspondence of the widest section of the aneurysm) and D_{healthy} is the diameter of the healthy segment (measured in the descending region of the aorta). The two considered cases are characterized by $D_{r1} = 1.7$ and $D_{r2} = 1.5$,

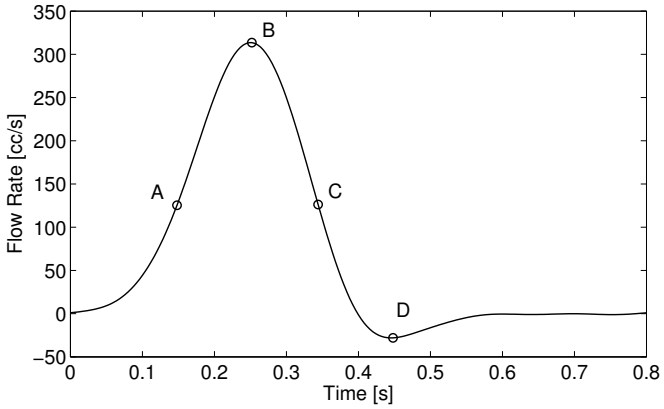


Figure 2: Flow rate profile imposed at the inlet section. The following characteristic time instants are highlighted: the maximum acceleration (A), the peak systole (B), the maximum deceleration (C) and early diastole (D).

respectively.

2.2 Simulation setup and numerical methodology

At the inlet section of the computational domain we imposed the physiological flow rate waveform of Figure 2 (see e.g. [14, 15]). The distribution of the velocity in the inlet section was assumed to be uniform.

The choice of outflow boundary conditions is more challenging, since they should accurately represent the effect of what happens outside the computational domain, modeling downstream organs and vessels (see e.g. [16] for a detailed overview). For this purpose, a three-element Windkessel model (also known as RCR model and sketched in Figure 3) was placed in correspondence of each outlet section, with a downstream pressure set to a constant reference value. Lumped parameter models are based on the analogy between electric circuits and hemodynamic problems: in particular, analogy is identified between the voltage difference and the drop in pressure, and between the current and the flow rate. In the presented scheme, the proximal and distal resistances (R_p and R_d) represent the viscous resistance the blood flow undergoes inside large and small vessels, respectively. The capacitance C quantifies the compliance, and thus the capability of storing fluid, of the major arteries. In the numerical deterministic computations used as a reference, these parameters were set in order to obtain a desired physiological behavior of the pressure profile ($125/80\,\mathrm{mmHg}$) in the simplified fully lumped model in which the contribution of the flow in the computational domain is not considered:

$$P(t) + R_d\, C \frac{dP(t)}{dt} = (R_p + R_d)Q(t) + R_p R_d\, C \frac{dQ(t)}{dt} \tag{1}$$

in which we imposed the inlet flow rate $Q(t)$ of Figure 2. Equation (1) was solved numerically. The resulting values are: $R_p = 106.5\,\mathrm{g\,cm^{-4}\,s^{-1}}$, $C = 10.4 \times 10^{-4}\,\mathrm{cm^4\,s^2\,g^{-1}}$ and $R_d = 1.67 \times 10^3\,\mathrm{g\,cm^{-4}\,s^{-1}}$.

Since descending from a fully lumped parameter model, the values of R_p, R_d and C were independent of the particular geometry considered. They were then distributed in the various

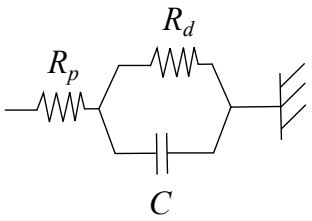

Figure 3: Scheme of a 3-Element Windkessel model.

Table 1: Summary of mechanical properties of the arterial wall used in the deformable simulations.

Quantity	Value
Density: ρ_{w} [$\mathrm{g\,cm^{-3}}$]	1.08
Young's Modulus: E_{w} [MPa]	3
Thickness: h_{w} [cm]	0.1
Poisson's Ratio: λ_{w}	0.499
Shear Correction Parameter: k_{w}	0.833

outlets as follows:

$$\begin{aligned} R_{p_i} &= R_p \frac{A_{\mathrm{tot}}}{A_i} \\ R_{d_i} &= R_d \frac{A_{\mathrm{tot}}}{A_i} \qquad \text{for } i = 1, \ldots, n_{\mathrm{outlets}} \\ C_i &= C \frac{A_i}{A_{\mathrm{tot}}} \end{aligned} \tag{2}$$

where n_{outlets} is the number of the outlets in the considered case (i.e., 3 in the first geometry and 4 in the second), A_i is the area of the outlet i and A_{tot} is the sum of the areas of all the outlets. The previous relations arise from the consideration that when increasing the vessel section the resistance opposed to the blood flow becomes smaller, while the wall compliance capability increases. Unlike R_p, R_d and C, the quantities obtained through Equation (2) are case-dependent.

On the arterial wall we imposed a no-slip condition. Both rigid and deformable simulations were performed. When considering the arterial wall compliance, for the sake of simplicity the aorta was assumed as an elastic, homogeneous and isotropic material, with a uniform wall thickness. The values of the mechanical properties chosen are reported in Table 1, where all dimensional properties, except for Young's Modulus, are expressed in *CGS* units.

The values of blood dynamic viscosity and density were specified as $\mu = 0.04\,\mathrm{g\,cm^{-1}\,s^{-1}}$ and $\rho = 1.06\,\mathrm{g\,cm^{-3}}$, respectively.

The hemodynamic simulations were performed with *SimVascular* (see [17]), an open-source comprehensive package specific for cardiovascular problems. The computational grid is unstructured and consists of tetrahedral elements, due to their adaptability to complex computational domains, like patient-specific geometries. The numerical code solves the three-dimensional incompressible Navier-Stokes equations by means of a stabilized finite element method, which makes it possible to choose linear shape functions for both velocity and pressure. For advancing in time, it uses the generalized α-method, which is an implicit technique that permits to achieve second order accuracy (see [18]).

The physical time step chosen for performing the numerical simulations was $0.001\,\mathrm{s}$ for both rigid and deformable cases, resulting in 800 time steps every cardiac cycle. After a grid sensitivity study, we chose a tetrahedral grid having approximately 2.2×10^5 for the geometry A and a tetrahedral grid with approximately 2.4×10^5 nodes for the geometry B.

Furthermore, each computation was run until the L_2 norms of the normalized differences between two successive pressure waveforms and between two successive flow rate waveforms were smaller than 10^{-5} (see [19]). These quantities were evaluated in correspondence of the descending aortic outlet section.

2.3 Quantities of interest and indicators

When considering the effects of the blood flow on the arterial wall, particular attention is given to the Wall Shear Stress (WSS), namely the modulus of the tangential stress $\boldsymbol{\tau}$ exerted by the flow on the arterial wall, i.e.

$$\mathrm{WSS}\left(\mathbf{x}, t\right) = \left|\boldsymbol{\tau}\left(\mathbf{x}, t\right)\right| \tag{3}$$

since it is thought to play an important role in the formation and growth of vascular diseases. Two additional parameters assume significant importance and are here used as hemodynamic descriptors: the Time-Averaged Wall Shear Stress (TAWSS), i.e. the wall shear stress throughout an entire cardiac cycle of period T, defined as:

$$\mathrm{TAWSS}\left(\mathbf{x}\right) = \frac{1}{T}\int_0^T \left|\boldsymbol{\tau}\left(\mathbf{x}, t\right)\right| \mathrm{d}t \tag{4}$$

and the Oscillatory Shear Index (OSI), which represents a measure of the deviation of the tangential stress from the predominant axial direction,

$$\mathrm{OSI}\left(\mathbf{x}\right) = \frac{1}{2}\left(1 - \frac{\left|\frac{1}{T}\int_0^T \boldsymbol{\tau}\left(\mathbf{x}, t\right) \mathrm{d}t\right|}{\frac{1}{T}\int_0^T \left|\boldsymbol{\tau}\left(\mathbf{x}, t\right)\right| \mathrm{d}t}\right) \tag{5}$$

This last indicator takes values in the range $[0, 0.5]$. Lower OSI values indicate that the tangential stresses at the wall are oriented predominately in the primary direction of the blood flow. On the other hand, high values indicate a very oscillatory behavior, 0.5 meaning that the instantaneous and the time-averaged vectors are never aligned.

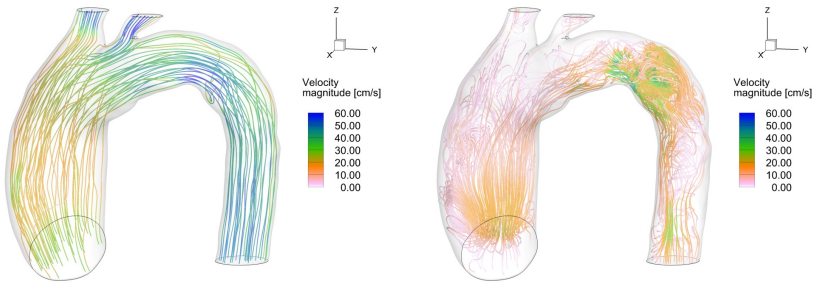
3 RESULTS OF THE REFERENCE DETERMINISTIC SIMULATIONS

This section presents the results obtained for the reference deterministic simulations. For the geometry A (Figure 1(a)) simulations were carried out both for rigid and deformable walls, while for the geometry B (Figure 1(b)) only rigid walls were considered.

3.1 Geometry A with rigid walls

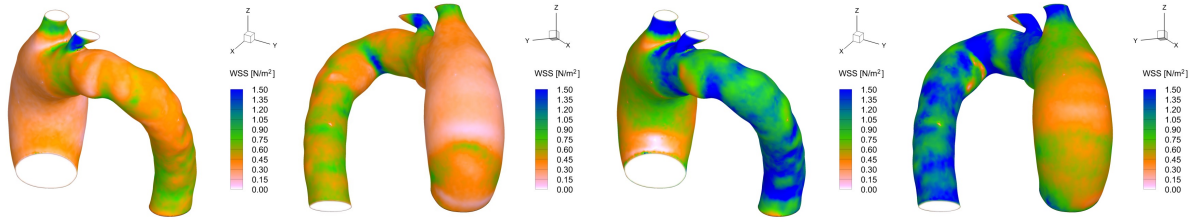
Figure 4 shows the instantaneous flow streamlines obtained in the simulation of the flow in the geometry A with rigid walls. The streamlines are colored according to the velocity magnitude. During systole they present a very regular behavior and the highest values of the velocity (Figure 4(a)), while recirculation areas occur in the diastolic phase (Figure 4(b)), which is characterized by reverse flow entering from the domain outlets.

In Figure 5 the WSS distributions at different time instants are shown. The four time instants marked in Figure 2 are considered. We selected the same WSS range in all the figures to highlight



(a) Peak systole (b) Early diastole

Figure 4: Instantaneous flow streamlines for the geometry A with rigid walls. The streamlines are colored according to the velocity magnitude.



(a) Max acceleration (front) (b) Max acceleration (back) (c) Peak systole (front) (d) Peak systole (back)

Figure 5: WSS distribution for the geometry A with rigid walls.

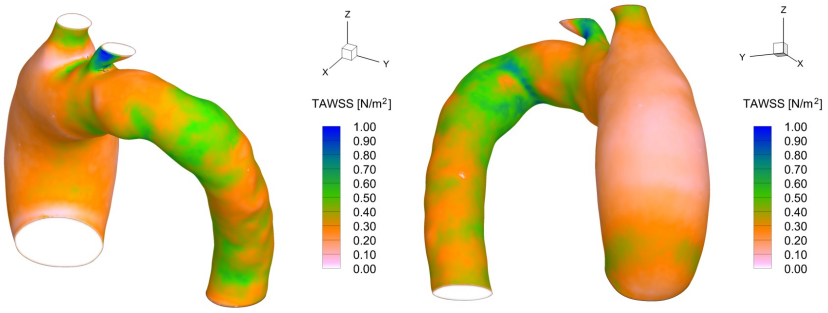
the different magnitude of the tangential stresses along a cardiac cycle. The highest values of the stresses are found at peak systole in correspondence of the two small branches The stresses on the ascending region of the aorta are rather low during the whole cardiac cycle, possibly due to the large size of the aneurysm.

TAWSS and OSI are presented in Figures 6 and 7. The TAWSS distribution gives information on the mean behavior of WSS during the cardiac cycle, and it summarizes what found in the instantaneous maps: the most stressed regions are the areas with high curvature, while the aneurysm region is characterized by low stress. Since these mean stresses during a cardiac cycle are much smaller if compared with the maximum ones occurring during peak systole, a smaller TAWSS range was chosen.

High values of OSI (i.e., close to its maximum limit of 0.5) are associated to recirculation areas, see Figure 4(b) for comparison. Note that they occur also inside the aneurysm.

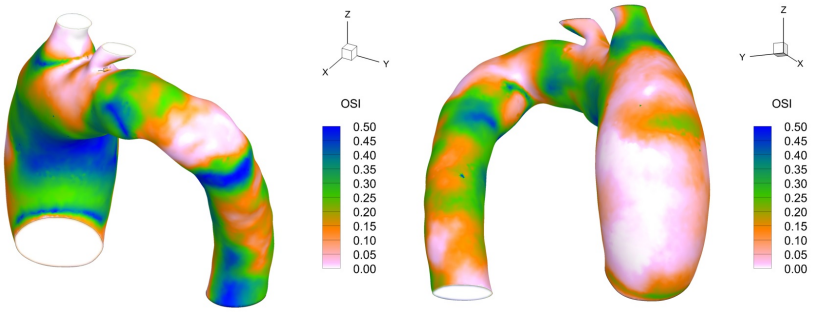
3.2 Effect of the wall compliance

In this section we evaluate the effect of the deformations of the arterial wall. The geometry A is considered.



(a) Front view (b) Back view

Figure 6: TAWSS distribution for the geometry A with rigid walls.

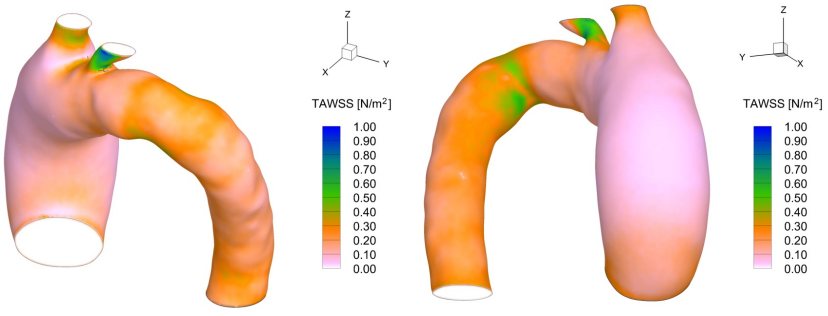


(a) Front view (b) Back view

Figure 7: OSI distribution for the geometry A with rigid walls.

The flow streamlines do not present significant differences if compared with the ones obtained with rigid walls, and thus they are not shown here. The only effect is a slight decrease of velocity magnitude, due to the widening of the vessel under the action of the blood flow.

The distributions of WSS and TAWSS are qualitatively very similar to the case of rigid walls, with only a variation in the quantitative values, which in the deformable case are lower (e.g., compare Figure 8 with Figure 6). This behavior could be expected given the possibility of the wall to move and relax.

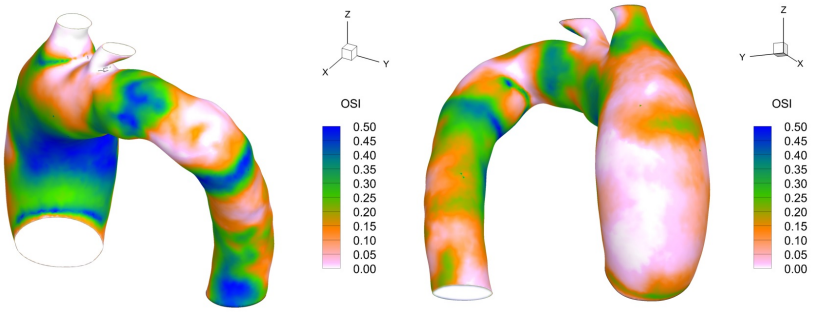


(a) Front view (b) Back view

Figure 8: TAWSS distribution for the geometry A with deformable walls.

The OSI distribution (Figure 9) does not present significant difference between deformable and rigid cases: this behavior is not surprising since this index is related to the velocity field,

which was found to be very similar in the two situations.



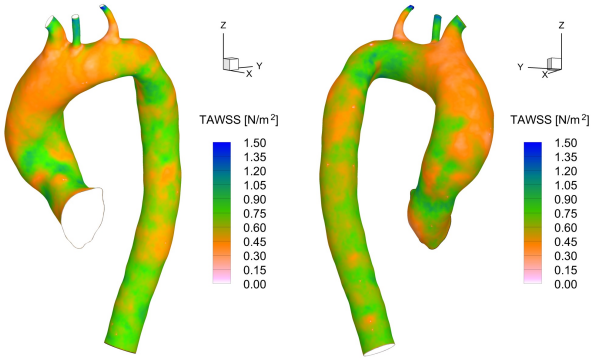
(a) Front view (b) Back view

Figure 9: OSI distribution for the geometry A with deformable walls.

3.3 Effect of the wall geometry

The effect of a different geometry and aneurysm size is evaluated by considering the geometry B (see Figure 1(b)). A simulation with rigid walls was performed with the same setup as for the geometry A.

Figure 10 shows the TAWSS distribution, and should be compared with Figure 6. The main effect of the geometry on TAWSS is the formation of areas of significant stress also in the ascending part of the aorta. This is due to the presence of a smaller aneurysm, and thus to the smaller size difference between the ascending and the descending regions.



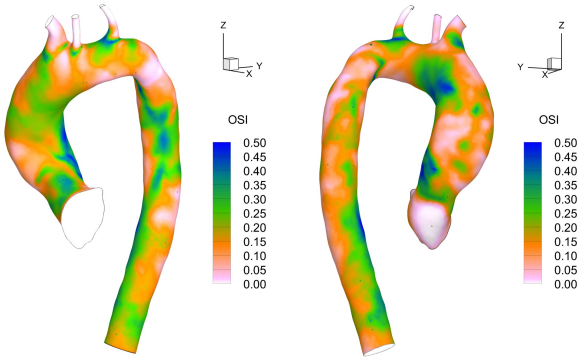
(a) Front view (b) Back view

Figure 10: TAWSS distribution for the geometry B with rigid walls.

High values of OSI can be found in the internal areas of both ascending and descending regions of the aorta, as shown in Figure 11, indicating thus that significant recirculation regions are present also inside the aneurysm.

4 UQ METHODOLOGY

The generalized Polynomial Chaos (gPC) approach, in its non-intrusive form, is an interpolant-type method, based on the projection of a given random process over an orthogonal known basis ([20]). The chaos expansion for a stochastic response output may be expressed as follows



(a) Front view (b) Back view

Figure 11: OSI distribution for the geometry B with rigid walls.

(term-based indexing):

$$X(\omega) = \sum_{k=0}^{\infty} a_k \Phi_k(\boldsymbol{\xi}(\omega)) \tag{6}$$

where $X(\omega)$ is the random process, $\boldsymbol{\xi}(\omega)$ is the vector consisting of the independent random variables in the event space Ω, corresponding thus to the set of considered uncertain parameters, $\Phi_k(\boldsymbol{\xi})$ is the gPC polynomial of index k and a_k is the corresponding Galerkin projection coefficient.

The response surface is obtained by a truncation of the spectral decomposition (Equation (6)) to a finite limit T. Applying polynomial order bounds for all one-dimensional polynomials (tensor-product expansion), T is obtained as follows:

$$T = \prod_{i=1}^{M} (P_i + 1) - 1 \tag{7}$$

where M is the dimension of the random parameter space and P_i is the polynomial order bound for the i^{th} dimension.

Thanks to the orthogonality of the polynomial basis, the coefficient a_k can be computed as follows:

$$a_k = \frac{\langle X, \Phi_k \rangle}{\langle \Phi_k, \Phi_k \rangle} = \frac{1}{\langle \Phi_k, \Phi_k \rangle} \int_{\omega \epsilon \Omega} X \Phi_k \rho(\boldsymbol{\xi}) \, \mathrm{d}\xi \tag{8}$$

where $\rho(\boldsymbol{\xi})$ is the weight function associated with the chosen polynomial family. The integrals can be computed through different mathematical methods: Gaussian quadrature was used in the present work. The polynomial family to be used must be a priori specified. When dealing with Gaussian quadrature, an optimal family has a weight function similar to the probability measure, $W(\boldsymbol{\xi})$, of the random variables; it depends, thus, on the Probability Density Function (PDF) shape of the uncertain parameters.

As previously explained, the uncertain parameters in the Windkessel model are the proximal resistance, R_p, the capacitance, C, and the distal resistance, R_d. Since a UQ analysis with three uncertain parameters and 3D unsteady simulations is extremely expensive, a preliminary stochastic analysis was carried out to evaluate the single effect of R_p, C and R_d on the output pressure cycle in the 0D Windkessel model, i.e. neglecting the contribution of the 3D geometry of the aorta. This allowed to single out the effect of each uncertain parameter and, thus, to

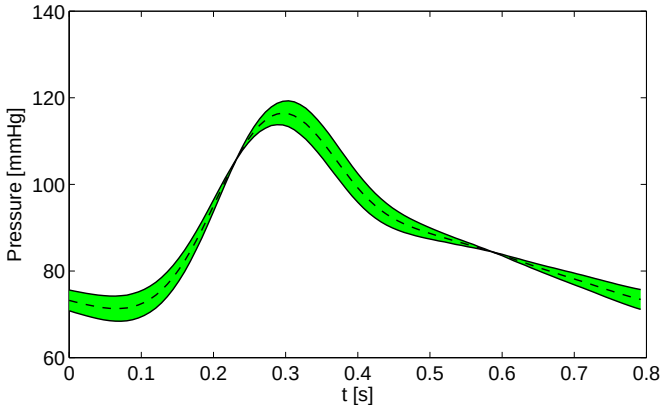


Figure 12: Effect of the variation of the capacitance C on the pressure waveform in correspondence of the descending aorta outlet section for the geometry A with rigid walls. The results are expressed in terms of stochastic mean (dashed line) $\pm$ stochastic standard deviation (continuous lines).

select the most important for the UQ analysis on 3D simulations, whose results are discussed in Sections 5 and 6.

After this 0D analysis, we selected R_p and C and allowed them to vary in the following ranges: $R_p \in [85.8, 148.4] \mathrm{g\,cm^{-4}\,s^{-1}}$ and $C \in [5.82 \times 10^{-4}, 12.6 \times 10^{-4}] \mathrm{cm^4\,s^2\,g^{-1}}$. First, we evaluated the effect of C alone: both rigid and deformable simulations were performed for the geometry A, while rigid walls were considered for the geometry B. Then, we investigated the combined effect of C and R_p: rigid simulations were performed for both the geometries.

The PDF of the input uncertain parameters is assumed to be uniform; this leads to the choice of Legendre polynomials for the gPC basis. The polynomial expansion is truncated to the third order for each dimension; hence, four quadrature points for each random variable are sufficient to compute the coefficients of the expansion. This leads to 4 or 16 hemodynamic simulations when considering one or two input parameters, respectively. These simulations were carried out for each quadrature point in the parameter space.

5 UQ ANALYSIS OF THE EFFECT OF UNCERTAINTIES IN THE VALUE OF C ON THE PRESSURE CYCLE AND ON THE FLOW FIELD

In this Section we evaluate how an uncertainty in the value of the capacitance C affects the quantities of interest reported in Section 2.3.

5.1 Geometry A with rigid walls

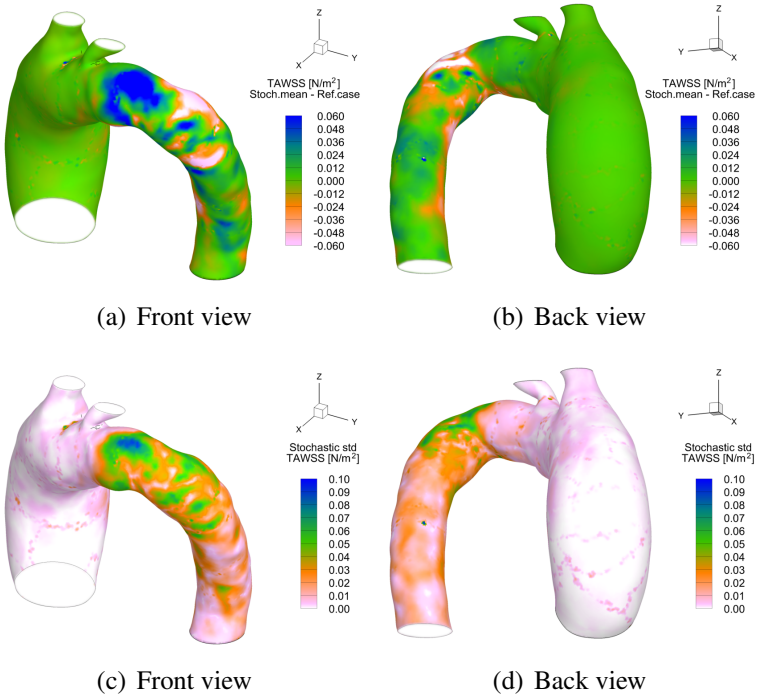
Figure 12 shows the output pressure waveform obtained in correspondence of the descending aorta outlet section. The results are presented in terms of the stochastic mean value $\pm$ the stochastic standard deviation. An increase of C leads to a reduction of the pulse pressure, as systolic and diastolic pressures become closer. On the other hand, the mean pressure P_{mean} is maintained practically constant.

The effect of the variation of C on TAWSS and OSI is evaluated in terms of the stochastic mean value and stochastic standard deviation, individually portrayed.

The stochastic mean distribution of TAWSS is almost equal to the reference deterministic result. The difference between the two TAWSS fields is shown in Figures 13(a) and 13(b) to allow a quantitative analysis. Differences are practically zero in most of the arterial lateral surface. Significant differences are found only in the upstream part of the descending aorta and

their absolute values are up to 10% of the corresponding stochastic mean values. In the same region we also find the largest stochastic variance of TAWSS (see Figures 13(c) and 13(d)). This means that this is the region in which TAWSS is most sensitive to the value of C.

Figures 14(a) and 14(b) report the difference between the stochastic mean distribution of OSI and the distribution obtained in the reference deterministic simulation. Again, differences are practically zero in the ascending aorta and in the two branches, independently of the value of OSI in those regions (note that in the reference deterministic simulation OSI assumes high values also in the internal part of the aneurysm, as shown in Figure 7(a)). On the other hand, significant positive and negative differences are found in localized regions of the aortic arch and of the descending aorta, where we also find the largest stochastic variance (see Figures 14(c) and 14(d)).



(a) Front view (b) Back view

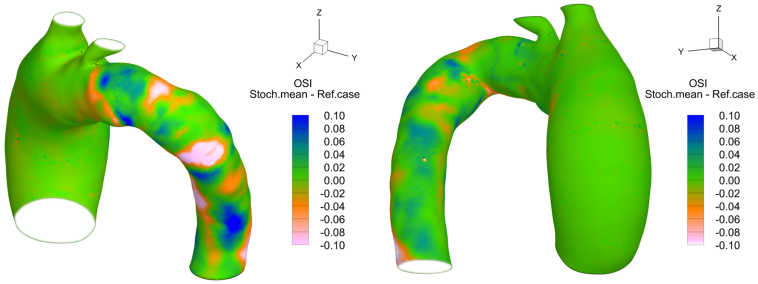
(c) Front view (d) Back view

Figure 13: Difference between the stochastic mean value and the reference deterministic value of TAWSS (a-b), and stochastic standard deviation of TAWSS (c-d) for the geometry A with rigid walls. Effect of uncertainties in the value of the capacitance C.

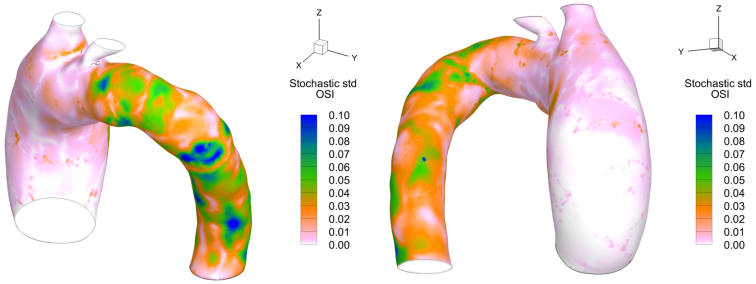
5.2 Effect of the wall compliance

In this Section we repeat the same UQ analysis as in Section 5.1 but considering the wall compliance. As before, the pressure waveform is evaluated in correspondence of the outlet section of the descending aorta, and the results are presented in terms of the stochastic mean value $\pm$ the stochastic standard deviation in Figure 15. The results obtained by considering the walls rigid are also reported in the same figure for comparison. It is clear that taking into account wall deformations leads to a smaller pulse pressure. This result could be expected, since the wall compliance acts as a further capacitance contribution and in both cases an increase of C reduces the difference between systolic and diastolic pressures, the mean pressure value being almost constant. The stochastic variance with C is also slightly reduced in the compliant case.

The indicators quantifying the stress levels on the arterial wall are again presented in terms of



(a) Front view (b) Back view



(c) Front view (d) Back view

Figure 14: Difference between the stochastic mean value and the reference deterministic value of OSI (a-b), and stochastic standard deviation of OSI (c-d) for the geometry A with rigid walls. Effect of uncertainties in the value of the capacitance C.

their stochastic mean value and of their stochastic standard deviation. As in the rigid case, for the sake of brevity we focus only on the cycle-averaged quantities.

Since the stochastic mean distribution of TAWSS is very close to the reference deterministic one, to allow a quantitative comparison in Figures 16(a) and 16(b) we present the difference between these two fields. As occurred in the rigid case, the differences are zero in most part of the aortic wall and are significant only in limited regions of the descending aorta. Their value never exceeds 10% of the corresponding stochastic mean. Figures 16(c) and 16(d) show the difference between the stochastic mean fields for deformable and rigid cases. This difference is uniform almost everywhere and negative in value, denoting that the arterial wall is subjected to smaller stresses when it has the possibility to expand and relax. However, the same qualitative behavior suggests that the flow topology does not significantly change.

The stochastic standard deviation of TAWSS is shown in Figures 16(e) and 16(f), while the difference between the deformable and the rigid cases is reported in Figures 16(g) and 16(h). The largest values of the stochastic standard deviation are found in the aortic arch and descending part (see Figures 16(e) and 16(f)) and they are smaller compared to the rigid case (see Figures 16(g) and 16(h)). As in the rigid case, the ascending region of the aorta presents no significant variability of the results.

Figures 17(a) and 17(b) show the difference between the stochastic mean distribution of OSI and the corresponding reference deterministic field. Again, most part of the aorta does not present significant differences. Differences can only be found in the distal aortic neck and in the descending region. However, they can reach about 30% of the corresponding stochastic mean value, thus being more important than the ones observed for TAWSS. Figures 17(c) and 17(d) highlight the difference between the OSI stochastic mean fields for deformable and rigid cases. Significant differences involve a larger portion of the aorta, mostly located at the aortic arch

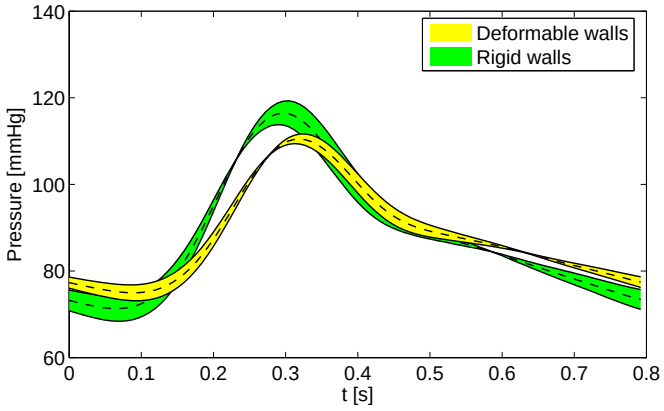


Figure 15: Effect of the variation of the capacitance C on the pressure waveform in correspondence of the descending aorta outlet section in the geometry A: comparison between deformable and rigid walls. The results are expressed in terms of stochastic mean (dashed line) $\pm$ stochastic standard deviation (continuous lines).

and descending part, but presenting some significant values also in the aneurysm region. This behavior can be related to the high sensitivity that OSI has to the flow field and to the locations of recirculation areas. A small variation in these locations can lead to a significant change in the OSI distribution. This can be deduced by analyzing the flow streamlines, here not shown for the sake of brevity.

Figures 17(e) and 17(f) show the stochastic standard deviation of OSI. Again, the descending aorta presents the largest variability, while the aneurysm region is characterized by small values of the stochastic variance. The comparison with the rigid case is evaluated in Figures 17(g) and 17(h), which illustrate the difference between the stochastic standard deviation of OSI for rigid and deformable walls. As observed for the stochastic mean distribution, the large differences in the descending aorta are possibly due to small changes in the flow field.

5.3 Effect of the wall geometry

In this Section we investigate the effect of the wall geometry by performing the UQ analysis on the geometry B with rigid walls. The output pressure waveform at the descending aorta outlet section is almost identical to the one obtained for geometry A with rigid walls (see Figure 12) and for sake of brevity is not shown.

The difference between the stochastic mean distribution of TAWSS and the corresponding reference deterministic distribution is presented in Figures 18(a) and 18(b). The effect of considering a smaller aneurysm is that the ascending and descending regions are closer in size. This produces a similar difference distribution in the whole aorta. These differences are not very high, except in some limited regions in which they reach 15% of the stochastic mean value at the same location.

Figures 18(c) and 18(d) show the stochastic standard deviation. Again, for the geometry B a significant variability is present also in the aneurysm region. The largest values of the stochastic standard deviation are about 25% of the corresponding stochastic mean value.

The difference between the stochastic mean value of OSI and the corresponding reference deterministic one is presented in Figures 19(a) and 19(b). Unlike what observed for the geometry A, differences affect not only the aortic arch and the descending aorta but also the aneurysm region. However, these differences may be again related to small changes in the flow field and small changes in location of recirculation areas.

Figures 19(c) and 19(d) illustrate the stochastic standard deviation obtained for OSI. High

variability is mostly found in the aneurysm region, where it can reach values about 35% of the stochastic mean value in the same location.

6 UQ ANALYSIS OF THE EFFECT OF UNCERTAINTIES IN THE VALUES OF R_p AND C ON THE PRESSURE CYCLE AND ON THE FLOW FIELD

The aim of this Section is to assess the effect of uncertainties in the proximal resistance R_p and in the capacitance C on the quantities of interest reported in Section 2.3.

6.1 Geometry A with rigid walls

Figure 20(a) shows the output pressure waveform at the descending aorta outlet section, again in terms of the stochastic mean value $\pm$ the stochastic standard deviation. The main difference compared to the case in which only the capacitance C was allowed to vary is an increased variability of the results, especially in the region near the maximum pressure value (see Figure 12 for comparison). Figure 20(b) confirms this indication, illustrating the partial sensitivities to the two uncertain parameters alone and combined. For most part of the cardiac cycle the capacitance C is the main responsible of the variability of the results. In these regions the uncertainty in the proximal resistance R_p does not produce significant effects on the pressure profile, which thus maintains substantially the behavior of Figure 12. R_p becomes predominant in a small portion of the cycle, near peak systole. This explains why an increased stochastic standard deviation can be

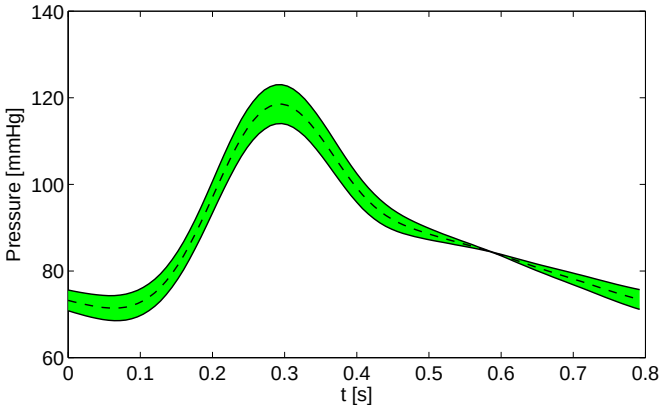
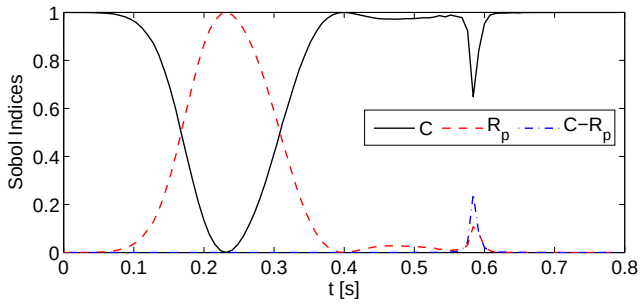
observed in the region near the maximum pressure value.

The effect of the second source of uncertainty (R_p) is evaluated considering the difference distributions between the stochastic outputs in the cases of two sources (C and R_p) and single source (C) of uncertainty. The averaged effect during a cardiac cycle of R_p on WSS is illustrated by the TAWSS distribution. Figures 21(a) and 21(b) show the difference distribution between the stochastic mean values of TAWSS in the two UQ analyses, while Figures 21(c) and 21(d) present the difference in the stochastic standard deviation. The effect of the second source of uncertainty on the stochastic mean value is very limited, with only small regions significantly affected. On the other side, its effect on the stochastic standard deviation is much more significant. The differences are mainly located in the region of the distal aortic neck and can reach 50% of the corresponding value obtained when considering only the variation of C.

Similar considerations apply also to OSI. The effect of considering R_p as an uncertain parameter has a limited effect on the stochastic mean value (see Figures 22(a) and 22(b)), while the stochastic standard deviation is in proportion much more affected (see Figures 22(c) and 22(d)). The difference respect to the case of single source of uncertainty is mainly located in the distal aortic neck. As found previously, this region presents again the highest sensitivity to the uncertain parameters.



(a)



(b)

Figure 20: Effect of the variation of the capacitance C and proximal resistance R_p on the pressure profile in correspondence of the descending aorta outlet section (geometry A with rigid walls). The results are expressed in terms of stochastic mean $\pm$ stochastic standard deviation (a) and partial sensitivities to the two parameters (b).

6.2 Effect of the wall geometry

In this Section we investigate the effect of the geometry of the aorta. A UQ analysis with two uncertain parameters (C and R_p) was thus performed on the geometry B with rigid walls. The output pressure waveform at the descending aorta outlet section is almost identical to the one obtained for the geometry A (Figure 20) and for the sake of brevity is not shown here. This behavior suggests that the two geometries have basically the same resistance contribution on the flow, thus producing very small changes in the output pressure. This confirms what found in Section 5.3 for the case of only one source of uncertainty.

To isolate the effect of R_p on TAWSS and OSI, we again present for each stochastic output the difference field between the distribution obtained with two sources of uncertainty (C and R_p) and that obtained with a single source of uncertainty (C).

Figure 23 quantifies these differences for the stochastic mean value and stochastic standard deviation of TAWSS. As found for the geometry A, the second source of uncertainty R_p has a small effect on both the stochastic mean distribution (see Figures 23(a) and 23(b)) and the stochastic standard deviation (see Figures 23(c)), even if the variation of the stochastic standard deviation is in percentage terms again more significant. The effect of the geometry B is that these difference distributions are more uniform in the whole aorta, due to the similar size of the ascending and descending regions.

Considerations similar to those made for TAWSS also apply to OSI. Both the stochastic mean value (Figures 24(a) and 24(b)) and the stochastic standard deviation (Figures 24(c) and 24(d)) are little affected by the introduction of the second uncertain parameter R_p. However, 0.5 is the

7 CONCLUDING REMARKS

The blood dynamics in two patient-specific ATAA geometries, characterized by different severity of the aneurysm pathology, was simulated. Deterministic simulations showed that the size of the aneurysm has a significant impact on the wall stress and flow feature, the smaller aneurysm being characterized by larger wall shear stresses and by a more recirculating flow. The wall compliance uniformly reduces the values of the shear stresses without changing their distribution, at least for the elastic, homogeneous, isotropic and constant thickness properties of the walls considered herein.

A stochastic sensitivity analysis to the uncertainties in the outflow boundary-condition parameters, namely the capacitance and the proximal resistance in the Winkdessel model, was also carried out. The mean stochastic values of TAWSS and OSI are very similar to those obtained in deterministic simulations carried out with values of the parameters guessed to obtain a desired physiological behavior of the pressure profile in a simplified fully lumped model. The stochastic variance of TAWSS and OSI was found to be very low inside the larger aneurysm, while more significant variations are present in localized regions of the aortic arch and of the descending aorta. For the geometry characterized by a smaller aneurysm, significant variability

is present also inside the aneurysm, indicating that the stress numerical predictions inside small aneurysms are more sensitive to the outflow boundary conditions. The effects of wall compliance on the stochastic mean value of TAWSS are the same as those observed in the deterministic simulations, i.e. a uniform reduction of TAWSS. The variability of TAWSS with the considered boundary-condition parameters is also reduced in the case with compliant walls.

Finally, considering the uncertainties in the capacitance only and in both the capacitance and the proximal resistance leads to very similar distributions of the stochastic mean values of TAWSS and OSI for both geometries. This means that the effect of the proximal resistance on the stochastic mean distributions is very limited. Conversely, its effect on the stochastic variability of TAWSS and OSI is more significant, again for both considered geometries.

The proposed methodology permits to quantify the propagation of the uncertainties in input data on the output quantities of interest in patient-specific ATAA configurations. In the present case, we focused on uncertainties in the outflow parameters, but the same methodology could be applied to different types of uncertainties, as e.g. uncertainties in the geometry due to imaging/reconstruction errors or in the mechanical properties of the vessel walls. Finally, if *in-vivo* measured hemodynamic quantities are available, calibration of different simulation parameters could be carried out using a stochastic approach, providing thus a platform integrating CFD simulations and *in-vivo* measurements.

Keywords: Metamodel, Optimization, Multifidelity, Radial Basis Function

Abstract. *The numerical optimization of a photoacoustic gas sensor is a challenging problem in terms of computational time. The signal detected by the gas sensor is a non-linear function depending on several geometrical parameters. The optimization requires a very large number of function calls, thus an important simulation time. In the case of photoacoustics, two different numerical models with different fidelity levels are available to simulate the behavior of the component. In order to reduce the computational burden of optimizing the gas sensor, a new multifidelity metamodeling framework, based on Radial Basis Function, is proposed. The present method offers an alternative to co-kriging (a widely used multifidelity metamodel). This multifidelity model is then used in an optimization sequence to enrich a training database, via a strategy inspired by Gutmann [1]. The process is applied to the optimization of geometrical parameters in the gas sensor problem.*

1 INTRODUCTION

Numerical simulation is widely employed in engineering to study the behavior of future devices and optimize their design. Nevertheless, each computation is often time consuming and, during an optimization sequence, the simulation code is evaluated a large number of times. An interesting way to reduce the computational burden is to resort to a metamodel (or surrogate model) of the simulation code. The process of metamodeling successively implies creating a design of experiment (DOE), evaluating the numerical model response of the DOE and then training the metamodel on the dataset previously obtained. Once the metamodel is built, it can predict the response of the numerical model for a new evaluation point at an extremely reduced time. Thus it can be used in a costly procedure in terms of number of evaluations such as sensibility analysis or optimization. The prediction accuracy depends on the number of points in the dataset and the complexity of the function to replace. Sometimes, models having different levels of fidelity are available and can be hierarchically ranked in accuracy. In this case, multifidelity surrogate modeling aims at efficiently combining information from the different levels of approximation in order to build a metamodel at a reduced cost.

Here the focus is set on the design of a photoacoustic gas sensor. Two different simulation codes are used to describe the performance of the component. The linearized Navier-Stokes equations constitute the high fidelity model and the coarse model consists in the decomposition of the pressure field onto the acoustic modes basis, obtained by solving the homogeneous Helmholtz equation. The computational time for the high fidelity model exceeds one hour on a twenty-core cluster node cadenced at 3 GHz. For the coarse model, the computational time is reported on the same node at 3 minutes. There is a potential time saving in using as much as possible information obtained from the coarse model and still keep good prediction accuracy by also using the expensive model.

Among metamodeling approaches, kriging models [2, 3, 4] are well known in the metamodeling community. This method is attractive because of its capability to estimate a confidence interval of the predicted function. It has recently been revised in order to allow the use of both coarse and complex versions of the computer simulation. This multifidelity approach enhances the prediction accuracy at a reduced computational cost [5]. Then several studies dealing with co-kriging (multifidelity version of kriging) and its use in optimization have been exposed [6, 7, 8]. Radial Basis Functions (RBF) based interpolation method is another existing choice as surrogate model. The new method offers an alternative to co-kriging that might be superior in high dimensional optimization problem, as stated by Regis and Shoemaker on single fidelity problems [9]. To the best of our knowledge, no version of multifidelity RBF-based method has been published at the moment.

The present work offers a new possible way to solve the optimization problem of the photoacoustic gas sensor design via RBF multifidelity metamodeling method (co-RBF). Since some optimization algorithms are already developed for RBF-based optimization [9, 1], they could be extended to a multifidelity version. Here only the so-called Gutmann-RBF method improved by Regis and Shoemaker [9] is used for the multifidelity metamodel based optimization of the gas sensor.

The optimization problem of the photoacoustic gas sensor is described in section 2 and the methodology of the co-RBF metamodeling method is detailed in section 3. The extension of RBF-based optimization algorithm to co-RBF is presented in section 4, together with the result of the gas sensor optimization.

2 MINIATURIZED PHOTOACOUSTIC GAS SENSOR DESIGN

2.1 Physical principle and numerical models

Photoacoustic (PA) spectroscopy is employed to detect gas traces with a high sensitivity, often below the part per billion by volume (ppbv) level. The principle of PA spectroscopy relies on the excitation of a molecule of interest by a light source emitting at the wavelength of an absorption line of the molecule. The light source, usually a laser in the mid-infrared range, is modulated at the acoustic frequency of a resonant cell, containing the gas mixture. During the molecules relaxation, the kinetic energy exchange with the surrounding gas creates local temperature modulation, and thus acoustic waves in the chamber [10].
The cell used in this work is of the differential Helmholtz resonator (DHR) [11] type. It is composed of two chambers linked by two capillaries (Figure 1). The gas excitation is ensured by illuminating one chamber with a laser source. At the Helmholtz resonance of the cavity, acoustic signals in the two chambers are in phase opposition. The signals provided by two microphones measuring the pressure into each chamber are subtracted to provide the PA signal. As the PA signal is inversely proportional to the volume of the resonant cell [10], a trend towards the size reduction of PA cells has been initiated during the last decade [12], [13]. Assuming

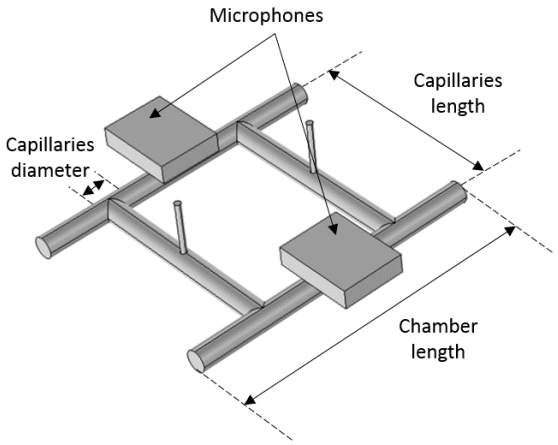

Figure 1: Geometry of a DHR cell.

no viscous and thermal losses and a harmonic heat source, the non-homogeneous Helmholtz equation can be used to compute the pressure field in the cell, and thus the differential PA signal:

$$\nabla^2 p + k^2 p = i\omega \frac{\gamma - 1}{c^2} \mathcal{H} \tag{1}$$

where ω is the modulation frequency, c the speed of sound, γ the Laplace coefficient of the gas, $k = \omega/c$ the wave number and $\mathcal{H}$ the Fourier transform of the power density of the heat source. This pressure acoustic model is computationally efficient and accurate at the macro-scale but fails at the micro-scale. In fact, various volume and surface dissipation processes, at work in the bulk of the propagation medium and close to the walls, cannot be neglected in miniaturized devices, where boundary layers occupy a non-negligible part of the overall cell volume. Numerous approximate models have been adapted from the pressure acoustic model to take into account the dissipation effects. For instance Kreuzer [14], rely on eigenmode expansion of the pressure field and a correction by quality factors. The latter model is fast and faithful enough to

constitute the coarse approximation used in our multifidelity approach.
The rigorous, but CPU time and memory consuming, model relies on the full linearized Navier-Stokes formulation (FLNS), that fully accounts for viscous and thermal dissipation effects. In that approach, small harmonic variations are assumed. The PDE equations system (2) is composed of the continuity equation, incorporating the ideal gas equation of state $p = \rho R_M T$, and the momentum and energy conservation laws:

$$\begin{aligned} i\omega\left(\frac{\tilde{p}}{p_0} - \frac{\tilde{T}}{T_0}\right) + \nabla\cdot\tilde{\mathbf{u}} &= 0 \\ i\omega\rho_0\tilde{\mathbf{u}} = -\nabla\tilde{p} + \nabla\cdot\left(\mu\left(\nabla\tilde{\mathbf{u}} + \nabla\tilde{\mathbf{u}}^T\right) + (\lambda - 2\mu/3)\left(\nabla\cdot\tilde{\mathbf{u}}\right)\mathbf{I}\right) \\ i\omega\rho_0 C_p\tilde{T} = -\nabla\cdot\left(-\kappa\nabla\tilde{T}\right) + i\omega\tilde{p} + Q \end{aligned} \tag{2}$$

where $\tilde{p}$, $\tilde{T}$ and $\tilde{\mathbf{u}}$ are respectively the pressure, temperature and velocity fields of the gas; p_0, T_0 and ρ_0 are the mean values of the pressure, temperature and density fields; λ and μ are the bulk viscosity and the shear viscosity. Q is the heat source.

2.2 Optimization problem

In the framework of the PA sensor case, the FLNS model represents the expensive code and the Kreuzer model the coarse version. The computational time for the FLNS model is actually around one hour and ten minutes on a twenty-core cluster node cadenced at 3 GHz. For the Kreuzer model, the computational time is reported on the same node at 3 minutes. Both models are solved using the commercial software COMSOL (COMSOL AB, Sweden), based on the finite element method.
The PA cell has a chamber diameter of 1 mm and three parameters are involved: chamber length, radius and length of capillaries. Parameters ranges are available in Table 1. The photoacoustic signal detected is the objective to maximize by varying the three geometrical parameters. The new metamodel developed to reduce the computational cost of model evaluations is described in the next section.

Input	Range (mm)
chamber length	[10,20]
capillaries radius	[0.3,0.5]
capillaries length	[5,20]

Table 1: Parameters and ranges of photoacoustic models.

3 MULTIFIDELITY RADIAL BASIS FUNCTION

The basics of RBF-based metamodelling [15, 16, 17, 18] are first briefly explained to introduce the derivation of the co-RBF method. The efficiency of the co-RBF method is not assessed here since it is out of the scope of this paper.

3.1 RBF interpolation model

Given a set of n distinct points $\mathcal{X} = \{\mathbf{x_1}, \ldots, \mathbf{x_n}\}(\mathbf{x_i} \in \mathbb{R}^\mathbf{d}, \mathbf{i} = \mathbf{1}, \ldots, \mathbf{n})$ where the corresponding function values $z_1, \ldots, z_n$ are known, the RBF approximation is defined as a linear combination of the radial basis function φ :

$$\hat{Y}(\mathbf{x}) = \sum_{i=1}^{n} \beta_i \varphi\left(\|\mathbf{x} - \mathbf{x}_i\|\right) + R(\mathbf{x}) \tag{3}$$

Where $\|\cdot\|$ denotes the Euclidean norm in $\mathbb{R}^d$, the coefficients β_i are real numbers and R belongs to the linear space of polynomials in d variables. The radial basis functions used in this paper and the corresponding polynomial forms are given in Table 2. Gaussian RBF gives more freedom to improve the generalization of Equation (3) at the expense of a more complex parameter estimation process. A procedure based on the minimization of the predict error is a possible way to estimate the Gaussian parameter. For a more complete list of available RBF, the reader is referred to Gutmann [1].

RBF	$\varphi(r),\ r>0$	$R(\mathbf{x})$
Cubic	r^3	$\mathbf{a}^T\mathbf{x}+b$
Gaussian	$\exp\left(-\sum_{i=1}^{d}\gamma_i {r_i}^2\right),\ \gamma_i>0$	0

Table 2: Different choices of radial basis functions.

Once a particular φ is selected, the interpolation condition rights:

$$\begin{gathered}\begin{pmatrix}\boldsymbol{\phi} & \mathbf{F}\\ \mathbf{F}^T & 0\end{pmatrix}\begin{pmatrix}\boldsymbol{\beta}\\ \mathbf{a}\\ b\end{pmatrix}=\begin{pmatrix}\mathbf{z}\\ 0\end{pmatrix}\\ \boldsymbol{\phi}_{ij}=\varphi\left(\|\mathbf{x}_i-\mathbf{x}_j\|\right),\ i=1,\dots,n\,,\ j=1,\dots,n\\ \mathbf{F}=\begin{pmatrix}\mathbf{x}_1^T & 1\\ \mathbf{x}_2^T & 1\\ \vdots & \vdots\\ \mathbf{x}_n^T & 1\end{pmatrix}\end{gathered}\tag{4}$$

In the Gaussian RBF case, the system is reduced to $\boldsymbol{\phi}\times\boldsymbol{\beta}=\mathbf{z}$. It can be shown that the system is invertible if and only if the data points are distinct. It is noteworthy that the inversion of this matrix is the most time demanding part of the training of the surrogate model and that, if points in $\mathcal{X}$ are close to each other, the matrix is ill-conditioned. An example of Gaussian and Cubic RBF for the approximation of the modified Branin function [19] is represented on Figure 2, where red dots are the training points and contour lines are the RBF-based metamodel. The training set is constructed with the Latin Hypercube Sampling method [20]. The third plot is the contour of the real Branin function. The Gaussian RBF emulates the Branin function better than the Cubic one because of the parameter $\boldsymbol{\gamma}$ that scales each inputs based on their impact on the output variance.

3.2 Co-RBF

In this work, a multifidelity version of RBF-based metamodel has been developed to solve the photoacoustic gas sensor optimization problem at a reduced computational time. It is now assumed that different levels of modeling in terms of accuracy are available for our physical problem. In the general context, it is possible to link multiple sets of data with different levels of fidelity, but, for sake of readability, the method description is limited here to two datasets. The more accurate set, which is also the more demanding in terms of computational time, is represented by training points $\mathcal{X}_e$ and their corresponding outputs $\mathbf{z}_e$. The coarse simulation model is represented by $\mathcal{X}_c$ and $\mathbf{z}_c$. These training sets can be obtained using the maximin optimized Nested Latin Hypercube designs [21] in order to improve prediction accuracy by better filling the whole input space.

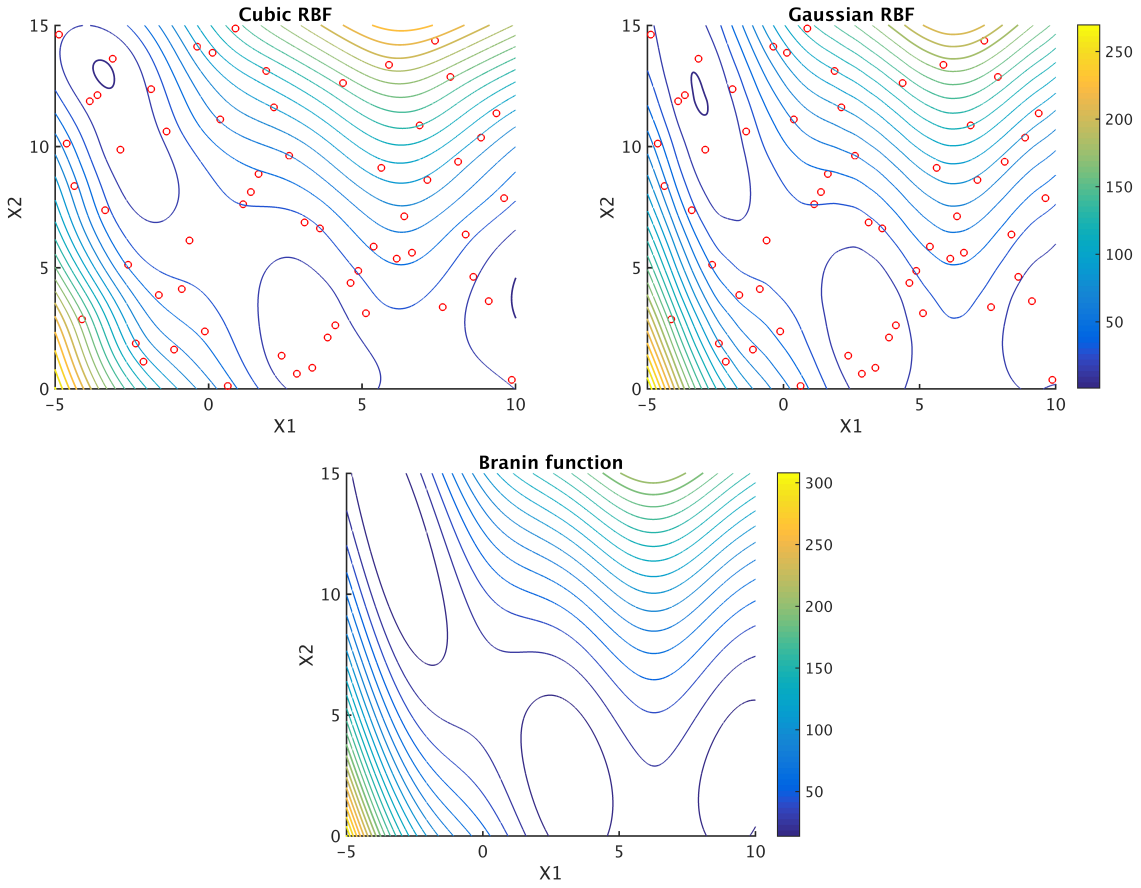

Figure 2: Cubic and Gaussian RBF-based metamodel of the modified Branin function.

The multifidelity approximation is built using the auto-regressive model of Kennedy and O'Hagan [5]:

$$\hat{y}_e(\mathbf{x}) = \rho \hat{y}_c(\mathbf{x}) + \hat{y}_d(\mathbf{x}) \tag{5}$$

where ρ is a scaling factor, y_c the RBF interpolant of the coarse model and y_d the RBF interpolant of the difference between the expensive process and the scaled coarse process. This formulation allows different levels of fidelity to have different correlation structures. The RBF parameters for the coarse and the difference model are not necessarily the same and are estimated separately. To build this multifidelity model, the coarse process is considered independently of the expensive one. Its parameters are estimated within the classical RBF framework described in section 3.1. Once $\begin{pmatrix} \boldsymbol{\beta}_c & \mathbf{a}_c & b_c \end{pmatrix}^T$ obtained, the RBF parameters of the difference function have to be estimated. The assumption is made that, given the point $\mathbf{x}_{c_i}$, no more information can be learnt about $\mathbf{z}_{e_i}$ from the coarse process. This Markov-like property implies that only $y_c(\mathbf{x}_e)$ is considered during the estimation of the difference model parameters. If the dataset $\mathcal{X}_e$ is not evaluated on the coarse model, his corresponding output is predicted by the previously built coarse model RBF. Then the following linear system has to be solved:

$$\begin{pmatrix} \boldsymbol{\phi}_d & \mathbf{F}_e \\ \mathbf{F}_e{}^T & 0 \end{pmatrix} \begin{pmatrix} \boldsymbol{\beta}_d \\ \mathbf{a}_d \\ b_d \end{pmatrix} = \begin{pmatrix} \mathbf{z}_e - \rho y_c(\mathbf{x}_e) \\ 0 \end{pmatrix} \tag{6}$$

The linear system, Equation 6, depends on the unknown scaling factor ρ. Rippa [22] derived a leave-one-out (LOO) formula that estimates the RBF model prediction error. This formula

was initially developed for calibrating the parameter of the Gaussian RBF by minimizing the LOO error. Here this method is used by adding the scaling factor ρ as a parameter to optimize. The LOO formula is given in Equation (7) and its optimization was solved using the covariance matrix adaptation evolution strategy (CMA-ES) [23]. In the Cubic RBF case, the LOO error depends only on the scaling factor:

$$LOO\left(\gamma,\rho\right)=\sum_{i=1}^{n}\left(\frac{\beta_{di}(\gamma)}{\phi_{d_{ii}}^{-1}(\rho)}\right)^{2} \tag{7}$$

An example of the evolution of the LOO depending on γ_d and ρ is available on Figure 3 left, in a test case defined by Forrester et al. [6]. The global minimum of the map is located at $\gamma_d = 1$ and $\rho = 1.74$. This map is obtained from a one-dimensional example displayed on the right plot. Four expensive points and eleven coarse points are evaluated to build the Gaussian co-RBF. The resulting interpolant is the red dashed line and it is close the real model (black solid line).

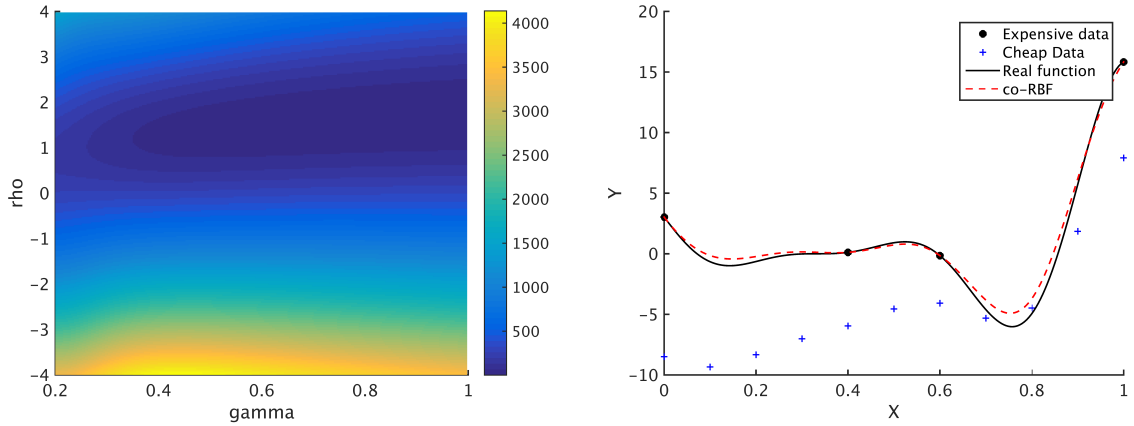

Figure 3: LOO cross-validation error on a one-dimensional example of co-RBF metamodeling.

4 OPTIMIZATION

4.1 Method

An optimization strategy has first been developed by Gutmann [1] in a single fidelity RBF metamodeling approach. It has then been improved by Regis and Shoemaker [9] and referred to as Controlled Gutmann RBF (CG-RBF). This method is an iterative algorithm similar to the Efficient Global Optimization (EGO) procedure derived by Jones [24] for kriging. A design of experiments of the function to optimize is first evaluated and interpolated by a RBF. At each optimization iteration, the RBF interpolant is updated with new evaluated points until the optimum is found. A criterion is defined to select the next infill points based on a measure of the bumpiness of the RBF interpolant [1]. A target value of the global minimum of the function to optimize is cyclically selected to orient the infill criterion toward global exploration or local refinement of the RBF. As a stopping criterion, the maximum number of evaluations is specified by the user.

Some assumptions are needed to transfer the CG-RBF method to the multifidelity framework. First we consider that only the expensive function is called to refine the prediction accuracy in

the vicinity of the global minimum. The evaluation time of the coarse model is considered to be so low that it can be evaluated a large number of time. The prediction accuracy on the coarse model is thus good enough and there is no need to add supplementary training points. Second, since the difference model is built using the expensive points, the infill criterion of the CG-RBF method is computed using the RBF function φ_d. As a result:

$$h_n(l) = \frac{(-1)^{m_\varphi+1}}{[\hat{y}_e(l) - f_n^*]} \times \left[\varphi_d(0) - \begin{pmatrix} u_n^T & F_l^T \end{pmatrix} \begin{pmatrix} \boldsymbol{\phi}_d & F_d \\ F_d{}^T & 0 \end{pmatrix}^{-1} \begin{pmatrix} u_n \\ F_l \end{pmatrix} \right] \tag{8}$$

where $u_n(l) := (\varphi(\|l - x_1\|), \ldots, \varphi(\|l - x_n\|))^T$, $F_l = \begin{bmatrix} l^T & 1 \end{bmatrix}$ and f_n^* corresponds to the targeted minimum value. The optimization of $\min_l - \log h_n(l)$ gives the next infill point.

4.2 Results of the optimization of the photoacoustic gas sensor

The photoacoustic signal detected is the objective to evaluate from simulation models, to surrogate with co-RBF and then to optimize with the CG-RBF-based procedure. The DOE of each model are first defined. For the coarse Kreuzer model, 100 points are evaluated and the RBF built on these data is assumed to be accurate enough. Then 5 points of the expensive FLNS model are evaluated. This allows the training of the co-RBF model in the Gutmann-RBF algorithm extension to multifidelity framework. Our stopping criterion is different from that described by Gutmann [1]. Here it is defined at the end of the target value cycle: once a cycle is over, the optimization stops if a better minimum value has not been evaluated compared to the previous cycle. Five different DOE are tested to check if the optimization leads to the same optimum. The number of evaluations needed to get the minimum location can also be assessed. The obtained results are summarized in Table 3. Two different areas are targeted at the end of the optimization algorithm. Parameters values are close to the upper bounds of the input space. This bound has been set up to fill some integration requirements of the gas sensor in a more complex system. It is either the capillaries length or the capillaries radius that is reduced to get an optimum value around 1.90 Pa. Both solutions provide an improved photoacoustic signal. Note that fabrication uncertainties have not been included yet in the design process but robustness could be a way to select one among the two solutions.

DOE	Optimum location	Optimum value	Number of function calls
1	[20 , 0.5 , 17.7]	1.90	18
2	[20 , 0.5 , 17.7]	1.90	24
3	[20 , 0.47 , 20]	1.90	18
4	[20 , 0.5 , 20]	1.88	12
5	[20 , 0.45 , 20]	1.91	24

Table 3: Results over five initial DOE of the optimization of the photoacoustic gas sensor.

The number of cycles needed to optimize the process is between 2 and 4. Each cycle has a cost of 6 calls to the expensive model. In a previous work, we used only the expensive model with the EGO procedure to get an optimal geometry. The algorithm converged after 40 function calls to a solution with an optimum value of 1.84 Pa and [20 , 0.36 , 19.6] as the optimum location. The benefit of the multifidelity approach developed in this work is clear, in terms of computational time and accuracy of the optimum obtained, when compared to this previous study.

5 CONCLUSIONS

A new multifidelity RBF-based metamodel has been proposed in this work. It is derived through the autoregressive model of Kennedy and O'Hagan [5] and combines the information from the coarse and the expensive numerical model of our design problem. An extension of the CG-RBF optimization algorithm is also suggested in the framework of the co-RBF. This allows the use of a complete multifidelity-based optimization procedure that is an alternative to the co-kriging method combined with EGO.
An optimal design of the photoacoustic gas sensor has been defined by to the new procedure. The extension of the CG-RBF optimization algorithm brings a way to refine the prediction accuracy toward the global optimum of our problem. The results obtained are superior than those obtained with a single fidelity approach in terms of accuracy and computational time.
This work in progress is a first step towards the creation of an efficient co-RBF based optimization algorithm. It has to be supplemented by a complete benchmark between this new procedure and the already existing co-kriging-based optimization method. Furthermore, other extension of already existing RBF-based optimization algorithms, such as the Constrained Optimization using Response Surfaces (CORS) algorithm [9] can be explored. The application of this method to the design of nanophotonic component is also considered.

Keywords: probabilistic analysis, strip footing, bearing capacity, spatial variability, kriging, Monte Carlo simulation, probability of failure.

Abstract. *The probabilistic analysis of geotechnical structures presenting spatial variability in the soil properties is generally performed using Monte Carlo simulation (MCS) methodology. This methodology is not suitable for the computation of a small failure probability because it becomes very time-expensive in such a case due to the large number of simulations required to calculate the failure probability. For this reason, one needs to keep to a minimum the number of calls to the deterministic model when performing the probabilistic analyses. In order to overcome the shortcoming related to the excessive number of calls of the deterministic model when performing Monte Carlo simulations, Echard et al. (2011) proposed an Active learning reliability method (called AK-MCS) combining Kriging and Monte Carlo Simulation. The method was shown to be very efficient as the obtained probability of failure is very accurate needing only a small number of calls to the deterministic model. The probabilistic analyses presented in this paper were performed using AK-MCS methodology by Echard et al. (2011). The present study involves a probabilistic analysis at the ultimate limit state of a strip footing resting on a spatially varying soil using AK-MCS approach. The objective is the computation of the probability P_f of exceeding the ultimate bearing capacity of the footing under a prescribed footing load. The soil cohesion and angle of internal friction were considered as two non-isotropic non-Gaussian random fields. The deterministic model was based on numerical simulations using the finite difference code FLAC^{3D}. Some probabilistic results are presented and discussed.*

1 INTRODUCTION

The spatial variability of the soil properties affects the behavior of geotechnical structures (bearing capacity, foundation settlement, slope stability, etc.). Several authors have considered the effect of the spatial variability of the soil properties in their calculation models. For the bearing capacity of foundations which is the subject of the present paper, one may cite among others [1, 2].

It should be mentioned that when dealing with probabilistic studies that involve spatially varying soil properties, the classical Monte Carlo Simulation (MCS) methodology is generally used to determine the probability of failure P_f. This method is known to be very time-consuming. This is because (i) it generally makes use of finite element or finite difference models which are generally time-expensive and (ii) it requires a great number of calls of the deterministic model for the computation of the small failure probabilities encountered in practice. Thus, one needs to keep to a minimum the number of calls to the deterministic model when performing the probabilistic analyses.

In order to overcome the shortcoming related to the excessive number of calls of the deterministic model when performing Monte Carlo simulations, Echard et al. [3] proposed an active learning reliability method (called AK-MCS) combining Kriging and Monte Carlo Simulation. The method was shown to be very efficient as the obtained probability of failure is very accurate needing only a small number of calls to the deterministic model. The probabilistic analyses presented in this paper were performed using AK-MCS methodology by [3]. They involve the probabilistic analysis at the ultimate limit state of a strip footing resting on a spatially varying soil using AK-MCS approach. The objective is the computation of the probability P_f of exceeding the ultimate bearing capacity of the footing under a prescribed footing load. The soil cohesion and angle of internal friction were considered as two non-isotropic non-Gaussian random fields. They are characterized by two specified marginal distribution functions and a common autocorrelation function. The methodology proposed by [4] is used to generate these two random fields. The deterministic model is based on numerical simulations using FLAC^{3D} software. Some probabilistic results are presented and discussed.

The paper is organized as follows: The next section aims at presenting the probabilistic method used for the computation of the failure probability of a strip footing resting on a spatially varying soil. It is followed by some numerical results. The paper ends with a conclusion.

2 PROBABILISTIC MODELS

The aim of this section is to present the probabilistic model used in the present paper. The impact of the soil spatial variability on the ultimate bearing capacity was considered. It should be remembered here that the system response involves the ultimate bearing capacity (P_u) of a strip footing resting on a spatially varying soil. The soil cohesion c and friction angle φ were modeled as two non-isotropic non-Gaussian random fields. The EOLE methodology [4] was used to discretize the two random fields (i.e. to obtain realizations of the soil cohesion c and friction angle φ that respect the correlation structure of those fields). The performance function used to calculate the probability P_f of exceeding the ultimate bearing capacity was defined as follow:

$$G = \frac{P_u}{P_s} - 1 \tag{1}$$

Where P_s is the prescribed footing load. As for the probabilistic method used in this paper, the active learning reliability method combining kriging and Monte Carlo Simulation (called AK-MCS) was employed. This method combines both the classical crude Monte Carlo Simulation (MCS) methodology and the Kriging meta-model technique.

In this section, the EOLE method of discretization of random fields was firstly presented. It is followed by a brief presentation of the crude Monte Carlo method, the kriging metamodeling technique and the combined use of the kriging and the Monte Carlo Simulation (i.e. AK-MCS methodology) used for the probabilistic analysis.

2.1 Method of generation of anisotropic non-Gaussian random fields

Let us consider two anisotropic non-Gaussian random fields $Z_i^{NG}(x, y)(i = c, \varphi)$ described by: (i) constant means and standard deviations (μ_i, σ_i; $i = c, \varphi$), (ii) non-Gaussian marginal cumulative distribution functions G_i ($i = c, \varphi$), and (iii) a common square exponential autocorrelation function ρ_Z^{LN}[(x, y), (x', y')] which gives the values of the correlation between two arbitrary points (x, y) and (x', y'). This autocorrelation function is given as follows:

$$\rho_z^{LN}[(x, y), (x', y')] = \exp\left(-\left(\frac{|x - x'|}{a_x} \right)^2 - \left(\frac{|y - y'|}{a_y} \right)^2 \right) \tag{2}$$

where a_x and a_y are the autocorrelation distances along x and y respectively. The Expansion Optimal Linear Estimation method (EOLE) and its extension to cover the case of non-Gaussian random fields are used herein to generate the two random fields of c and φ. Notice that EOLE was first proposed by [4] for the case of uncorrelated Gaussian fields, and then extended by [5] to cover the case of correlated and uncorrelated non-Gaussian fields. In this method, one should first define a stochastic grid composed of q grid points (or nodes) $\{(x_1, y_1), ..., (x_q, y_q)\}$ for which the values of the field are assembled in a vector $\chi = \{Z(x_1, y_1), ..., Z(x_q, y_q)\}$. The number of grid points within the stochastic mesh is determined in such a manner that in each direction (x or y), there are five grid points within each autocorraltion distance. Secondly, one should determine the correlation matrix for which each element $\left(\Sigma_{\chi;\chi}\right)_{i,j}^{NG}$ is calculated as follows:

$$\left(\Sigma_{\chi;\chi}\right)_{i,j}^{NG} = \rho_z^{NG}\left[(x_i, y_i), (x_j, y_j)\right] \tag{3}$$

The common non-Gaussian autocorrelation matrix $\Sigma_{\chi;\chi}^{NG}$ should be transformed into the Gaussian space using Nataf model [6] since the discretization of the random fields using EOLE is done in the Gaussian space. As a result, one obtains two Gaussian autocorrelation matrices $\Sigma_{\chi;\chi}^{c}$ and $\Sigma_{\chi;\chi}^{\varphi}$ that can be used to discretize the two random fields as follows:

$$\tilde{Z}_i(x, y) = \mu_i + \sigma_i \sum_{j=1}^{N} \frac{\xi_{i,j}}{\sqrt{\lambda_j^i}} . \phi_j^i . \Sigma_{Z(x,y);\chi}^i \qquad i = c, \varphi \tag{4}$$

where $(\xi_{i,j}; i = c, \varphi)$ are two non-correlated blocks of independent standard normal random variables. Notice finally that $(\lambda_j^i, \phi_j^i; i = c, \varphi)$ in equation (4) are the eigenvalues and eigenvectors of the two Gaussian autocorrelation matrices $\Sigma_{\chi;\chi}^{c}$ and $\Sigma_{\chi;\chi}^{\varphi}$ respectively, and $\Sigma_{Z(x,y);\chi}$ is the correlation vector between the random vector χ and the value of the field at an

arbitrary point (x, y). Once the two Gaussian random fields are obtained, they should be transformed into the non-Gaussian space by applying the following formula:

$$\tilde{Z}_i^{NG}(x, y) = G_i^{-1}\left\{\Phi\left[\tilde{Z}_i(x, y)\right]\right\} \qquad i = c, \varphi \tag{5}$$

where $\Phi(.)$ is the standard normal cumulative density function.

2.2 Monte Carlo method

The Monte Carlo simulation method consists in generating *N* samples which respect the joint probability density function $f_X(X)$ of the *M* random variables ($X_1, \ldots, X_M$) gathered in a vector *X*. For each sample, the system response is calculated. Thus; for the *N* samples, one obtains *N* values of the system response gathered in a vector $\boldsymbol{G} = [G(\boldsymbol{x}_1), G(\boldsymbol{x}_2), \ldots, G(\boldsymbol{x}_N)]$ which may be used to determine the failure probability for a prescribed threshold of this system response. A very large number of realizations is required to obtain a rigorous value of the failure probability especially when computing small failure probabilities. It should be noted herein that the random variables considered in the present paper are the standard normal variables ξ_j ($j=1, \ldots, N$) that appear in Eq. (4) for the computation of a given realization of the cohesion c and the friction angle random fields.

2.3 Kriging metamodeling technique

The metamodeling technique aims at replacing the response (or the performance function in this paper) of a computationally-expensive mechanical model by a metamodel (i.e. a simple analytical equation). The kriging metamodeling technique is based on the idea that the performance function $G(\boldsymbol{x})$ is seen as a realization of a stochastic field $\hat{G}(\boldsymbol{x})$ [12]. The kriging metamodeling needs a design of experiments DoE of length *N* to define the stochastic parameters of this field and then, predictions of the response can be obtained on any unknown point. Let us define the design of experiments by the vector $\boldsymbol{X} = [\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_N]$, with $\boldsymbol{x}_i$ the i[th] experiment, and $\boldsymbol{G} = [G(\boldsymbol{x}_1), G(\boldsymbol{x}_2), \ldots, G(\boldsymbol{x}_N)]$ the corresponding response vector. The approximate relationship between any experiment $\boldsymbol{x}$ and the response G($\boldsymbol{x}$) can be denoted as:

$$\hat{G}(\boldsymbol{x}) = \boldsymbol{F}(\boldsymbol{x}, \boldsymbol{\beta}) + \boldsymbol{Z}(\boldsymbol{x}) \tag{6}$$

Where:

- $\boldsymbol{F}(\boldsymbol{x}, \boldsymbol{\beta})$ is the deterministic part which gives an approximation of the mean value of the performance function. It corresponds to a regression model that can be written as:

$$\boldsymbol{F}(\boldsymbol{x}, \boldsymbol{\beta}) = \boldsymbol{f}^{\boldsymbol{T}}(\boldsymbol{x}).\boldsymbol{\beta} \tag{7}$$

Where $\boldsymbol{\beta}^T = [\beta_1, \ldots, \beta_p]$ is the vector of coefficients to be determined, $\boldsymbol{f}^T(\boldsymbol{x}) = [f_1(\boldsymbol{x}), f_2(\boldsymbol{x}), \ldots, f_p(\boldsymbol{x})]^T$ is a collection of regression functions (or regressors). The number *p* of regression functions is assumed to be less than or equal to the number *N* of observations so that the problem is not under-determined (i.e. it does not lack equations to compute the unknowns). In this paper, ordinary kriging is selected which means that $\boldsymbol{F}(\boldsymbol{x}, \boldsymbol{\beta})$ is a scalar to be determined [i.e. $\boldsymbol{F}(\boldsymbol{x}, \boldsymbol{\beta})=\beta$]. So the estimated $\hat{G}(\boldsymbol{x})$ can be simplified as:

$$\hat{G}(\boldsymbol{x}) = \boldsymbol{F}(\boldsymbol{x}, \boldsymbol{\beta}) + \boldsymbol{Z}(\boldsymbol{x}) = \beta + \boldsymbol{Z}(\boldsymbol{x}) \tag{8}$$

- $\boldsymbol{Z(x)}$ represents the fluctuation around the mean value. It is given by a Gaussian random process (or a random field) with zero mean and covariance defined by

$$Cov\left[Z(\boldsymbol{x_i}), Z(\boldsymbol{x_j})\right] = \sigma_z^2\, R(\boldsymbol{x_i}, \boldsymbol{x_j}) \tag{9}$$

where σ_z^2 is the process variance; $\boldsymbol{x}_i$, $\boldsymbol{x}_j$ are two points from the whole samples X and $R(\boldsymbol{x}_i, \boldsymbol{x}_j)$ is the correlation function between these two points with a correlation parameter vector $\boldsymbol{\theta}$. Several models exist to define the correlation function R. However, in this paper, the anisotropic squared-exponential function is selected. It is given by:

$$R(\boldsymbol{x_i}, \boldsymbol{x_j}) = \prod_{i=1}^{N} e^{\left(-\theta_i (x_i - x_j)^2\right)} \tag{10}$$

Where N is the number of random variables, x_i and x_j are the i[th] coordinates of the points $\boldsymbol{x}_i$ and $\boldsymbol{x}_j$ and θ_i is a scalar which is equal to the inverse of the correlation length in the i[th] direction.

As may be seen from equation (6), the kriging metamodel consists of a linear regression model $\boldsymbol{F(x, \beta)}$ and a stochastic process $\boldsymbol{Z(x)}$.

As $\boldsymbol{R}$ is a square matrix of dimension *N*x*N*, i.e. $\boldsymbol{R} = \left[R(\boldsymbol{x_i}, \boldsymbol{x_j})\right]_{N \times N}$ and **F** is a unit vector of dimension N, then β and σ_z^2 can be estimated as:

$$\hat{\beta} = (\boldsymbol{F}^T \boldsymbol{R}^{-1} \boldsymbol{F})^{-1}\, \boldsymbol{F}^T\, \boldsymbol{R}^{-1}\, \boldsymbol{G} \tag{11}$$

$$\hat{\sigma}_z^2 = \frac{1}{N} (\boldsymbol{G} - \beta \boldsymbol{F})^T\, \boldsymbol{R}^{-1} (\boldsymbol{G} - \beta \boldsymbol{F}) \tag{12}$$

The correlation parameter θ can be obtained through the maximum likelihood estimation:

$$\theta = arg_\theta \min(N \ln \sigma_z^2 + \ln|\boldsymbol{R}|) \tag{13}$$

Once the parameters $\hat{\beta}$, $\hat{\sigma}_z^2$ and θ are determined, the Best Linear Unbiased Predictor (BLUP) of the response $\hat{G}(\boldsymbol{x})$ at an unknown point $\boldsymbol{x}$ is shown to be a Gaussian random variate $\hat{G}(\boldsymbol{x}) \sim N\,(\mu_{\hat{G}(x)}, \sigma_{\hat{G}(x)})$ where

$$\mu_{\hat{G}(x)} = \beta + \boldsymbol{r}(\boldsymbol{x}) \boldsymbol{R}^{-1} (\boldsymbol{G} - \beta \boldsymbol{F}) \tag{14}$$

$$\sigma^2_{\hat{G}\,(x)} = \sigma_z^2(\boldsymbol{x})(\boldsymbol{1} + u^T(\boldsymbol{x})(\boldsymbol{F}^T \boldsymbol{R}^{-1} \boldsymbol{F})^{-1} u^T(\boldsymbol{x}) - \boldsymbol{r}^T(\boldsymbol{x}) R^{-1} \boldsymbol{r}(\boldsymbol{x})) \tag{15}$$

Where $\boldsymbol{r(x)}$= [**R**(**x, x**$_1$), **R**(**x, x**$_2$), . . . , **R**(**x, x**$_N$)], u(**x**) = $\boldsymbol{F}^T \boldsymbol{R}^{-1} \boldsymbol{r}(\boldsymbol{x}) - 1$. Notice that $\mu_{\hat{G}(x)}$ is usually taken as the estimated $\hat{G}(\boldsymbol{x})$ at point $\boldsymbol{x}$. The computation of $\mu_{\hat{G}(x)}$ and $\sigma^2_{\hat{G}\,(x)}$ can be obtained by MATLAB toolbox DACE [7].

Notice that the variance $\sigma^2_{\hat{G}\,(x)}$ is defined as the minimum of the mean squared error between $\hat{G}(\boldsymbol{x})$ and G(x). The variances of points in the initial DoE are zero, but the variances of the

other points are always not zero. A large value of $\sigma^2_{\hat{G}\ (x)}$ means that the prediction is not exact. Therefore, the variance prediction $\sigma^2_{\hat{G}\ (x)}$ is important in the unexplored areas and presents a good index to improve the initial DoE. This property is interesting and is used in the following paragraph.

2.4 AK-MCS methodology

In a first stage, a significant number of realizations (about 1 million) of the spatially varying soil medium were generated by MCS using the Expansion Optimal Linear Estimation (EOLE) method. The response of most of these realizations will not be computed from the original deterministic model; only a few numbers of realizations will be computed using this model depending on their corresponding learning function values. In a second stage, an initial small Design of Experiments (DoE) based on a random selection of some realizations among the MCS population was determined and employed to compute the Kriging model (based on the values of the responses obtained using the original deterministic model). In a third stage, the adopted learning function U (which makes use of the already-obtained kriging model) is employed to choose the best next realization (among all the realizations of the MCS population) to be used for the computation of the system response from the original deterministic model. This realization is the one that leads to the minimal value of the learning function U. In a final stage (stage 4), the response obtained from this realization is employed to update the kriging model with this new response value (only in case where the adopted stopping condition has not been reached). Notice that stages 3-4 should be repeated several times until reaching the adopted stopping condition. At the end, the surrogate kriging model is considered to be enough accurate for the estimation of the failure probability and the corresponding value of the coefficient of variation, for the prescribed number of simulations. If the coefficient of variation of the failure probability is found to be too high, the initial MCS population should be increased. A more comprehensive step-by-step procedure describing the implementation of the AK-MCS methodology for the computation of the failure probability may be given as follows:

1. Generate a population S of n_{MC} (say 1,000,000) realizations of the spatially varying soil parameters c and φ using Monte Carlo Simulation. It should be emphasized here that the computation of the performance function for these realizations (as defined in equation 1 based on the computationally-expensive $FLAC^{3D}$ model) is not required at this stage.
2. Randomly select from the S population a small number of realizations (called initial Design of Experiments DoE) containing N_1 realizations (say 20). For those N_1 realizations, one should evaluate the performance function given by equation (1) based on the computationally expensive $FLAC^{3D}$ model. The required initial DOE may be greater than 20 for a great number of random variables (i.e. for a spatially varying soil property with small values of the autocorrelation distances). This is because for high dimensional problems (i.e. when a large number of random variables is needed to discretize the c and φ random fields), the kriging model needs more points (i.e. realizations) in order to compute correlation parameters θ_i given by equation (10).
3. Compute the kriging model according to the small initial DoE containing the N_1 realizations. This kriging model is given by equation (14). It should be mentioned here that this stage was performed using the Matlab toolbox DACE [7]. In this paper,

ordinary kriging model was used (i.e. the regression model is considered to be constant) and a square exponential correlation function was adopted in the analysis.

4. By using DACE toolbox, compute (for the whole population S containing the n_{MC} realizations of the random field) both the kriging predictor values $\mu_{\hat{G}}$ of the performance function (based on equation 14) and their corresponding kriging variance values $\sigma_{\hat{G}}^2$ (based on equation 15). From the obtained values of the kriging predictors $\mu_{\hat{G}}$, obtain an estimation of the probability of failure $\hat{P}_f$ by counting the number of negative predictors $N_{\hat{G}\leq 0}$ and dividing it by the total number of samples in S as follows:

$$\hat{P}_f = \frac{N_{\hat{G}\leq 0}}{n_{MC}} \tag{16}$$

Also compute the coefficient of variation of $\hat{P}_f$ as follows:

$$\hat{COV}(\hat{P}_f) = \sqrt{\frac{1-\hat{P}_f}{\hat{P}_f n_{MC}}} \tag{17}$$

5. Identify the best next realization in S for which one will compute the performance function using FLAC^{3D}. This is performed by evaluating a learning function U for each realization in S. The learning function U is given by:

$$U(x_i) = \frac{\left|\mu_{\hat{G}(x_i)}\right|}{\sigma_{\hat{G}(x_i)}} \qquad i = 1, \ldots, n_{MC} \tag{18}$$

The best next candidate realization is the one with minimum value of U. If this minimum value of U is smaller than 2, the performance function based on FLAC^{3D} is evaluated for this best candidate and the initial DoE is updated. Thus one should go back to step 3 and evaluate a new kriging model based on the updated DoE. Steps 3, 4 and 5 are repeated until the minimum value of U becomes larger than 2. At this stage the learning stops and the metamodel is considered accurate enough based on the n_{MC} realizations.

6. When the learning stops, one must compute the estimated values of both the probability of failure $\hat{P}_f$ and the coefficient of variation $\hat{COV}\left(\hat{P}_f\right)$. The obtained value of $\hat{P}_f$ is considered to be accurate if $\hat{COV}\left(\hat{P}_f\right) \leq 5\%$. If the estimated coefficient of variation is larger than 5%, one must increase the population S in step 1 and repeat the procedure.

It should be emphasized herein that a small initial DoE is chosen within the present approach (see step 2) in order to keep to a minimum the number of calls to the deterministic model. This initial DoE is successively increased by a single realization at each time (see step 5). The chosen realization is the one that is improving the most the metamodel because equation (18) searches for the realization that has a small kriging predictor (i.e. a realization that is close to the limit state surface) and/or a high kriging variance (i.e. a high uncertainty in the sign of its performance function value). Notice that the realizations with high uncertainties in the sign of their performance function values (positive or negative) are those that are close to the limit state surface. Finally, notice that the stopping criterion min(U)>2 corresponds to a maximal probability of making a mistake

on the sign of the performance function of Φ(-2)=0.023. This means that the stopping criterion is relevant making use of the realizations with a small uncertainty in making a mistake in their performance functions' signs, the probability of making a mistake in the signs of their performance function values being negligible.

2.5 Probabilistic numerical results

The aim of this section is to present the probabilistic numerical results of a strip footing resting on a spatially varying soil and subjected to a vertical loading. The soil shear strength parameters (c and φ) were considered as anisotropic non-Gaussian random fields. The soil cohesion c was modeled by a lognormal distribution. Its mean value and its coefficient of variation (referred to in this paper as reference values) were taken as follows: $\mu_c = 20\ kPa$, $COV_c = 25\%$. On the other hand, the soil friction angle φ was assumed to be bounded (i.e $0 \leq \varphi \leq 45^{\circ}$). A beta distribution was selected for this parameter with a mean value and a coefficient of variation given as follows: $\mu_\varphi = 30^{\circ}$, $COV_\varphi = 10\%$. **.** The soil dilation angle ψ was considered to be related to the soil friction angle φ by $\psi = 2\varphi / 3$. This means that the soil dilation angle was implicitly assumed as a random field that is perfectly correlated to the soil friction angle random field. Notice that the same autocorrelation function (square exponential) was used for both c and φ.

As for the autocorrelation distances ax and ay of the two random fields c and φ, both cases of isotropic (i.e. ax=ay) and anisotropic (i.e. ax>ay) random fields will be treated although the soil is rarely isotropic in reality. In our study, the reference values adopted for ax and ay were ax=10m and ay=1m. For the considered soil domain and for the different values of the autocorrelation distances (ax, ay) used in the analysis, the total number N of random variables (or eigenmodes) that is used to discretize the two random fields c and φ is determined based on a variance of the error ≤10%. It should be mentioned here that the initial design of experiment (DoE) contain 20 samples.

2.5.1 Deterministic model

The deterministic model was based on numerical simulations using the finite difference code FLAC^{3D}. The soil behavior was modeled using a conventional elastic-perfectly plastic model based on Mohr-Coulomb failure criterion. Notice that the soil Young modulus E and Poisson ratio υ were assumed to be deterministic since the ultimate bearing capacity is not sensitive to these variables. Their corresponding values are respectively $E = 60MPa$ and $\nu = 0.3$. Finally, concerning the footing, a weightless strip foundation of 1m width and 0.25m height is used. It is assumed to follow an elastic linear model ($E = 25GPa, \nu = 0.4$). The connection between the footing and the soil mass is modeled by interface elements having the same mean values of the soil shear strength parameters in order to simulate a perfectly rough soil-footing interface. These parameters have been considered as deterministic in this study. Concerning the elastic properties of the interface, they also have been considered as deterministic and their values are as follows: $K_s = 1GPa$, $K_n = 1GPa$ where K_s and K_n are respectively the shear and normal stiffness of the interface.

As shown in Figure 1, a strip footing of width B=1m that rests on a soil domain of width 13B and depth 5B was considered in the analysis. For the displacement boundary conditions, the bottom boundary was assumed to be fixed and the vertical boundaries were constrained in motion in the horizontal direction. For the computation of the bearing capacity of the rigid rough strip footing subjected to a central vertical load using FLAC^{3D}, the following method is adopted: an optimal controlled downward vertical velocity of 5×10^{-6} m/timestep (i.e. displacement per timestep) was applied to the bottom central node of the footing. Damping of

the system is introduced by running several cycles until a steady state of plastic flow is developed in the soil underneath the footing. At each cycle, the vertical footing load is obtained by using a FISH function that calculates the integral of the normal stress components for all elements in contact with the footing. The value of the vertical footing load at the plastic steady state is the ultimate footing load.

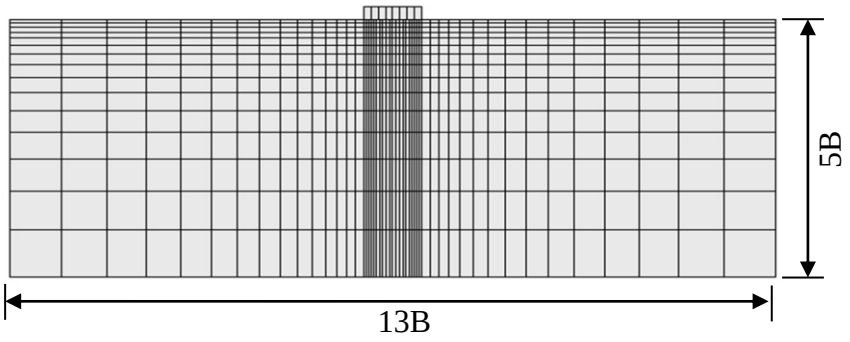

Figure 1. Soil domain and mesh in the FLAC^{3D}

2.5.2 Probabilistic results for the reference case

Figure (2) presents for the reference case (a_x=10m, a_y=1m) the failure probability P_f, the coefficient of variation COV_{Pf} and the learning function values U as function of the added points (i.e. added realizations) for a number of realizations n_{MC} equal to 500000. It should be mentioned here that 491 additional points were added to the initial DoE before the algorithm stops (U>2). The final obtained values of P_f and COV_{Pf} are respectively $1.408x10^{-3}$ and 3.766%. Figure (2) shows that the probability of failure starts to converge at about 480 calls to the deterministic model.

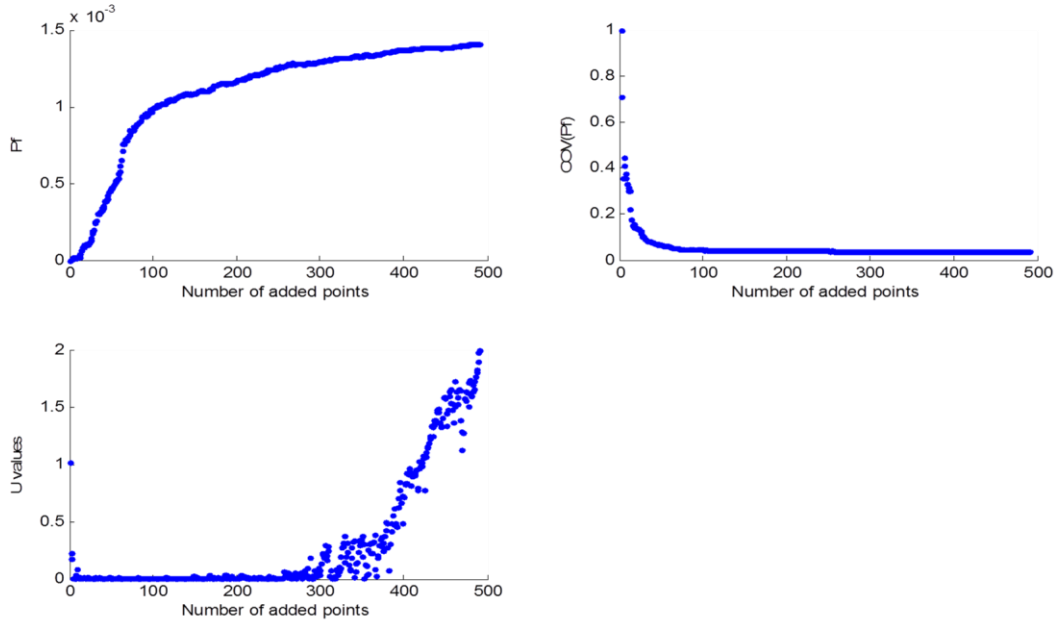

Figure 2. P_f, cov(P_f) and U values as function of the added points for the reference case

Figures (3) presents typical realizations and the corresponding velocity field of the random fields for the reference case. As may be seen from this figure, the spatial variability of the soil

properties can produce a non-symmetrical mechanism even though the footing is subjected to a symmetrical vertical load.

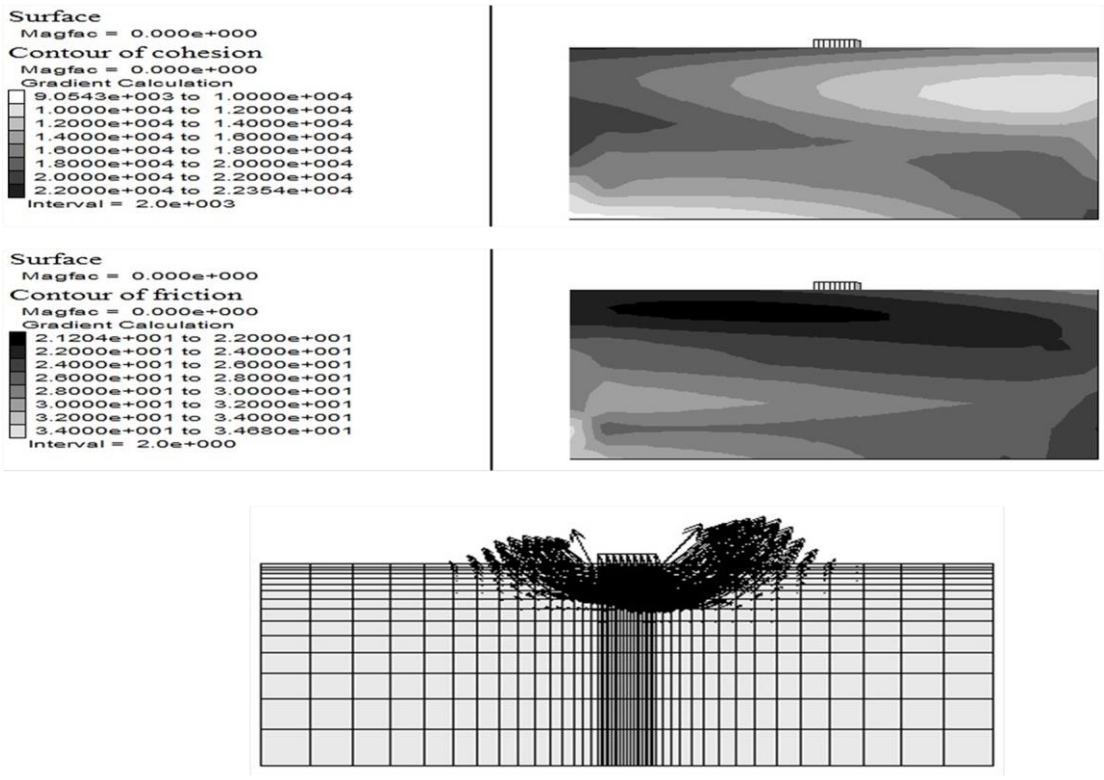

Figure 3. Typical realization and the corresponding velocity field of the random fields for the reference case (a_x=10m, a_y=1m) (n_{MC} = 500000)

2.5.3 Effect of the number of simulations on COV_{Pf}

To ensure a small uncertainty on the estimation of the failure probability, the number of realizations n_{MC} to be used must be sufficient to provide a small value of the coefficient of variation COV_{Pf} of this failure probability. Figure (4) shows for the reference case the variation of COV_{Pf} (as computed by AK-MCS methodology) with the number of realizations n_{MC}. As expected, Figure (4) shows that COV_{Pf} decreases (i.e. the accuracy of the failure probability increases) with the increase of n_{MC}.

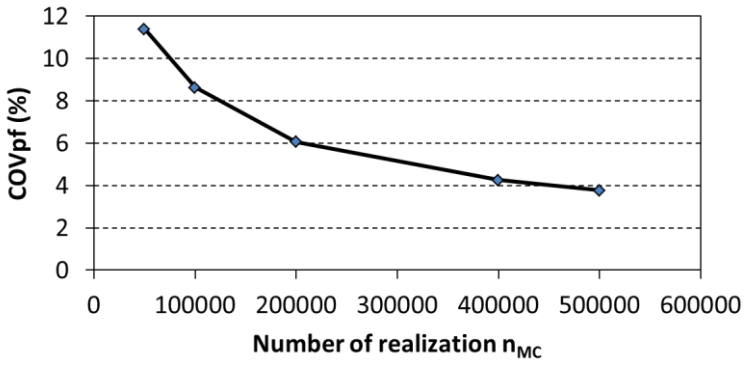

Figure 4. Coefficient of variation of P_f versus the number of realizations n_{MC}

2.5.4 Effect of the autocorrelation distance

Table 1 presents the effect of the isotropic autocorrelation distance (ax=ay) on the failure probability (P_f) and the corresponding coefficient of variation COV_{Pf} as computed by AK-MCS methodology using n_{MC}=1,000,000 realizations of the random field. This table also gives, for each autocorrelation distance, (i) the number of eigenmodes that is needed to satisfy the criterion imposed on the variance of the error of the random field (i.e. variance error<10%), (ii) the number of added points (i.e. the number of added realizations) and (iii) the obtained value of the learning function U for which the learning stops. As may be seen from this table, P_f increases with the increase in the autocorrelation distance. A small value of the coefficient of variation of the failure probability (smaller than 3%) was obtained for the adopted value of n_{MC}. The number of added realizations required to lead to a good approximation of the kriging model seems to be greater for the smaller values of the autocorrelation distance, although there is no regular increase in the number of added points with the decrease of the autocorrelation distance. Indeed, this number depends on the evolution of the learning function value to satisfy the stopping conditions.

Table 1. Number of random variables used to discretize the random field in EOLE method, P_f, COV_{Pf} and number of added points in the case of an isotropic case

ax=ay (m)	Number of needed random variables for the two random fields (c, φ)	$P_f \times 10^{-3}$	Cov_{pf} %	Number of added points	U
10	4	2.407	2.0358	243	2.033194
20	4	3.509	1.685	342	2.007373
50	4	3.824	1.614	65	2.292211
100	4	3.87	1.604	76	2.147826

3 CONCLUSION

The probabilistic analysis of shallow foundations resting on a spatially varying soil was generally performed in literature using MCS methodology. The mean value and the standard deviation of the system response were extensively investigated. This was not the case for the failure probability because MCS methodology requires a large number of calls of the deterministic model to accurately calculate a small failure probability. This paper mainly presented a probabilistic analysis at the ultimate limit state of a strip footing resting on a spatially varying soil using an active learning reliability method combining kriging and Monte Carlo Simulation (called AK-MCS). The method was shown to be very efficient as the obtained probability of failure is very accurate needing only a small number of calls to the deterministic model. Within this method, one performs a Monte Carlo simulation without evaluating the whole population using the original deterministic model. Indeed, the population is predicted using a kriging metamodel which is defined using only a few points of the population that are evaluated employing the original deterministic model. The objective of this paper is the computation of the probability P_f of exceeding the ultimate bearing capacity of the footing under a prescribed footing load. The soil cohesion and angle of internal friction were considered as two non-isotropic non-Gaussian random fields. The deterministic model

was based on numerical simulations using the finite difference code FLAC^{3D}. The main findings of this study can be summarized as follows:

1. The probabilistic analysis has shown that the small failure probability P_f was computed accurately (i.e. with a small COV_{Pf}) using only a small number of calls of the deterministic model.
2. The failure probability P_f increases with the increase in the autocorrelation distance. The number of added realizations required to lead to a good approximation of the kriging model seems to be greater for the smaller values of the autocorrelation distance.

Keywords: Structural Health Monitoring, Damage Detection, Optimal Sensor Placement, Bayesian Inference, Uncertainty Quantification.

Abstract. *We present an optimal sensor placement methodology for structural health monitoring (SHM) purposes, relying on a Bayesian experimental design approach. The unknown structural properties, e.g. the residual strength and stiffness, are inferred from data collected through a network of sensors, whose architecture, i.e., type and position may largely affect the accuracy of the monitoring system. In tackling this issue, an optimal network configuration is herein sought by maximizing the expected information gain between prior and posterior probability distributions of the parameters to be estimated. Since the objective function linked to the network topology cannot be analytically computed, a numerical approximation is provided by means of a Monte Carlo analysis, wherein each realization is obtained via finite element modeling. Since the computational burden linked to this procedure often grows infeasible, a Polynomial Chaos Expansion (PCE) approach is adopted for accelerating the computation of the forward problem. The analysis expands over joint samples covering both structural state and design variables, i.e., sensor locations. Via increase of the number of deployed sensors in the network, the optimization procedure soon turns computationally costly due to the curse of dimensionality. To this end, a stochastic optimization method is adopted for accelerating the convergence of the optimization process and thereby the damage detection capability of the SHM system. The proposed method is applied to thin flexible structures, and the resulting optimal sensor configuration is shown. The effects of the number of training samples, the polynomial degree of the approximation expansion and the optimization settings are also discussed.*

1 INTRODUCTION

Let us consider a structural system, monitored through a network of sensors. The measured response of the system subjected to a set of given actions is collected in the vector $\mathbf{y} \in \mathbb{R}^{n_\mathbf{y}}$, where entries can be either displacements or rotations. Here $n_\mathbf{y}$ is the number of measurements, i.e., the number of sensors to be deployed multiplied by the number of physical quantities that can be measured by each sensor.
Let us define a set of mechanical properties like Young modulus, stiffness, modal parameters, collected in the vector $\boldsymbol{\theta} \in \mathbb{R}^{n_{\boldsymbol{\theta}}}$, to be identified using the measured data $\mathbf{y}$. The capability of a SHM system to detect and identify the said mechanical properties is basically affected by two aspects [1]: the mathematical tools exploited to estimate the parameters; and the experimental setting, i.e., the physical quantities to be measured and the procedure to measure them. Considering the experimental design alone, the estimation capability is affected by several aspect, including:

- sensor characteristics such as accuracy, resolution, sensitivity, noise, etc.;
- number of sensors;
- orientation and deployment of sensors;

which should be appropriately set to ensure high accuracy at a reduced cost.
Optimal sensor placement (OSP) forms a fundamental task for real SHM applications, as it can allow decreasing the cost and complexity of the SHM system. As summarized in [2, 3, 4], among the most commonly adopted OSP methods we find: the effective independence method (EFI); the driving-point residue method (EFI-DPR); the kinetic energy method (KEM); the modified variance method (MVM); methods based on topology optimization [5]. All aforementioned methods do not take into account that measurements are inevitably corrupted with errors, and hence they should be treated as stochastic quantities. The main goal of the present work is to determine the optimal configuration of sensors, that guarantees the best estimation of mechanical parameters or, in other words, the maximum amount of inferred information, under noise corrupted variables. The general purpose framework proposed in [6] is applied to the OSP problem, in order to find the sensor configuration guaranteeing a maximal amount of information, as already proposed in [7] and [8].
The remainders of the paper is organized as follows: in Section 2, the main theoretical aspects of the adopted methodology, such as the problem settings, the numerical solution of the problem and the optimization scheme, are described. In section 3, the framework is implemented on a simple benchmark problem consisting in a flexible simply supported plate. Finally, some concluding remarks and possible future developments are friefly summarized in Section 4.

2 BAYESIAN EXPERIMENTAL DESIGN FOR OPTIMAL SENSOR PLACEMENT

2.1 Problem settings

Moving from a space discretized system, the position of the sensors is defined through an appropriate design variable vector $\mathbf{d} \in \mathbb{R}^{n_\mathbf{d}}$, that can be set alternatively as:

- vector of spatial nodal coordinates

$$\mathbf{d} = \{x_1 \;\; y_1 \;\; z_1 \;\; \boldsymbol{\delta}_1 \;\; \ldots \;\; x_{n_{sens}} \;\; y_{n_{sens}} \;\; z_{n_{sens}} \;\; \boldsymbol{\delta}_{n_{sens}}\}^T \tag{1}$$

where $1 \leqslant n_{sens} \leqslant n_{nodes}$ is the number of sensors to be deployed; variable $\boldsymbol{\delta}_i = \{u_i, v_i, w_i\}^T$ identifies the orientation of the $i-$th sensor; the spatial coordinates x_i, y_i, z_i are defined in the discrete domain of all the nodes of the Finite Element (FE) model;

- vector of nodal labels
$$\mathbf{d} = \{d_1 \ \boldsymbol{\delta}_1 \ \ \ldots \ \ d_{n_{sens}} \ \boldsymbol{\delta}_{n_{sens}}\}^T \tag{2}$$
with d_i designating the FE model node where the $i-$th sensor is placed.

The measured quantities $\mathbf{y}$ are related to the model output $\mathbf{u} \in \mathbb{R}^{n_{nodes}n_{dof}}$, n_{dof} denoting the number of degrees of freedom of each node associated to the FE model, through the relation:

$$\mathbf{y} = \mathbf{L}\mathbf{u} + \boldsymbol{\epsilon} \tag{3}$$

where $\boldsymbol{\epsilon} \in \mathbb{R}^{n_{sens}}$ is the model prediction error, accounting for the modelling and measurement errors, and is therefore related to the type of sensors deployed. $p_{\boldsymbol{\epsilon}} = p(\boldsymbol{\epsilon})$ is defined as the probability density function associated with the model prediction error. $\mathbf{L} \in \mathbb{R}^{n_{sens} \times n_{nodes}n_{dof}}$ is a configuration matrix, linking the measurements $\mathbf{y}$ to the model response $\mathbf{u}$, defined as a boolean matrix, with 1 or 0 entries corresponding respectively to the measured and non-measured quantities. $\mathbf{L}$ depends both on the sensors positions, i.e., the nodes in which the sensors are placed, and the direction of the measured displacement or accelerations. Therefore, $\mathbf{L} = \mathbf{L(d)}$ is function of the experimental variable $\mathbf{d}$.
Since the structure is modeled through a FE model, the model response $\mathbf{u}$ depends on the meachanical properties of the system, according to:

$$\mathbf{u} = \mathbf{K}(\boldsymbol{\theta})^{-1}\mathbf{F} \tag{4}$$

where $\mathbf{K} \in \mathbb{R}^{n_{nodes}n_{dof} \times n_{nodes}n_{dof}}$ is the stiffness matrix associated with the discretized structure and $\mathbf{F} \in \mathbb{R}^{n_{nodes}n_{dof}}$ is the load vector. The load is assumed implemented as a quasi-static way and therefore any dynamic effect on the response is disregarded.
Eqs. (3) and (4) lead to:

$$\mathbf{y} = \mathbf{G}(\mathbf{d}, \boldsymbol{\theta}) + \boldsymbol{\epsilon} \tag{5}$$

where:

$$\mathbf{G}(\mathbf{d}, \boldsymbol{\theta}) = \mathbf{L(d)}\mathbf{K}(\boldsymbol{\theta})^{-1}\mathbf{F} \tag{6}$$

is the forward model operator $\mathbb{R}^{n_{\mathbf{d}}} \times \mathbb{R}^{n_{\boldsymbol{\theta}}} \to \mathbb{R}^{n_{\mathbf{u}}}$ that maps the design variable and the parameters to be estimated onto the response domain.
The main goal of the OSP problem is to determine the optimal sensor configuration $\mathbf{d}^*$, for the Bayesian inference of the mechanical parameters $\boldsymbol{\theta}$. Here we use the general framework proposed in [6, 9], which is applicable to any Bayesian inference problem; $\boldsymbol{\theta}$ and $\mathbf{y}$ are therefore treated as random variables, with their appropriate probability densities, accounting for their respective uncertainties.
Bayes' theorem allows to compute the conditional probability density of the parameters to be inferred, given the acquired data, i.e., the measurements. In the case of experimental design, the Bayes' rule can be specialized, taking also into account the design variable, as:

$$p(\boldsymbol{\theta}|\mathbf{y}, \mathbf{d}) = \frac{p(\mathbf{y}|\boldsymbol{\theta}, \mathbf{d})p(\boldsymbol{\theta}|\mathbf{d})}{p(\mathbf{y}|\mathbf{d})} \tag{7}$$

where $p(\boldsymbol{\theta}|\mathbf{y}, \mathbf{d})$ is the posterior distribution (probability density of $\boldsymbol{\theta}$, given $\mathbf{y}$ and $\mathbf{d}$), $p(\mathbf{y}|\boldsymbol{\theta}, \mathbf{d})$ is the likelihood, $p(\boldsymbol{\theta}|\mathbf{d})$ is the prior distribution and $p(\mathbf{y}|\mathbf{d})$ is the evidence. In the following, the

evidence is assumed to be independent of the design variable, therefore $p(\boldsymbol{\theta}|\mathbf{d}) = p(\boldsymbol{\theta})$. Hence, the prior knowledge of $\boldsymbol{\theta}$ is not affected by the experimental procedure.
Following [10], the optimal experimental design in a Bayesian sense can be obtained by maximizing the following expression:

$$\max_{\mathbf{d}\in\boldsymbol{\mathcal{D}}} \int_{\boldsymbol{\mathcal{Y}}} \int_{\boldsymbol{\Theta}} U(\mathbf{d},\mathbf{y},\boldsymbol{\theta}) p(\boldsymbol{\theta},\mathbf{y}|\mathbf{d}) d\boldsymbol{\theta} d\mathbf{y} \tag{8}$$

where $\boldsymbol{\mathcal{Y}}$ and $\boldsymbol{\Theta}$ respectively designate the supports of $p(\mathbf{y}|\mathbf{d})$ and $p(\boldsymbol{\theta})$. Within a decision theory formulation, $U(\mathbf{d},\mathbf{y},\boldsymbol{\theta})$ is a utility function defined in $(\boldsymbol{\mathcal{D}},\boldsymbol{\mathcal{Y}},\boldsymbol{\Theta}) \rightarrow \mathbb{R}$ that takes into account the usefulness of the experimental decision $\mathbf{d}$, given a particular value of $\boldsymbol{\theta}$ and $\mathbf{y}$. The optimal experimental design aims to maximize the expected utility function specified by Eq. (8). As summarized in [11], the choice of the utility function is strictly related to the type of problem, whether it is a prediction or an estimation one. As suggested in [7], the most common utility function for the inference problems is the expected Kullbach-Leibler divergence (also called expected gain in Shannon information [12] or relative entropy) between the posterior and the prior probability distributions [13]:

$$D_{KL}(p(\boldsymbol{\theta}|\mathbf{y},\mathbf{d})||p(\boldsymbol{\theta})) = \int_{\boldsymbol{\mathcal{Y}}} \int_{\boldsymbol{\Theta}} \log \frac{p(\boldsymbol{\theta}|\mathbf{y},\mathbf{d})}{p(\boldsymbol{\theta})} p(\mathbf{y},\boldsymbol{\theta}|\mathbf{d}) d\mathbf{y} d\boldsymbol{\theta} \tag{9}$$

The rationale behind this choice relies on the concept that the optimal configuration should yield the largest increase in information between the prior and the posterior.
Recasting Eq. (9) into the experimental design problem, the utility function becomes:

$$U(\mathbf{d},\mathbf{y},\boldsymbol{\theta}) = U(\mathbf{d},\mathbf{y}) = \int_{\boldsymbol{\Theta}} \log \frac{p(\bar{\boldsymbol{\theta}}|\mathbf{y},\mathbf{d})}{p(\bar{\boldsymbol{\theta}})} p(\bar{\boldsymbol{\theta}}|\mathbf{y},\mathbf{d}) d\bar{\boldsymbol{\theta}} \tag{10}$$

Remebering that $\bar{\boldsymbol{\theta}}$ is a dummy variable and using Eq. (10), the optimization statement of Eq. (8) becomes:

$$\max_{\mathbf{d}\in\boldsymbol{\mathcal{D}}} \int_{\boldsymbol{\mathcal{Y}}} \int_{\boldsymbol{\Theta}} p(\boldsymbol{\theta}|\mathbf{y},\mathbf{d}) \ln \frac{p(\boldsymbol{\theta}|\mathbf{y},\mathbf{d})}{p(\boldsymbol{\theta})} d\boldsymbol{\theta} p(\mathbf{y}|\mathbf{d}) d\mathbf{y} \tag{11}$$

Rearranging Eq. (11) using Eq. (7), we can rewrite the optimization problem as:

$$\begin{aligned} &\text{find} \quad \mathbf{d}^* = \arg\max_{\mathbf{d}\in\mathcal{D}} \bar{U}(\mathbf{d}) \\ &\text{such that} \quad \bar{U}(\mathbf{d}) = \int_{\boldsymbol{\mathcal{Y}}} \int_{\boldsymbol{\Theta}} \{\ln[p(\mathbf{y},\boldsymbol{\theta}|\mathbf{d})] - \ln[p(\mathbf{y}|\mathbf{d})]\} p(\mathbf{y},\boldsymbol{\theta}|\mathbf{d}) p(\boldsymbol{\theta}) d\boldsymbol{\theta} d\mathbf{y} \end{aligned} \tag{12}$$

where $\bar{U}(\mathbf{d})$ is the so-called expected information gain in $\boldsymbol{\theta}$.

2.2 Surrogate modeling

The optimization problem defined in Eq. (12) is handled through Monte Carlo sampling as:

$$\bar{U}(\mathbf{d}) \approx \frac{1}{N_{out}} \sum_{i=1}^{N_{out}} \left\{ \ln\left[p(\mathbf{y}^i|\boldsymbol{\theta}^i,\mathbf{d})\right] - \ln\left[p(\mathbf{y}^i|\mathbf{d})\right] \right\} \tag{13}$$

where N_{out} represents the number of samples $\boldsymbol{\theta}^i$ to be drawn in the outer Monte Carlo sum.
The evidence computed at $\mathbf{y}^{(i)}$ is approximated as:

$$p(\mathbf{y}^i|\mathbf{d}) \approx \frac{1}{N_{in}} \sum_{j=1}^{N_{in}} p(\mathbf{y}^i|\boldsymbol{\theta}^j,\mathbf{d}) \tag{14}$$

The samples $\boldsymbol{\theta}^i$ and $\boldsymbol{\theta}^j$ are drawn from the prior distribution $p(\boldsymbol{\theta})$, which is chosen a priori. In SHM applications, the main goal is to identify the mechanical properties of a damaged structure, and it is common to assume parameters $\boldsymbol{\theta}$ as drawn from a uniform distribution $\mathcal{U}(\boldsymbol{\Theta})$. In reducing the associated computational cost, the same set of samples $\boldsymbol{\theta}$ is used for both the inner and the outer sum, resulting in $N_{in} = N_{out}$; the computational complexity is thus reduced from $O(N_{out}N_{in})$ to $O(N_{out})$. For further details on the bias introduced by this assumption and on the numerical approximation, the interested reader is referred to [6].
The term $p(\mathbf{y}|\boldsymbol{\theta}, \mathbf{d})$ corresponds to the probability density of the measured data $\mathbf{y}$, given a specific set of mechanical parameters $\boldsymbol{\theta}$ and a specific sensor configuration $\mathbf{d}$. Using Eq. (5), we can conclude that:

$$p(\mathbf{y}|\boldsymbol{\theta}, \mathbf{d}) = p_{\boldsymbol{\epsilon}}(\boldsymbol{\epsilon}) = p_{\boldsymbol{\epsilon}}(\mathbf{y} - \mathbf{G}(\mathbf{d}, \boldsymbol{\theta})) \tag{15}$$

Hence, via use of Eqs. (6) and (15), Eq. (13) becomes:

$$\begin{aligned} \bar{U}(\mathbf{d}) &\approx \frac{1}{N_{out}} \sum_{i=1}^{N_{out}} \left\{ \ln \left[p_{\boldsymbol{\epsilon}}(\boldsymbol{\epsilon}^i) \right] - \ln \left[\frac{1}{N_{in}} \sum_{j=1}^{N_{in}} p_{\boldsymbol{\epsilon}}(\mathbf{G}(\mathbf{d}, \boldsymbol{\theta}^i) + \boldsymbol{\epsilon}^i - \mathbf{G}(\mathbf{d}, \boldsymbol{\theta}^j)) \right] \right\} = \\ &= \frac{1}{N_{out}} \sum_{i=1}^{N_{out}} \left\{ \ln \left[p_{\boldsymbol{\epsilon}}(\boldsymbol{\epsilon}^i) \right] - \ln \left[\frac{1}{N_{in}} \sum_{j=1}^{N_{in}} p_{\boldsymbol{\epsilon}}(\mathbf{L(d)}[\mathbf{K}^{i^{-1}} - \mathbf{K}^{j^{-1}}]\mathbf{F} + \boldsymbol{\epsilon}^i) \right] \right\} \end{aligned} \tag{16}$$

where $\mathbf{K}^{i,j} = \mathbf{K}(\boldsymbol{\theta}^{i,j})$. The samples $\boldsymbol{\epsilon}^i$ are drawn from the density distribution $p_{\boldsymbol{\epsilon}}$, that is chosen once again a priori.
From a computational point of view, the most time-consuming part of the procedure is the evaluation of the system response through the model mapping $\mathbf{G}(\mathbf{d}, \boldsymbol{\theta})$ of Eq. (6). Assuming that we use the same batch of samples $\boldsymbol{\theta}$ for both sums, the Monte Carlo approximation would require N_{out} evaluations of the system output, each one associated to a stiffness matrix inversions, rendering the computation practically infeasable. In order to overcome this problem, in [6] the adoption of a Polynomial Chaos Expansion (PCE) scheme has been proposed. Given an input random vector with independent components $\mathbf{x} \in \mathbb{R}^{n_{\mathbf{x}}}$, described by a joint probability density function $f_{\mathbf{x}}$, and an output random vector $\mathbf{y}$ calculated through a certain computational model $\mathcal{M}$, the PCE allows to build a map, or metamodel, relating the two spaces. Assuming that:

$$\mathbb{E}[\mathbf{y}^2] = \int_{\mathcal{D}_{\mathbf{x}}} \mathcal{M}^2(\mathbf{x}) f_{\mathbf{x}}(\mathbf{x}) d\mathbf{x} \; < \; \infty \tag{17}$$

it is possible to define (see [14]):

$$\mathbf{y} = \mathcal{M}(\mathbf{x}) = \sum_{\boldsymbol{\alpha} \in \mathbb{N}^M} y_{\boldsymbol{\alpha}} \boldsymbol{\psi}_{\boldsymbol{\alpha}}(\mathbf{x}) \tag{18}$$

where $\boldsymbol{\psi}_{\boldsymbol{\alpha}}$ are multivariate polynomials of order p orthonormal to $f_{\mathbf{x}}$, $\boldsymbol{\alpha} \in \mathbb{N}^M$ is a multi-index associated with $\boldsymbol{\psi}_{\boldsymbol{\alpha}}$, and $y_{\boldsymbol{\alpha}} \in \mathbb{R}$ are the corresponding coefficients. For practical purposes, the sum is truncated to a sub-set of the multi-indeces $\boldsymbol{\alpha} \in \mathcal{A} \subset \mathbb{N}^M$, according to:

$$\mathbf{y} \cong \mathbf{y}^{PCE} = \mathcal{M}^{PCE}(\mathbf{x}) = \sum_{\boldsymbol{\alpha} \in \mathcal{A}} y_{\boldsymbol{\alpha}} \boldsymbol{\psi}_{\boldsymbol{\alpha}}(\mathbf{x}) \tag{19}$$

where $\mathcal{M}^{PCE}$ stands for the surrogate model, and $\mathbf{y}^{PCE}$ is the approximated response computed through it.

Recalling Eq. (5), the forward model maps the design variable and the parameters into the measurement domain $(\boldsymbol{\mathcal{D}}, \boldsymbol{\Theta}) \rightarrow \boldsymbol{\mathcal{Y}}$ as:

$$\mathbf{y} = \mathcal{M}(\mathbf{x}) = \mathbf{G}(\mathbf{d}, \boldsymbol{\theta}) \tag{20}$$

As suggested in [6], the PCE is applied jointly as:

$$\mathbf{x} = \begin{bmatrix} \boldsymbol{\theta} \\ \mathbf{d} \end{bmatrix} \tag{21}$$

with $\mathbf{x} \in \mathbb{R}^{n_{\boldsymbol{\theta}}+n_{\mathbf{d}}}$. In this way, it is not necessary to build a different PCE for each possible design variable $\mathbf{d}$, which would lead to a larger computational cost. In order to compute the surrogate model, two sets of samples $\boldsymbol{\theta}_k$ and $\mathbf{d}_k$ with $k = 1, \cdots, N_{PCE}$ are drawn from the respective aforementioned probability densities; the output samples are then calculated through the complete model $\mathbf{y}_k = \mathcal{M}(\mathbf{x}_k)$. Once the input and output populations have been built, the truncated bases and the relative coefficients are computed through the Least Angle Regression (LAR) algorithm, as specified in [14, 15]. The accuracy of the surrogate model with respect to the complete one is affected by both the population size N_{PCE} and the poynomial degree p; these settings should be chosen so as to minimize the leave-one-out (LOO) cross-validation error, as defined in [16].

2.3 Optimization algorithm

The optimization statement summarized in Eq. (12) is herein solved by applying the Covariance Matrix Adaptation Evolution Strategy (CMA-ES) [17], which comprises a stochastic search algorithm for numerical optimization of non-linear non-convex functions. The basic idea is to sample the design variable $\mathbf{d}$ from a multivariate normal distribution, and produce a new mutation of the generated population that is closer to the maximum of the function $\bar{U}(\mathbf{d})$.
The algorithm can be summarized as follows:

1. for each iteration, a population of design points $\mathbf{d}$ is sampled from the Normal multivariate distribution $\mathbf{d}_i \sim \mathbf{m} + \sigma\mathcal{N}_i(\mathbf{0}, \mathbf{C})$ for $i = 1, \cdots, \lambda$, where $\mathbf{m} \in \mathbb{R}^{\mathbf{n_d}}$ is the mean vector, $\sigma \in \mathbb{R}$ is the step size and $\mathbf{C} \in \mathbb{R}^{\mathbf{n_d} \times \mathbf{n_d}}$ is the covariance matrix;

2. $\mathbf{m}$ and $\mathbf{C}$ are updated through cumulation, in order the likelihood of the successive iterations to be increased;

3. the previous steps are repeated until a certain tolerance on the function evaluation is attained.

Further details on the algorithm can be found in [18].

3 RESULTS

The method discussed in Section 2 is now applied to a simple SHM benchmark case; a square plate, simply supported at four edges and subjected to a static force applied at its centre point (see node 1 in Figure 1). The structure is ideally subdivided into four zones and the aim of the SHM system is the estimation of the Young modulus E_j, $j = 1, ..., 4$, of each zone. The sensors can be positioned at each node of the adopted 10x10 FE model and, for the sake of simplicity, only the out-of-plane deflections are assumed to be measured. The structure is discretized through conventional shell elements, with 6 degrees of freedom per node. The mechanical behaviour of the material is supposed to be linear elastic.
Two cases are considered herein:

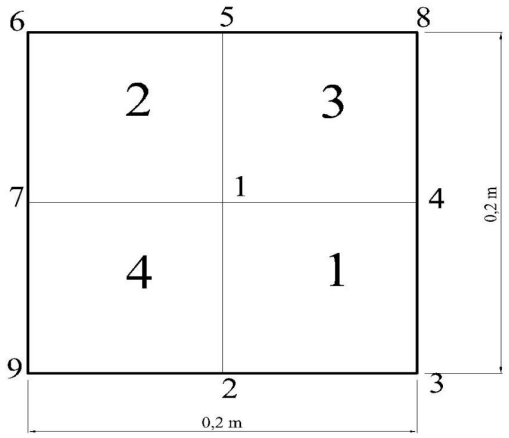

Figure 1: Benchmark structural case.

(a) the position of the damaged zone is known, therefore the input variables of the PCE surrogate model are summarized in vector:

$$\mathbf{x} = \{E_2 \;\; d_1 \;\; \cdots \;\; d_{n_{sens}}\}^T \tag{22}$$

(b) the position of the damaged zone is unknown:

$$\mathbf{x} = \{E_1 \;\; E_2 \;\; E_3 \;\; E_4 \;\; d_1 \;\; \cdots \;\; d_{n_{sens}}\}^T \tag{23}$$

Let us consider the simplest case: only one sensor is deployed. Figures 2 and 3 demonstrate the contour plot of the objective function defined by Eq. (12) computed on each node of the plate, respectively related to cases (a) and (b). The parameters to be estimated, aggregated in vector $\boldsymbol{\theta}$, are sampled from a uniform distribution $\mathcal{U}(0, E)$, where E is the Young modulus of the undamaged material. The probability distribution of the model prediction error ϵ is supposed to be Gaussian $\mathcal{N}(0, \sigma^2)$ with standard deviation $\sigma = 10^{-5}$ m. In order to compute the PCE coefficients and bases, the design variable **d** is sampled uniformly with coordinates defined over the interval $[0, 0.2]$, both along the width and the length of the plate.
The optimal configuration, i.e., maximizing the objective function, is determined at position $(x^*, y^*) = (0.08, 0.12)$ for case (a), i.e., as expected near the zone in which the damage will occur, see [5]. In case (b), the problem settings are perfectly symmetric and therefore the objective function as well: the optimal is determined in point $(x^*, y^*) = (0.10, 0.10)$. The figures show the optimization paths obtained through the CMA-ES algorithm: each path corresponds to a different initial condition, i.e., the four corner points, and the red circles identify the results reached after 25 objective function evaluations. It is demonstrated that, for both cases, the results are stable with respect to the initialization settings and they correspond to the maximum of the contour plot.
The accuracy of the optimization process is largely affected by the PCE approximation phase. The error introduced by the PCE surrogate model with respect to the FE model can be measured through the leave-one-out (LOO) error, as defined in [16]:

$$\epsilon_{LOO} = \frac{\sum_{i=1}^{N} \left(\mathcal{M}(\mathbf{x}^i) - \mathcal{M}^{PCE}(\mathbf{x}^i)\right)^2}{1 - h_i} \Bigg/ \left(\sum_{i=1}^{N} \left(\mathcal{M}(\mathbf{x}^i) - \hat{\mu}_Y\right)^2\right) \tag{24}$$

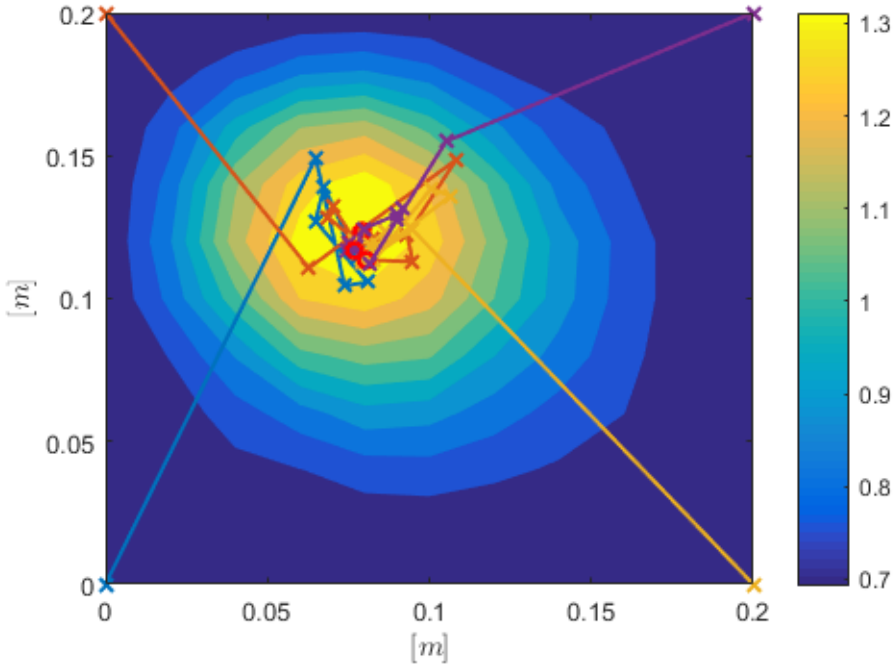

Figure 2: Contour plot of the objective function $\hat{U}(\mathbf{d})$ with one sensor for case (a) and CMA-ES optimization paths ($N^{PCE} = 10^4$, $p = 10$, $N^{MC} = 5 \cdot 10^3$).

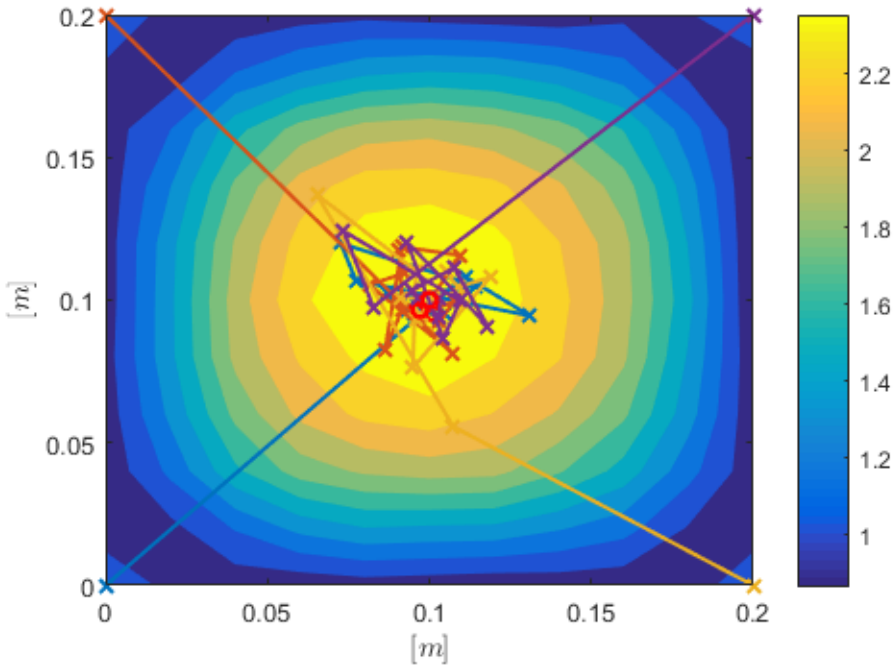

Figure 3: Contour plot of the objective function $\hat{U}(\mathbf{d})$ with one sensor for case (b) and CMA-ES optimization paths ($N^{PCE} = 10^4$, $p = 10$, $N^{MC} = 5 \cdot 10^3$).

where $\hat{\mu}_Y = \frac{1}{N} \sum_{i=1}^{N} \mathcal{M}(\mathbf{x}^i)$ is the sample mean of the set of quadrature points and h_i is the i^{th} component of the vector given by:

$$h = \text{diag}\left(\mathbf{A}(\mathbf{A}^T\mathbf{A})^{-1}\mathbf{A}^T\right) \tag{25}$$

where **A** is the experimental matrix that contains the values of all the basis polynomials in the experimental design points.
Figures 4 and 5 report the LOO error as a function of the polynomial order p and the number of samples N^{PCE} in a log-log plot. Figures show that, as expected, the error decreses as N^{PCE} and p increase; we can point out that for increase beyond a certain value of N^{PCE}, the error trend remains basically stable.

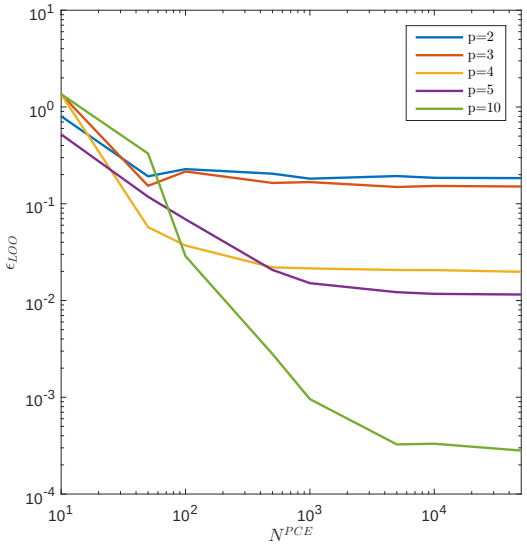

Figure 4: LOO error ϵ_{LOO} associated to the PCE surrogate model for case (a).

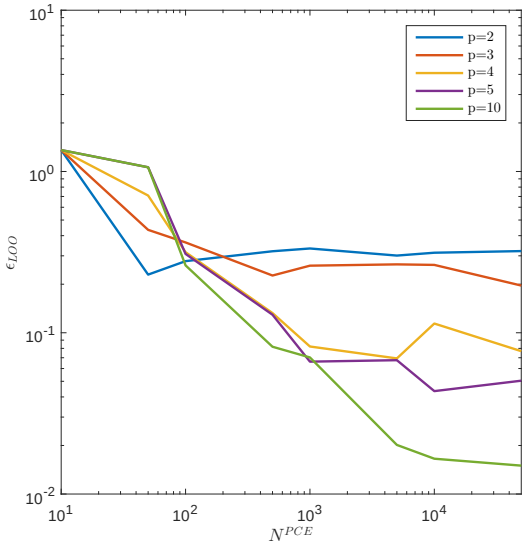

Figure 5: LOO error ϵ_{LOO} associated to the PCE surrogate model for case (b).

4 CONCLUSIONS

In the present paper, a new method has been proposed for optimal sensor placement in structural health monitoring applications, having supposed the measurements are noise-corrupted. The method is adapted from the general framework proposed in [6] for the optimal design of experiments; the procedure is coupled with a Covariance Matrix Adaptation Evolution Strategy optimization scheme, which allows for determining the optimal sensor configuration, associated with the maximum amount of information given by the measurements. In order to reduce the computational cost linked to the multiple forward problem simulations required, a Polynomial Chaos Expansion metamodeling scheme is adopted.
The method is herein applied to a simple benchmark problem of a simply supported plate under bending loads. It has been demonstrated that the optimization algorithm is able to find the optimal sensor configuration, further taking also into account measurement error. The method proves successful and yielding a design of experiments corresponding to reduced approximation error.
Further developments will concern the application to more complex structures, with multiple sensors configurations.

Abstract. *Thanks to computing power increase, risk quantification relies more and more on computer modelling. Methods of risk quantification based on a fixed computational budget exist, but computer models are almost always considered as a single black box.*

In this paper, we are interested in analyzing the behavior of a complex phenomenon, whose evolution can be modelled via two nested parametrized computer models. By two nested computer models, we mean that some inputs of the second model are outputs of the first model. Based on series of observations of the considered phenomenon, the idea is, first, to calibrate the parameters of each model, and then, to construct a predictor for the output of the second model, which takes into account the fact that, on the first hand, the two models are not perfect, and on the other hand, there exist uncertainties in the parameters' calibration.

Concerning the calibration of the models' parameters we distinguish between the classic "black-box" method, parallel method and grouped method. In the case of a parallel calibration, each model is calibrated separately whereas in the case of a grouped calibration, the parameters of the two models are calibrated all together. In both cases, the extent to which the proposed predictor integrates the uncertainties of the nested system is demonstrated. The proposed methods are then applied to an example.

1 INTRODUCTION

In this paper, we are interested in analyzing the behavior of a complex phenomenon, whose evolution can be modeled by two nested parametrized computer models. By two nested computer models, we mean that some inputs of the second model are outputs of the first model. The computer models are assumed linear with respect to the models' parameters $\beta_{\mathbf{1}}$ and $\beta_{\mathbf{2}}$. Both models are supposed to be affected by model errors ϵ_1 and ϵ_2. These errors are assumed to be independent. So we have :

$$\begin{aligned} y_1(x_1) &= \mathbf{h_1}(x_1)^t \beta_{\mathbf{1}} + \epsilon_1(x_1) \\ y_2(x_2) &= \mathbf{h_2}(x_2)^t \beta_{\mathbf{2}} + \epsilon_2(x_2) \\ x_2 &= y_1 \end{aligned} \tag{1}$$

where :

- $x_1 \mapsto y_1$ and $x_2 \mapsto y_2$ are the considered phenomena, $x_1 \in \mathbb{R}$, $x_2 \in \mathbb{R}$, $y_1 \in \mathbb{R}$ and $y_2 \in \mathbb{R}$
- $\mathbf{h_1}(x_1)^t \beta_{\mathbf{1}}$ and $\mathbf{h_2}(x_2)^t \beta_{\mathbf{2}}$ the deterministic computer codes, $\mathbf{h_1}(x_1) \in \mathbb{R}^{p_1} \times 1$, $\mathbf{h_2}(x_2) \in \mathbb{R}^{p_2} \times 1$, $\beta_{\mathbf{1}} \in \mathbb{R}^{p_1} \times 1$, $\beta_{\mathbf{2}} \in \mathbb{R}^{p_2} \times 1$,
- ϵ_1 and ϵ_2 the real-valued models' errors. They are modelled by centered Gaussian processes.

The outline of this paper is the following. In section 2 is presented the general method to calibrate these two nested codes. We suppose we have access to observations of the phenomena $x_1 \mapsto y_1$, $x_2 \mapsto y_2$ and $x_1 \mapsto y_2$. In sections 3 to 5 three special cases of the general method are presented. These cases, depending on the available information, are the following :

- the parallel method. In this case, there are observations only for the phenomena $x_1 \mapsto y_1$ and $x_2 \mapsto y_2$ which are denoted by $\left(\mathbf{x_{1,obs}}^{(1)}, \mathbf{y_{1,obs}}^{(1)}\right)$ and $\left(\mathbf{x_{2,obs}}^{(2)}, \mathbf{y_{2,obs}}^{(2)}\right)$,
- the "black-box" method. In this case, there are observations only for the nested phenomenon ($x_1 \mapsto y_2$), which are denoted by $\left(\mathbf{x_{1,obs}}^{(3)}, \mathbf{y_{2,obs}}^{(3)}\right)$,
- the "grouped" method. In this case, there are observations for the phenomenon $x_1 \mapsto y_1 \mapsto y_2$, which are denoted by $\left(\mathbf{x_{1,obs}}^{(1)}, \mathbf{y_{1,obs}}^{(1)}\right)$, $\left(\mathbf{x_{2,obs}}^{(2)}, \mathbf{y_{2,obs}}^{(2)}\right)$ and $\left(\mathbf{x_{1,obs}}^{(3)}, \mathbf{y_{2,obs}}^{(3)}\right)$, where $\mathbf{y_{1,obs}}^{(1)} = \mathbf{x_{2,obs}}^{(2)}$, $\mathbf{x_{1,obs}}^{(3)} = \mathbf{x_{1,obs}}^{(1)}$ and $\mathbf{y_{2,obs}}^{(2)} = \mathbf{y_{2,obs}}^{(3)}$.

Note : notations $^{(1)}$, $^{(2)}$ and $^{(3)}$ correspond to first phenomenon, second phenomenon and nested phenomenon.
Finally in section 6 the three specific cases of the general method are applied on a numerical example.

2 THE GENERAL METHOD

In this section we propose a general framework to calibrate nested codes and build posterior predictors of these codes by taking into account observations of the three phenomena ($x_1 \mapsto y_1$, $x_2 \mapsto y_2$ and $x_1 \mapsto y_2$).

2.1 Nested model linearization

According to equation (1) the relation between y_2 and x_1 is given by :

$$y_2(x_1) = \mathbf{h_2}\left(\mathbf{h_1}(x_1)^t \beta_\mathbf{1} + \epsilon_1(x_1)\right)^t \beta_\mathbf{2} + \epsilon_2\left(\mathbf{h_1}(x_1)^t \beta_\mathbf{1} + \epsilon_1(x_1)\right), \tag{2}$$

Assuming that nominal values $\bar{\beta}_\mathbf{1}$ and $\bar{\beta}_\mathbf{2}$ of $\beta_\mathbf{1}$ and $\beta_\mathbf{2}$ are available such that in the vicinity of $\bar{\beta}_\mathbf{1}$, $\mathbf{h_1}(x_1)^t\left(\beta_\mathbf{1} - \bar{\beta}_\mathbf{1}\right) + \epsilon_1(x_1)$ is small, we get a linear approximation of the nested code and its error :

$$y_3(x_1) = \mathbf{h_3}(x_1)^t \beta_\mathbf{c} + \epsilon_3(x_1), \tag{3}$$

where $\epsilon_3(x_1)$ is the proposed model error :

$$\epsilon_3(x_1) = \Delta F_{2c}\left(x_1, \bar{\beta}_\mathbf{c}\right)\epsilon_1(x_1) + \epsilon_2\left(\mathbf{h_1}(x_1)^t \bar{\beta}_\mathbf{1}\right), \tag{4}$$

and :

$$\begin{aligned}
\mathbf{h_3}(x_1) &= \begin{bmatrix} \mathbf{h_{31}}(x_1) \\ \mathbf{h_{32}}(x_1) \end{bmatrix} \\
y_3(x_1) &= y_2(x_1) + \mathbf{h_{31}}(x_1)^t \bar{\beta}_\mathbf{1} \\
\mathbf{h_{31}}(x_1) &= \Delta F_{2c}\left(x_1, \bar{\beta}_\mathbf{c}\right)\mathbf{h_1}(x_1) \\
\mathbf{h_{32}}(x_1) &= \mathbf{h_2}\left(\mathbf{h_1}(x_1)^t \bar{\beta}_\mathbf{1}\right) \\
\Delta F_{2c}\left(x_1, \bar{\beta}_\mathbf{c}\right) &= \tfrac{\partial \mathbf{h_2}}{\partial x_2}\left(\mathbf{h_1}(x_1)^t \bar{\beta}_\mathbf{1}\right)^t \bar{\beta}_\mathbf{2} \\
\bar{\beta}_\mathbf{c} &= \begin{bmatrix} \bar{\beta}_\mathbf{1} \\ \bar{\beta}_\mathbf{2} \end{bmatrix}.
\end{aligned} \tag{5}$$

Given equations (1) and (3) a joint model for the three phenomena ($x_1 \mapsto y_1$, $x_2 \mapsto y_2$ and $x_1 \mapsto y_2$) is proposed :

$$\mathbf{y_{gp}}(\mathbf{x_{gp}})\,|\beta_\mathbf{c} \sim \mathcal{N}\left(\mathbf{h_{gp}}(\mathbf{x_{gp}})^t \beta_\mathbf{c},\ \mathbf{C_{gp}}\left(\mathbf{x_{gp}}; \mathbf{x'_{gp}}\right)\right) \tag{6}$$

where :

$$\beta_\mathbf{c} = \begin{bmatrix} \beta_\mathbf{1} \\ \beta_\mathbf{2} \end{bmatrix}, \tag{7}$$

$$\mathbf{x_{gp}} = \left(x_1^{(1)}, x_2^{(2)}, x_1^{(3)}\right), \tag{8}$$

$$\mathbf{y_{gp}}\left(\mathbf{x_{gp}}\right) = \begin{bmatrix} y_1\left(x_1^{(1)}\right) \\ y_2\left(x_2^{(2)}\right) \\ y_3\left(x_1^{(3)}\right) \end{bmatrix}, \tag{9}$$

$$\mathbf{h_{gp}}\left(\mathbf{x_{gp}}\right)^t = \begin{bmatrix} \mathbf{h_1}\left(x_1^{(1)}\right)^t & 0 \\ 0 & \mathbf{h_2}\left(x_2^{(2)}\right)^t \\ \mathbf{h_{31}}\left(x_1^{(3)}\right)^t & \mathbf{h_{32}}\left(x_1^{(3)}\right)^t \end{bmatrix}, \tag{10}$$

$$\mathbf{C_{gp}}\left(x_1^{(1)}, x_2^{(2)}, x_1^{(3)}; x_1^{'(1)}, x_2^{'(2)}, x_1^{'(3)}\right) = \tag{11}$$

$$\begin{bmatrix} C_1\left(x_1^{(1)}, x_1^{'(1)}\right) & 0 & C_1\left(x_1^{(1)}, x_1^{'(3)}\right)\Delta F_{2c}\left(x_1^{'(3)}, \bar{\beta}_{\mathbf{c}}\right) \\ 0 & C_2\left(x_2^{(2)}, x_2^{'(2)}\right) & C_2\left(x_2^{(2)}, \mathbf{h_1}\left(x_1^{'(3)}\right)^t \bar{\beta}_{\mathbf{1}}\right) \\ \Delta F_{2c}\left(x_1^{(3)}, \bar{\beta}_{\mathbf{c}}\right) C_1\left(x_1^{(3)}, x_1^{'(1)}\right) & C_2\left(\mathbf{h_1}\left(x_1^{(3)}\right)^t \bar{\beta}_{\mathbf{1}}, x_2^{'(2)}\right) & C_3\left(x_1^{(3)}, x_1^{'(3)}\right) \end{bmatrix},$$

and C_1, C_2 and C_3 are the covariance functions of ϵ_1, ϵ_2 and ϵ_3 errors.
Given equation (6), in the case of uninformative prior or Gaussian prior for $\beta_{\mathbf{c}}$, the parameters' distribution and the posterior predictive distribution given the observations, are Gaussian (see [1], [6], [7], [11] [12]).
The following sections present the parameters' calibration and the prediction given series of observations according to the model presented above.

2.2 Calibration of the codes' parameters and posterior predictive distributions

Given equation (6), we have :

$$\mathbf{y_{gp,obs}}|\beta_{\mathbf{c}} \sim \mathcal{N}\left(\mathbf{H_{gp}}\beta_{\mathbf{c}}\,,\,\mathbf{R_{gp}}\right), \tag{12}$$

where :

$$\mathbf{y_{gp,obs}} = \begin{bmatrix} \mathbf{y_{1,obs}}^{(1)} \\ \mathbf{y_{2,obs}}^{(2)} \\ \mathbf{y_{3,obs}}^{(3)} \end{bmatrix}, \tag{13}$$

$$\mathbf{y_{3,obs}}^{(3)} = \mathbf{y_{2,obs}}^{(3)} + \mathbf{h_{31}}\left(\mathbf{x_{1,obs}}^{(3)}\right)^t \bar{\beta}_{\mathbf{1}}, \tag{14}$$

$$\mathbf{x_{gp,obs}} = \begin{bmatrix} \mathbf{x_{1,obs}}^{(1)} \\ \mathbf{x_{2,obs}}^{(2)} \\ \mathbf{x_{1,obs}}^{(3)} \end{bmatrix}, \tag{15}$$

$$\mathbf{H_{gp}} = \mathbf{h_{gp}}\left(\mathbf{x_{gp,obs}}\right)^t, \tag{16}$$

$$\mathbf{R_{gp}} = \mathbf{C_{gp}}\left(\mathbf{x_{gp,obs}}; \mathbf{x_{gp,obs}}\right). \tag{17}$$

Given equation (12), the posterior distribution of $\beta_{\mathbf{c}}$ given the observations $\mathbf{y_{gp,obs}}$ can be modeled in a Bayesian framework. We distinguish two cases :

- No prior information case :
$$\pi^{prior}\left[\beta_{\mathbf{c}}\right] \sim 1 \tag{18}$$

- Gaussian prior case :
$$\pi^{prior}\left[\beta_{\mathbf{c}}\right] \sim \mathcal{N}\left(\ \widehat{\beta}_{\mathbf{c}}^{prior}\ ,\ {\mathbf{R}_{\beta_{\mathbf{c}}}}^{prior}\ \right) \tag{19}$$

In a Bayesian framework, in these two cases, the parameters' posterior distribution is Gaussian :

$$\beta_{\mathbf{c}} \mid \mathbf{y_{gp,obs}} \sim \mathcal{N}\left(\ \mathbb{E}\left(\beta_{\mathbf{c}} \mid \mathbf{y_{gp,obs}}\right)\ ,\ cov\left(\beta_{\mathbf{c}} \mid \mathbf{y_{gp,obs}}\right)\ \right) \tag{20}$$

where :

- in the no prior information case :
$$\begin{aligned} cov\left(\beta_{\mathbf{c}} \mid \mathbf{y_{gp,obs}}\right) &= \mathbf{R}_{\beta_{\mathbf{c}}} = \left(\mathbf{H_{gp}}^t {\mathbf{R_{gp}}}^{-1} \mathbf{H_{gp}}\right)^{-1} \\ \mathbb{E}\left(\beta_{\mathbf{c}} \mid \mathbf{y_{gp,obs}}\right) &= \widehat{\beta}_{\mathbf{c}} = \mathbf{R}_{\beta_{\mathbf{c}}} \mathbf{H_{gp}}^t {\mathbf{R_{gp}}}^{-1} \mathbf{y_{gp,obs}} \end{aligned} \tag{21}$$

- in the Gaussian prior case :
$$\begin{aligned} \left(\mathrm{cov}\left(\beta_{\mathbf{c}} \mid \mathbf{y_{gp,obs}}\right)\right)^{-1} &= \widetilde{\mathbf{R}}_{\beta_{\mathbf{c}}}^{-1} = {\mathbf{R}_{\beta_{\mathbf{c}}}}^{-1} + \left({\mathbf{R}_{\beta_{\mathbf{c}}}}^{prior}\right)^{-1} \\ \mathbb{E}\left(\beta_{\mathbf{c}} \mid \mathbf{y_{gp,obs}}\right) &= \widetilde{\beta}_{\mathbf{c}} = \widetilde{\mathbf{R}}_{\beta_{\mathbf{c}}} \left[{\mathbf{R}_{\beta_{\mathbf{c}}}}^{-1} \widehat{\beta}_{\mathbf{c}} + \left({\mathbf{R}_{\beta_{\mathbf{c}}}}^{prior}\right)^{-1} \widehat{\beta}_{\mathbf{c}}^{prior}\right] \end{aligned} \tag{22}$$

Given equations (6), (12) and (20), the posterior predictive distribution $\mathbf{y_{gp}}\left(\mathbf{x_{gp}}\right) | \mathbf{y_{gp,obs}}$ is Gaussian. Its properties are :

$$\mathbf{y_{gp}}\left(\mathbf{x_{gp}}\right)\ |\ \mathbf{y_{gp,obs}} \sim \mathcal{N}\left(\ \widehat{y}_{gp}\left(\mathbf{x_{gp}}, \mathbb{E}\left(\beta_{\mathbf{c}} \mid \mathbf{y_{gp,obs}}\right)\right)\ ,\ \widehat{\mathbf{C}}_{\mathbf{gp}}\left(\mathbf{x_{gp}}; \mathbf{x_{gp}}\right)\ \right) \tag{23}$$

where for all $\beta_{\mathbf{c}}$:

$$\widehat{y}_{gp}\left(\mathbf{x_{gp}}, \beta_{\mathbf{c}}\right) = \mathbf{h_{gp}}\left(\mathbf{x_{gp}}\right)^t \beta_{\mathbf{c}} + \mathbf{r_{gp}}\left(\mathbf{x_{gp}}\right)^t {\mathbf{R_{gp}}}^{-1} \left(\mathbf{y_{gp,obs}} - \mathbf{H_{gp}} \beta_{\mathbf{c}}\right) \tag{24}$$

$$\mathbf{r_{gp}}\left(\mathbf{x_{gp}}\right) = \mathbf{C_{gp}}\left(\mathbf{x_{gp,obs}}; \mathbf{x_{gp}}\right) \tag{25}$$

$$\begin{aligned} \widehat{\mathbf{C}}_{\mathbf{gp}}\left(\mathbf{x_{gp}}; \mathbf{x'_{gp}}\right) = \ & \mathbf{C_{gp}}\left(\mathbf{x_{gp}}; \mathbf{x'_{gp}}\right) - \mathbf{r_{gp}}\left(\mathbf{x_{gp}}\right)^t {\mathbf{R_{gp}}}^{-1} \mathbf{r_{gp}}\left(\mathbf{x'_{gp}}\right) \\ & + \mathbf{u_{gp}}\left(\mathbf{x_{gp}}\right)^t \mathrm{cov}\left(\beta_{\mathbf{c}} \mid \mathbf{y_{gp,obs}}\right) \mathbf{u_{gp}}\left(\mathbf{x'_{gp}}\right) \end{aligned} \tag{26}$$

$$\mathbf{u_{gp}}\left(\mathbf{x_{gp}}\right) = \mathbf{h_{gp}}\left(\mathbf{x_{gp}}\right) - \mathbf{H_{gp}}{\mathbf{R_{gp}}}^{-1}\mathbf{r_{gp}}\left(\mathbf{x_{gp}}\right) \tag{27}$$

In the following sections are presented three specific cases of the general method previously introduced. The cases are distinguished according to the type of available observations.

3 THE PARALLEL APPROACH

In this section we present a particular case of the previously presented general framework. The parallel method corresponds to the case where only observations of the phenomena $x_1 \mapsto y_1$ and $x_2 \mapsto y_2$ are available.

3.1 Key features of the approach

In the parallel approach, there is no observation for the nested phenomenon, that is : $\left({\mathbf{x_{1,obs}}}^{(3)}, {\mathbf{y_{2,obs}}}^{(3)}\right) = \emptyset$.
This method includes the following steps :

1. the parameters' calibration given the observations $\left({\mathbf{x_{1,obs}}}^{(1)}, {\mathbf{y_{1,obs}}}^{(1)}\right)$ and $\left({\mathbf{x_{2,obs}}}^{(2)}, {\mathbf{y_{2,obs}}}^{(2)}\right)$. Considering that the covariance matrix given by equation (11) is a block diagonal matrix, it is like $\beta_{\mathbf{1}}$ and $\beta_{\mathbf{2}}$ were calibrated separately given the observations $\left({\mathbf{x_{1,obs}}}^{(1)}, {\mathbf{y_{1,obs}}}^{(1)}\right)$ and $\left({\mathbf{x_{2,obs}}}^{(2)}, {\mathbf{y_{2,obs}}}^{(2)}\right)$.
2. the construction of the posterior predictors given the observations :
   (a) for the phenomenon 1 : the proposed predictor is an interpolating Gaussian predictor given the observations $\left({\mathbf{x_{1,obs}}}^{(1)}, {\mathbf{y_{1,obs}}}^{(1)}\right)$
   (b) for the phenomenon 2 : the proposed predictor is an interpolating Gaussian predictor given the observations $\left({\mathbf{x_{2,obs}}}^{(2)}, {\mathbf{y_{2,obs}}}^{(2)}\right)$
   (c) for the nested phenomenon : the proposed predictor is Gaussian thanks to a linearization of the coupling of the Gaussian predictors of the phenomena 1 and 2 (see 3.2).

The following section presents how the predictor of the nested code is built in the parallel approach.

3.2 Parallel predictor for the nested code

As shown above, we have two posterior Gaussian predictors given the observations :

$$y_{pred,i}\left(x_i\right) = y_i\left(x_i\right) \mid \left({\mathbf{x_{i,obs}}}^{(i)}, {\mathbf{y_{i,obs}}}^{(i)}\right) \sim \mathcal{N}\left(\, \widehat{y}_i\left(x_i, \beta_{\mathbf{i}}\right) \,,\, \widehat{C}_i\left(x_i, x_i\right) \right) \quad i = \{1, 2\} \tag{28}$$

where :

$$\widehat{y}_i\left(x_i, \beta_{\mathbf{i}}\right) = \mathbf{h_i}\left(x_i\right)^t \beta_{\mathbf{i}} + \mathbf{r_i}\left(x_i\right)^t {\mathbf{R_i}}^{-1}\left({\mathbf{y_{i,obs}}}^{(i)} - \mathbf{h_i}\left({\mathbf{x_{i,obs}}}^{(i)}\right)^t \beta_{\mathbf{i}}\right) \tag{29}$$

$$\mathbf{r_i}\left(x_i\right) = C_i\left(\mathbf{x_{i,obs}}^{(i)}; x_i\right) \tag{30}$$

$$\mathbf{R_i} = C_i\left(\mathbf{x_{i,obs}}^{(i)}; \mathbf{x_{i,obs}}^{(i)}\right) \tag{31}$$

$$\widehat{C}_i\left(x_i; x_i'\right) = C_i\left(x_i; x_i'\right) - \mathbf{r_i}\left(x_i\right)^t \mathbf{R_i}^{-1}\mathbf{r_i}\left(x_i'\right) - \mathbf{u_i}\left(x_i\right)^t \mathbf{R_{\beta_i}}^{-1}\mathbf{u_i}\left(x_i'\right) \tag{32}$$

$$\mathbf{u_i}\left(x_i\right) = \mathbf{h_i}\left(x_i\right) - \mathbf{h_i}\left(\mathbf{x_{i,obs}}^{(i)}\right)\mathbf{R_i}^{-1}\mathbf{r_i}\left(x_i\right) \tag{33}$$

Given equation (28) the posterior predictor for the nested phenomenon can be written :

$$y_{pred,3}\left(x_1, \beta_{\mathbf{c}}\right) = \widehat{y}_2\left(\widehat{y}_1\left(x_1, \beta_{\mathbf{1}}\right) + \delta\widehat{y}_1\left(x_1\right), \beta_{\mathbf{2}}\right) + \delta\widehat{y}_2\left(\widehat{y}_1\left(x_1, \beta_{\mathbf{1}}\right) + \delta\widehat{y}_1\left(x_1\right)\right) \tag{34}$$

where :

$$\delta\widehat{y}_i\left(x_i\right) \sim \mathscr{N}\left(0\ ,\ \widehat{C}_i\left(x_i; x_i\right)\right) \quad i = \{1, 2\} \tag{35}$$

Thanks to a first order Taylor series expansion and making the following approximation according to equation (29)

$$\frac{\partial\widehat{y}_2}{\partial x_2}\left(x, \beta\right) = \left[\frac{\partial\mathbf{h_2}}{\partial x_2}\left(x\right)\right]^t \beta \tag{36}$$

the posterior predictor for the nested code is :

$$y_{pred,3}\left(x_1, \widehat{\beta}_{\mathbf{c}}\right) \simeq \widehat{y}_2\left(\widehat{y}_1\left(x_1, \widehat{\beta}_{\mathbf{1}}\right), \widehat{\beta}_{\mathbf{2}}\right) + \left[\frac{\partial\mathbf{h_2}}{\partial x_2}\left(\widehat{y}_1\left(x_1, \widehat{\beta}_{\mathbf{1}}\right)\right)\right]^t \widehat{\beta}_{\mathbf{2}}\delta\widehat{y}_1\left(x_1\right) + \delta\widehat{y}_2\left(\widehat{y}_1\left(x_1, \widehat{\beta}_{\mathbf{1}}\right)\right) \tag{37}$$

It is a linear combination of the independent Gaussian processes $\delta\widehat{y}_1$ and $\delta\widehat{y}_2$, thus it is a Gaussian predictor.
Table 1 summarizes the 'parallel' method's characteristics.

Table 2 presents the MSE of the calibrated codes and predictors for the 'parallel' method.

4 THE 'BLACK-BOX' APPROACH

In this section we present a particular case of the previously presented general framework (see 2). The 'black-box' method corresponds to the case where only observations of the phenomenon $x_1 \mapsto y_2$ are available, that is $\left(\mathbf{x_{1,obs}}^{(1)}, \mathbf{y_{1,obs}}^{(1)}\right) = \emptyset$ and $\left(\mathbf{x_{2,obs}}^{(2)}, \mathbf{y_{2,obs}}^{(2)}\right) = \emptyset$.
About the nested model's error, the following cases are distinguished :

- ϵ_1 and ϵ_2, are known, so the error is given by equation (4),
- ϵ_1 and ϵ_2 are unknown, so a specific model error for the nested code is proposed (it is assumed to be a zero-mean stationary Gaussian process).

Nested model error	The nested model error is not used because there is no observation for the nested phenomenon.
Calibration of parameters $\beta_{\mathbf{c}} = (\beta_{\mathbf{1}}, \beta_{\mathbf{2}})$	• $\beta_{\mathbf{1}}$ is calibrated given the observations for $x_1 \mapsto y_1$, • $\beta_{\mathbf{2}}$ is calibrated given the observations for $x_2 \mapsto y_2$.
Posterior predictor for phenomenon $x_1 \mapsto y_1$	Gaussian predictor given the observations of the phenomenon $x_1 \mapsto y_1$
Posterior predictor for phenomenon $x_2 \mapsto y_2$	Gaussian predictor given the observations of the phenomenon $x_2 \mapsto y_2$
Posterior predictor for phenomenon $x_1 \mapsto y_2$	Gaussian predictor thanks to a linearization of the coupling of the Gaussian predictors of the phenomena $x_1 \mapsto y_1$ and $x_2 \mapsto y_2$.

Table 1: This table summarizes the 'parallel' method's characteristics

Phenomenon	Empirical normalized integrated squared error (Empirical MSE) of the calibrated codes	Empirical normalized integrated squared error (Empirical MSE) of the posterior predictors
$x_1 \mapsto y_1$	$\frac{\sum_{x_1}\left(y_1(x_1) - \mathbf{h_1}(x_1)^t \widehat{\beta}_{\mathbf{1}}\right)^2}{\sum_{x_1}(y_1(x_1))^2}$	$\frac{1}{\sum_{x_i}(y_i(x_i))^2}\sum_{x_i}(y_i(x_i) - \mathbf{h_i}(x_i)^t \widehat{\beta}_{\mathbf{i}} - \mathbf{r_i}(x_i)^t \mathbf{R_i}^{-1}\left(\mathbf{y_{i,obs}} - \mathbf{h_i}(\mathbf{x_{i,obs}})^t \widehat{\beta}_{\mathbf{i}}\right))^2$ $i = \{1, 2\}$
$x_2 \mapsto y_2$	$\frac{\sum_{x_2}\left(y_2(x_2) - \mathbf{h_2}(x_2)^t \widehat{\beta}_{\mathbf{2}}\right)^2}{\sum_{x_2}(y_2(x_2))^2}$	
$x_1 \mapsto y_2$	$\frac{1}{\sum_{x_1}(y_2(x_1))^2}\sum_{x_1}(y_2(x_1) - \mathbf{h_2}\left(\mathbf{h_1}(x_1)^t \widehat{\beta}_{\mathbf{1}}\right)^t \widehat{\beta}_{\mathbf{2}})^2$	$\frac{\sum_{x_1}\left(y_2(x_1) - \widehat{y}_2\left(\widehat{y}_1\left(x_1, \widehat{\beta}_{\mathbf{1}}\right), \widehat{\beta}_{\mathbf{2}}\right)\right)^2}{\sum_{x_1}(y_2(x_1))^2}$

Table 2: This table presents the normalized empirical integrated mean squared error of the calibrated codes and predictors for the 'parallel' method

Nested model error	Two cases are distinguished : • ϵ_1 and ϵ_2, are known, so the error is given by equation (4), • ϵ_1 and ϵ_2 are unknown, so a specific model error for the nested code is proposed (it is assumed to be a zero-mean stationary Gaussian process).
Calibration of parameters $\beta_{\mathbf{c}} = (\beta_{\mathbf{1}}, \beta_{\mathbf{2}})$	$\beta_{\mathbf{c}}$ is calibrated given the observations for $x_1 \mapsto y_2$
Posterior predictor for phenomenon $x_1 \mapsto y_1$	First code using the posterior distribution of $\beta_{\mathbf{1}}$
Posterior predictor for phenomenon $x_2 \mapsto y_2$	Second code using the posterior distribution of $\beta_{\mathbf{2}}$
Posterior predictor for phenomenon $x_1 \mapsto y_2$	Gaussian predictor given the observations of the phenomenon $x_1 \mapsto y_2$

Table 3: This table summarizes the 'black-box' method's characteristics

The method includes the following steps :

1. the parameters' calibration given the observations $\left({\mathbf{x}_{\mathbf{1},\mathbf{obs}}}^{(3)}, {\mathbf{y}_{\mathbf{2},\mathbf{obs}}}^{(3)}\right)$,
2. the construction of the posterior predictors given the observations :
   (a) for the phenomenon 1 : there is no observation $\left({\mathbf{x}_{\mathbf{1},\mathbf{obs}}}^{(1)}, {\mathbf{y}_{\mathbf{1},\mathbf{obs}}}^{(1)}\right)$, so the proposed predictor is the calibrated code. Thanks to the code's linearity and the parameters' Gaussian distribution the calibrated code's distribution is Gaussian with :
      - mean : $\mathbf{h_1}\left(x_1\right)^t \mathbb{E}\left(\beta_{\mathbf{1}} \mid \left({\mathbf{x}_{\mathbf{1},\mathbf{obs}}}^{(3)}, {\mathbf{y}_{\mathbf{2},\mathbf{obs}}}^{(3)}\right)\right)$
      - and variance : $\mathbf{h_1}\left(x_1\right)^t \mathrm{cov}\left(\beta_{\mathbf{1}} \mid \left({\mathbf{x}_{\mathbf{1},\mathbf{obs}}}^{(3)}, {\mathbf{y}_{\mathbf{2},\mathbf{obs}}}^{(3)}\right)\right) \mathbf{h_1}\left(x_1\right)$

   (b) for the phenomenon 2 : there is no observation $\left({\mathbf{x}_{\mathbf{2},\mathbf{obs}}}^{(2)}, {\mathbf{y}_{\mathbf{2},\mathbf{obs}}}^{(2)}\right)$, so the proposed predictor is the calibrated code. Thanks to the code's linearity and the parameters' Gaussian distribution the calibrated code's distribution is Gaussian with :
      - mean : $\mathbf{h_2}\left(x_2\right)^t \mathbb{E}\left(\beta_{\mathbf{2}} \mid {\mathbf{y}_{\mathbf{2},\mathbf{obs}}}^{(2)}\left({\mathbf{x}_{\mathbf{1},\mathbf{obs}}}^{(3)}\right)\right)$
      - and variance : $\mathbf{h_2}\left(x_2\right)^t \mathrm{cov}\left(\beta_{\mathbf{2}} \mid \left({\mathbf{x}_{\mathbf{1},\mathbf{obs}}}^{(3)}, {\mathbf{y}_{\mathbf{2},\mathbf{obs}}}^{(3)}\right)\right) \mathbf{h_2}\left(x_2\right)$

   (c) for the nested phenomenon : the proposed predictor is an interpolating Gaussian predictor given the observations $\left({\mathbf{x}_{\mathbf{1},\mathbf{obs}}}^{(3)}, {\mathbf{y}_{\mathbf{2},\mathbf{obs}}}^{(3)}\right)$

Table 3 summarizes the 'black-box' method's characteristics.
Table 4 presents the normalized empirical integrated mean squared error of the calibrated codes and predictors of this method.

Phenomenon	Empirical normalized integrated squared error (Empirical MSE) of the calibrated codes	Empirical normalized integrated squared error (Empirical MSE) of the posterior predictors
$x_1 \mapsto y_1$	$\frac{\sum_{x_1}\left(y_1(x_1)-\mathbf{h_1}(x_1)^t\widehat{\beta}_\mathbf{1}\right)^2}{\sum_{x_1}(y_1(x_1))^2}$	
$x_2 \mapsto y_2$	$\frac{\sum_{x_2}\left(y_2(x_2)-\mathbf{h_2}(x_2)^t\widehat{\beta}_\mathbf{2}\right)^2}{\sum_{x_2}(y_2(x_2))^2}$	
$x_1 \mapsto y_2$	$\frac{1}{\sum_{x_1}(y_2(x_1))^2}\sum_{x_1}(y_2(x_1) -\mathbf{h_2}\left(\mathbf{h_1}(x_1)^t\widehat{\beta}_\mathbf{1}\right)^t\widehat{\beta}_\mathbf{2})^2$	$\frac{1}{\sum_{x_1}(y_2(x_1))^2}\sum_{x_1}(y_3(x_1) - \mathbf{h_3}(x_1)^t\widehat{\beta}_\mathbf{c} -\mathbf{r_3}(x_1)^t\mathbf{R_3}^{-1}\left(\mathbf{y_{3,obs}} - \mathbf{h_3}(\mathbf{x_{1,obs}})^t\widehat{\beta}_\mathbf{c}\right))^2$ where : $\mathbf{r_3}(x_1)^t = C_3(x_1;\mathbf{x_{1,obs}})$ $\mathbf{R_3} = C_3(\mathbf{x_{1,obs}};\mathbf{x_{1,obs}})$

Table 4: This table presents the normalized empirical integrated mean squared error of the calibrated codes and predictors for the 'black-box' method

Nested model error	Zero-mean Gaussian process, combination of the propagation of the first phenomenon's uncertainty ϵ_1 and the second phenomenon's uncertainty ϵ_2 (ϵ_1 et ϵ_2 zero-mean Gaussian process with covariance function Matérn $\frac{5}{2}$), see equation (4)
Calibration of parameters $\beta_{\mathbf{c}} = (\beta_{\mathbf{1}}, \beta_{\mathbf{2}})$	$\beta_{\mathbf{c}}$ is calibrated given the observations of the three phenomena ($x_1 \mapsto y_1$, $x_2 \mapsto y_2$ and $x_1 \mapsto y_2$)
Posterior predictor for phenomenon $x_1 \mapsto y_1$	Gaussian predictor given the observations of the three phenomena ($x_1 \mapsto y_1$, $x_2 \mapsto y_2$ and $x_1 \mapsto y_2$)
Posterior predictor for phenomenon $x_2 \mapsto y_2$	Gaussian predictor given the observations of the three phenomena ($x_1 \mapsto y_1$, $x_2 \mapsto y_2$ and $x_1 \mapsto y_2$)
Posterior predictor for phenomenon $x_1 \mapsto y_2$	Gaussian predictor given the observations of the three phenomena ($x_1 \mapsto y_1$, $x_2 \mapsto y_2$ and $x_1 \mapsto y_2$)

Table 5: This table summarizes the 'grouped' method's characteristics

5 THE 'GROUPED' APPROACH

In this section we present a particular case of the previously presented general framework (see 2). The 'grouped' method corresponds to the case where observations are chosen for the phenomenon $x_1 \mapsto y_1 \mapsto y_2$. So we have ${\mathbf{x}_{\mathbf{1},\mathbf{obs}}}^{(1)} = {\mathbf{x}_{\mathbf{1},\mathbf{obs}}}^{(3)}$, ${\mathbf{x}_{\mathbf{2},\mathbf{obs}}}^{(2)} = {\mathbf{y}_{\mathbf{1},\mathbf{obs}}}^{(1)}$ and ${\mathbf{y}_{\mathbf{2},\mathbf{obs}}}^{(2)} = {\mathbf{y}_{\mathbf{2},\mathbf{obs}}}^{(3)}$.
The method includes the following steps :

1. the parameters' calibration given the observations $\left({\mathbf{x}_{\mathbf{1},\mathbf{obs}}}^{(1)}, {\mathbf{y}_{\mathbf{1},\mathbf{obs}}}^{(1)}\right)$, $\left({\mathbf{x}_{\mathbf{2},\mathbf{obs}}}^{(2)}, {\mathbf{y}_{\mathbf{2},\mathbf{obs}}}^{(2)}\right)$ and $\left({\mathbf{x}_{\mathbf{1},\mathbf{obs}}}^{(3)}, {\mathbf{y}_{\mathbf{2},\mathbf{obs}}}^{(3)}\right)$,
2. the construction of the posterior predictors given the observations :
   (a) for the phenomenon 1 : the proposed predictor is an interpolating Gaussian predictor given the observations $\left({\mathbf{x}_{\mathbf{1},\mathbf{obs}}}^{(1)}, {\mathbf{y}_{\mathbf{1},\mathbf{obs}}}^{(1)}\right)$, $\left({\mathbf{x}_{\mathbf{2},\mathbf{obs}}}^{(2)}, {\mathbf{y}_{\mathbf{2},\mathbf{obs}}}^{(2)}\right)$ and $\left({\mathbf{x}_{\mathbf{1},\mathbf{obs}}}^{(3)}, {\mathbf{y}_{\mathbf{2},\mathbf{obs}}}^{(3)}\right)$,
   (b) for the phenomenon 2 : the proposed predictor is an interpolating Gaussian predictor given the observations $\left({\mathbf{x}_{\mathbf{1},\mathbf{obs}}}^{(1)}, {\mathbf{y}_{\mathbf{1},\mathbf{obs}}}^{(1)}\right)$, $\left({\mathbf{x}_{\mathbf{2},\mathbf{obs}}}^{(2)}, {\mathbf{y}_{\mathbf{2},\mathbf{obs}}}^{(2)}\right)$ and $\left({\mathbf{x}_{\mathbf{1},\mathbf{obs}}}^{(3)}, {\mathbf{y}_{\mathbf{2},\mathbf{obs}}}^{(3)}\right)$,
   (c) for the nested phenomenon : the proposed predictor is an interpolating Gaussian predictor given the observations $\left({\mathbf{x}_{\mathbf{1},\mathbf{obs}}}^{(1)}, {\mathbf{y}_{\mathbf{1},\mathbf{obs}}}^{(1)}\right)$, $\left({\mathbf{x}_{\mathbf{2},\mathbf{obs}}}^{(2)}, {\mathbf{y}_{\mathbf{2},\mathbf{obs}}}^{(2)}\right)$ and $\left({\mathbf{x}_{\mathbf{1},\mathbf{obs}}}^{(3)}, {\mathbf{y}_{\mathbf{2},\mathbf{obs}}}^{(3)}\right)$.

Table 5 summarizes the 'grouped' method's characteristics. Table 6 presents the normalized empirical integrated mean squared error of the calibrated codes and predictors of this method.

6 NUMERICAL EXAMPLE

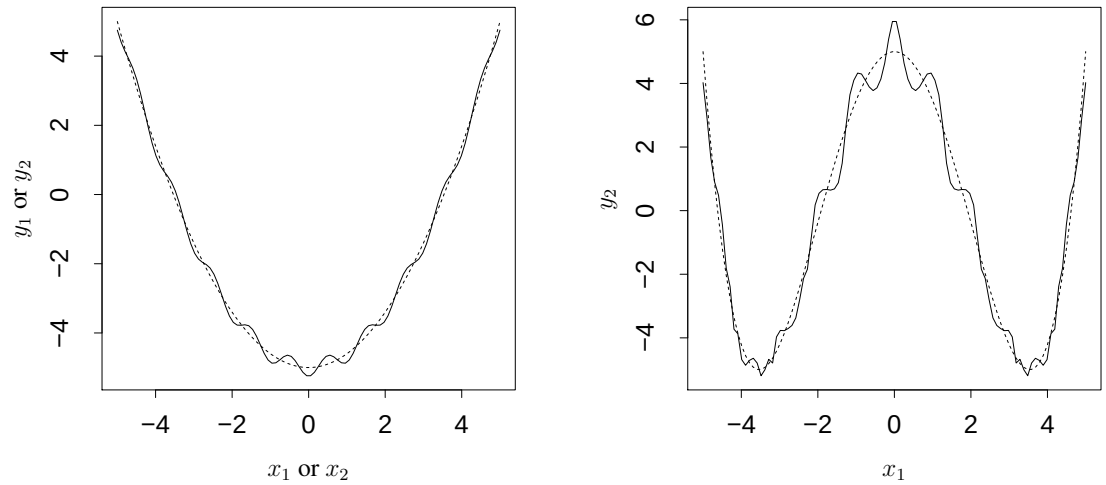
In this section we apply the previously presented particular cases of the general method on a numerical example. In this example we study a computer model coupled with itself.

Phenomenon	Empirical normalized integrated squared error (Empirical MSE) of the calibrated codes	Empirical normalized integrated squared error (Empirical MSE) of the posterior predictors
$x_1 \mapsto y_1$	$\frac{\sum_{x_1}\left(y_1(x_1) - \mathbf{h_1}(x_1)^t \widehat{\beta}_{\mathbf{1}}\right)^2}{\sum_{x_1}(y_1(x_1))^2}$	$\frac{1}{\sum_{x_1}(y_1(x_1))^2}\sum_{x_1}(y_1(x_1) - \mathbf{h_{gp}}(\mathbf{x_{gp,1}})^t \widehat{\beta}_{\mathbf{c}}$ $-\mathbf{r_{gp}}(\mathbf{x_{gp,1}})^t \mathbf{R_{gp}}^{-1}\left(\mathbf{y_{gp,obs}} - \mathbf{h_{gp}}(\mathbf{x_{gp,obs}})^t \widehat{\beta}_{\mathbf{c}}\right))^2$ where : $\mathbf{x_{gp,1}} = (x_1, \emptyset, \emptyset)$
$x_2 \mapsto y_2$	$\frac{\sum_{x_2}\left(y_2(x_2) - \mathbf{h_2}(x_2)^t \widehat{\beta}_{\mathbf{2}}\right)^2}{\sum_{x_2}(y_2(x_2))^2}$	$\frac{1}{\sum_{x_2}(y_2(x_2))^2}\sum_{x_2}(y_2(x_2) - \mathbf{h_{gp}}(\mathbf{x_{gp,2}})^t \widehat{\beta}_{\mathbf{c}}$ $-\mathbf{r_{gp}}(\mathbf{x_{gp,2}})^t \mathbf{R_{gp}}^{-1}\left(\mathbf{y_{gp,obs}} - \mathbf{h_{gp}}(\mathbf{x_{gp,obs}})^t \widehat{\beta}_{\mathbf{c}}\right))^2$ where : $\mathbf{x_{gp,2}} = (\emptyset, x_2, \emptyset)$
$x_1 \mapsto y_2$	$\frac{1}{\sum_{x_1}(y_2(x_1))^2}\sum_{x_1}(y_2(x_1)$ $-\mathbf{h_2}\left(\mathbf{h_1}(x_1)^t \widehat{\beta}_{\mathbf{1}}\right)^t \widehat{\beta}_{\mathbf{2}})^2$	$\frac{1}{\sum_{x_1}(y_2(x_1))^2}\sum_{x_1}(y_3(x_1) - \mathbf{h_{gp}}(\mathbf{x_{gp,3}})^t \widehat{\beta}_{\mathbf{c}}$ $-\mathbf{r_{gp}}(\mathbf{x_{gp,3}})^t \mathbf{R_{gp}}^{-1}\left(\mathbf{y_{gp,obs}} - \mathbf{h_{gp}}(\mathbf{x_{gp,obs}})^t \widehat{\beta}_{\mathbf{c}}\right))^2$ where : $\mathbf{x_{gp,3}} = (\emptyset, \emptyset, x_1)$

Table 6: This table presents the normalized empirical integrated mean squared error of the calibrated codes and predictors for the 'grouped' method

Method	Average variance over a test set according to the source of uncertainty
General method	$\epsilon_{cond} = \mathbb{E}_{\mathbf{x_{gp}}^{gal}=(\emptyset,\emptyset,x_1)}\left[\mathbf{C_{gp}}\left(\mathbf{x_{gp}}^{gal};\mathbf{x_{gp}}^{gal}\right) - \mathbf{r_{gp}}\left(\mathbf{x_{gp}}^{gal}\right)^t \mathbf{R_{gp}}^{-1}\mathbf{r_{gp}}\left(\mathbf{x_{gp}}^{gal}\right)\right]$ $\epsilon_{\beta} = \mathbb{E}_{\mathbf{x_{gp}}^{gal}=(\emptyset,\emptyset,x_1)}\left[\mathbf{u_{gp}}\left(\mathbf{x_{gp}}^{gal}\right)^t \text{cov}\left(\beta_{\mathbf{c}} \mid \mathbf{x_{gp,obs}}\right)\mathbf{u_{gp}}\left(\mathbf{x_{gp}}^{gal}\right)\right]$
Parallel method	$\epsilon_{cond} = \epsilon_{cond,1} + \epsilon_{cond,2}$ $\epsilon_{cond,1} = \mathbb{E}_{x_1}\left[\left[\frac{\partial \mathbf{h_2}}{\partial x_2}\left(\widehat{y}_1\left(x_1,\widehat{\beta}_{\mathbf{1}}\right)\right)\right]^t \widehat{\beta}_{\mathbf{2}}\left(\sigma_1^2 - \mathbf{r_1}\left(x_1\right)^t \mathbf{R_1}^{-1}\mathbf{r_1}\left(x_1\right)\right)\right]$ $\epsilon_{cond,2} = \mathbb{E}_{x_1}\left[\sigma_2^2 - \mathbf{r_2}\left(\widehat{y}_1\left(x_1,\widehat{\beta}_{\mathbf{1}}\right)\right)^t \mathbf{R_2}^{-1}\mathbf{r_2}\left(\widehat{y}_1\left(x_1,\widehat{\beta}_{\mathbf{1}}\right)\right)\right]$ $\epsilon_{\beta} = \epsilon_{\beta,1} + \epsilon_{\beta,2}$ $\epsilon_{\beta,1} = \mathbb{E}_{x_1}\left[\left[\frac{\partial \mathbf{h_2}}{\partial x_2}\left(\widehat{y}_1\left(x_1,\widehat{\beta}_{\mathbf{1}}\right)\right)\right]^t \widehat{\beta}_{\mathbf{2}}\mathbf{u_1}\left(x_1\right)^t \text{cov}\left(\beta_{\mathbf{1}} \mid \mathbf{y_{1,obs}}^{(1)}\right)\mathbf{u_1}\left(x_1\right)\right]$ $\epsilon_{\beta,2} = \mathbb{E}_{x_1}\left[\mathbf{u_2}\left(\widehat{y}_1\left(x_1,\widehat{\beta}_{\mathbf{1}}\right)\right)^t \text{cov}\left(\beta_{\mathbf{2}} \mid \mathbf{y_{2,obs}}^{(2)}\right)\mathbf{u_2}\left(\widehat{y}_1\left(x_1,\widehat{\beta}_{\mathbf{1}}\right)\right)\right]$
'Black-box' method	$\epsilon_{cond} = \mathbb{E}_{x_1}\left[C_3\left(x_1;x_1\right) - \mathbf{r_3}\left(x_1\right)^t \mathbf{R_3}^{-1}\mathbf{r_3}\left(x_1\right)\right]$ $\epsilon_{\beta} = \mathbb{E}_{x_1}\left[\mathbf{u_3}\left(x_1\right)^t \text{cov}\left(\beta_{\mathbf{c}} \mid \mathbf{y_{2,obs}}^{(3)}\right)\mathbf{u_3}\left(x_1\right)\right]$ $\mathbf{u_3}\left(x_1\right) = \mathbf{h_3}\left(x_1\right) - \mathbf{h_3}\left(\mathbf{x_{1,obs}}^{(3)}\right)\mathbf{R_3}^{-1}\mathbf{r_3}\left(x_1\right)$
Grouped method	see General method

Table 7: This table presents the sources of uncertainty of the nested phenomenon's predictors. We denote by ϵ_{cond} the part of variance coming from the conditional Gaussian process and by ϵ_{β} the part of variance coming from the parameters' posterior distribution.



(a) Model (code 1 or 2) (b) Nested model

Figure 1: The continuous line corresponds to reality i.e. $y_1(x_1)$, $y_2(x_2)$ or $y_2(x_1)$ and the dashed line correspond to the codes $\mathbf{h_1}(x_1)^t \beta_\mathbf{1}$, $\mathbf{h_2}(x_2)^t \beta_\mathbf{2}$ or $\mathbf{h_2}\left(\mathbf{h_1}(x_1)^t \beta_\mathbf{1}\right)^t \beta_\mathbf{2}$. Figure 1a presents phenomena $x_1 \mapsto y_1$, $x_2 \mapsto y_2$ and figure 1b phenomenon $x_1 \mapsto y_2$.

This section is organised as follow. Firstly, the phenomenon and its associated computer code are introduced. Secondly, the way to choose the observations is presented. Thirdly, the method to estimate the hyperparameters of the model error is exposed. Fourthly, the test sets of the posterior predictors are presented. Finally the achieved results for the 'parallel', 'black-box' and 'grouped' methods on this example are showed.

6.1 Presentation of the phenomenon

The model properties of the numerical example are :

$$\mathbf{h_1}(x) = \mathbf{h_2}(x) = \begin{bmatrix} 1 \\ x^2 \end{bmatrix} \tag{38}$$

$$\begin{gathered} \beta_\mathbf{1} = \beta_\mathbf{2} = \begin{bmatrix} -5 \\ 0.4 \end{bmatrix} \\ y_1(x) = y_2(x) = \mathbf{h_1}(x)^t \beta_\mathbf{1} - \tfrac{1}{4}\cos(2\pi x) = \mathbf{h_2}(x)^t \beta_\mathbf{2} - \tfrac{1}{4}\cos(2\pi x) \end{gathered} \tag{39}$$

Figure 1 presents the model alone and the nested model. It can be seen that the errors of the phenomena $x_1 \mapsto y_1$ and $x_2 \mapsto y_2$ are regular. The error of the nested phenomenon is more chaotic.

The three previously presented methods are applied on this example.

6.2 Observations' choice

Regarding the number of observations three cases are studied : 4, 8 or 12 observations. The observations are generated given a maximin Latin Hypercube Sampling for $\mathbf{x_{1,obs}}^{(1)}$

and $\mathbf{x_{2,obs}}^{(2)}$ in the parallel method (in this example $\mathbf{x_{1,obs}}^{(1)} = \mathbf{x_{2,obs}}^{(2)}$), for $\mathbf{x_{1,obs}}^{(3)}$ for the 'black-box' method and for $\mathbf{x_{1,obs}}^{(1)}$ and $\mathbf{x_{1,obs}}^{(3)}$ for the grouped method (in this example $\mathbf{x_{1,obs}}^{(1)} = \mathbf{x_{1,obs}}^{(3)}$). The observations' sampling, the parameters' calibration and the posterior predictors' construction are repeated 50 times for each case.

6.3 Covariance functions' hyperparameters

The covariance functions' hyperparameters are assumed to be known before the parameters' calibration. In the parallel and the grouped methods the hyperparameters of the Matérn covariance functions of ϵ_1 and ϵ_2 are estimated by a Restricted Maximum Likelihood Estimator (see [1]). In the 'black-box' method, ϵ_3 is assumed to be a zero-mean stationary Gaussian process. The hyperparameters of its Matérn covariance function ϵ_3 are estimated by a Restricted Maximum Likelihood Estimator.

6.4 Analysis of the predictors' performances

Once the predictors are built, their performances are analyzed on 100 points' grids over the input space of each phenomenon. For the three phenomena the input space is $[-5, 5]$.

6.5 The parallel approach

In the parallel approach, there are observations for the phenomena $x_1 \mapsto y_1$ and $x_2 \mapsto y_2$ which are denoted by $\left(\mathbf{x_{1,obs}}^{(1)}, \mathbf{y_{1,obs}}^{(1)}\right)$ and $\left(\mathbf{x_{2,obs}}^{(2)}, \mathbf{y_{2,obs}}^{(2)}\right)$. Figure 2 presents for the phenomena $x_1 \mapsto y_1$, $x_2 \mapsto y_2$ and $x_1 \mapsto y_2$ the calibrated codes' and the predictors' accuracy for the 'parallel' method. Figure 3 presents an example of posterior predictor for each phenomenon (1, 2 and nested). Figure 4 presents the sources of uncertainty of the nested phenomenon's predictor. The findings are :

- The more observations there are, the more accurate predictions and the better calibrated codes are.
- The predictors' performance is less sensitive to the observations' choice when the number of observations increases.
- Both mean and confidence interval of 95% of all predictors are accurate.
- The predictors for the phenomena $x_1 \mapsto y_1$ and $x_2 \mapsto y_2$ are interpolating. The predictor for the phenomenon $x_1 \mapsto y_2$ is a linearization of coupling the predictors of the first and the second phenomena, thus it is not interpolating because there is no observation of phenomenon $x_1 \mapsto y_2$.
- When there are few observations, the uncertainty of the nested phenomenon's predictor mainly comes from the parameters' posterior distribution. The uncertainty lowers with the numbers of observations. This reduction with the number of observations is particularly significant for the uncertainty coming from the parameters' distribution.

6.6 The 'black-box' approach

In the 'black-box' approach there are observations for the nested phenomenon only, which are denoted by $\left(\mathbf{x_{1,obs}}^{(3)}, \mathbf{y_{2,obs}}^{(3)}\right)$. Figure 5 presents for the phenomena $x_1 \mapsto y_1$,

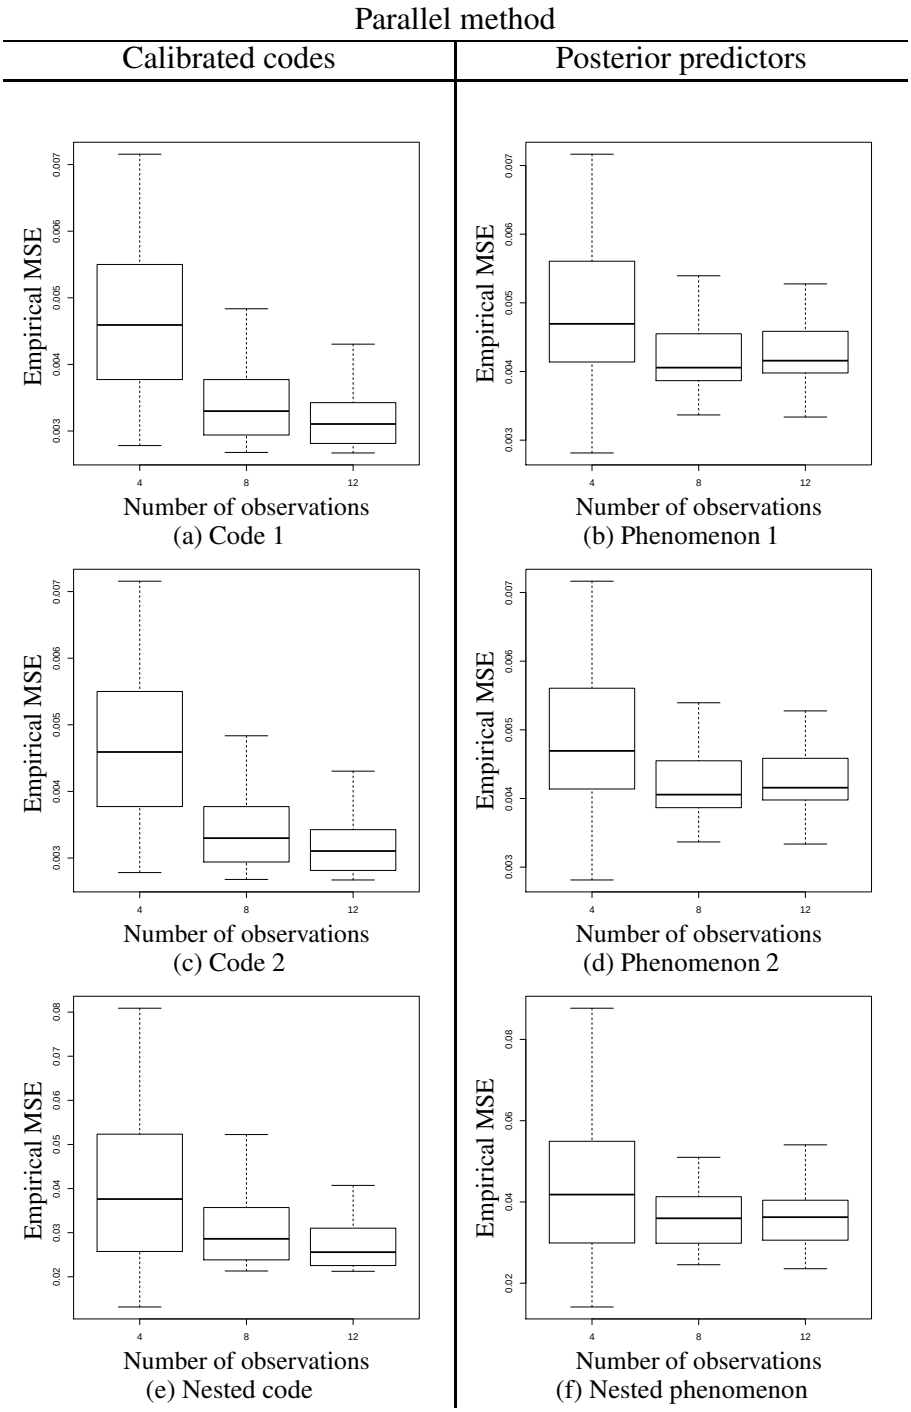


Figure 2: The figures present the empirical MSE (see table 2) of the calibrated codes (2a, 2c, 2e) and the predictors (2b, 2d, 2f) for the "parallel" method. The parameters' calibration and the posterior predictors' construction have been repeated with 50 series of observations. The same observations were used for both codes ($\mathbf{x_{1,obs}}^{(1)} = \mathbf{x_{2,obs}}^{(2)}$). The lower the empirical MSE is, the more accurate the calibrated code is. It can be seen that the accuracy of the predictors and calibrated codes increases with the number of observations and that all codes are well calibrated.

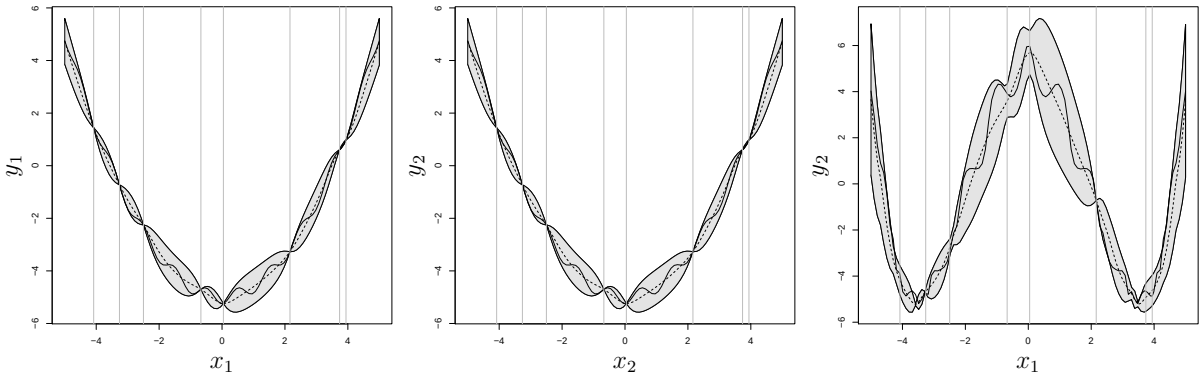
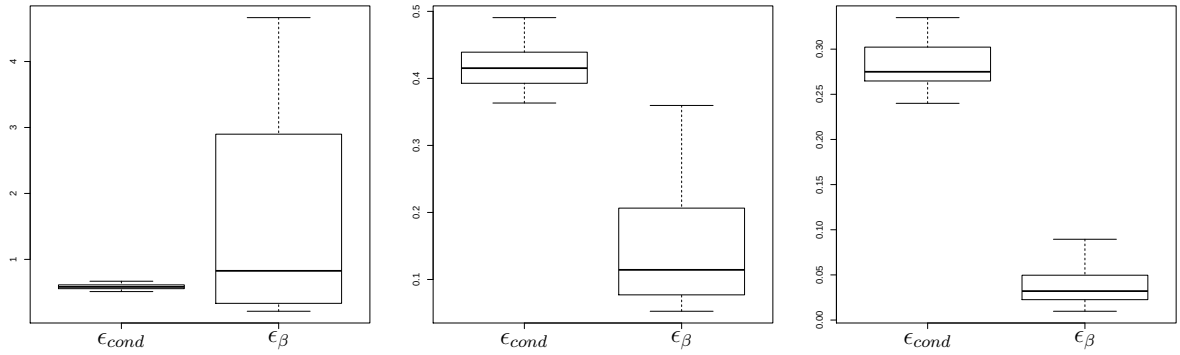
Parallel method : Posterior predictors' mean and confidence interval



(a) Phenomenon 1 (b) Phenomenon 2 (c) Nested phenomenon

Figure 3: Each figure presents an example of posterior predictor for each phenomenon. The dotted line represents the predictor's mean, the continuous line the real phenomenon and the grey area the predictor's confidence interval of 95%. The predictors are built with the same 8-point LHS maximin designs for $x_1 \mapsto y_1$ and $x_2 \mapsto y_2$ phenomena ($\mathbf{x_{1,obs}}^{(1)}$=$\mathbf{x_{2,obs}}^{(2)}$). It can be seen that the predictors' means and confidence intervals of 95% are accurate. The predictor of the nested code is not an interpolating Gaussian predictor because there is no observation for the phenomenon $x_1 \mapsto y_2$.

Parallel method : sources of uncertainty of the nested phenomenon's predictor



(a) 4 observations (b) 8 observations (c) 12 observations

Figure 4: The figures above present the distribution of the average variance of the nested phenomenon's predictor over a test set of 100 points. We denote by ϵ_{cond} the part of variance coming from the conditional Gaussian process and by ϵ_β the part of variance coming from the parameters' posterior distribution (see table 7). It can be seen that the variance lowers with the number of observations. This reduction is particularly significant for the uncertainty coming from the parameters' distribution.

$x_2 \mapsto y_2$ and $x_1 \mapsto y_2$ the calibrated codes' and predictors' accuracy for the 'black-box' method. Figure 6 presents an example of posterior predictor for each phenomenon (1, 2 and nested). Figure 7 presents the sources of uncertainty of the nested phenomenon's predictor. The findings are :

- The more observations there are, the more accurate the nested predictor is.
- When the number of observations increases, the parameters' calibration is less sensitive to the observations' choice.
- The second code is better calibrated than the first code.
- The nested code is never well calibrated.
- The mean of the nested phenomenon's predictor is accurate, but its variance is relatively high.
- The predictors of the first and the second phenomena are just calibrated codes. Their variances are relatively high.
- When there are few observations, the uncertainty of the nested phenomenon's predictor mainly comes from the parameters' posterior distribution. The uncertainty lowers with the number of observations. This reduction is particularly significant for the uncertainty coming from the parameters' distribution.

6.7 The 'grouped' approach

In this case observations of the three phenomena are available, which are denoted by $\left(\mathbf{x_{1,obs}}^{(1)}, \mathbf{y_{1,obs}}^{(1)}\right)$, $\left(\mathbf{x_{2,obs}}^{(2)}, \mathbf{y_{2,obs}}^{(2)}\right)$ and $\left(\mathbf{x_{1,obs}}^{(3)}, \mathbf{y_{2,obs}}^{(3)}\right)$. In this example we consider that $\mathbf{x_{1,obs}}^{(1)} = \mathbf{x_{1,obs}}^{(3)}$, $\mathbf{y_{1,obs}}^{(1)} = \mathbf{x_{2,obs}}^{(2)}$ and $\mathbf{y_{2,obs}}^{(2)} = \mathbf{y_{2,obs}}^{(3)}$. Figure 8 presents for the phenomena $x_1 \mapsto y_1$, $x_2 \mapsto y_2$ and $x_1 \mapsto y_2$ the calibrated codes' and the predictors' accuracy for the 'grouped' method. Figure 9 presents an example of the posterior predictors for each phenomenon (1, 2 and nested). Figure 10 presents the sources of uncertainty of the nested phenomenon's predictor. The findings are :

- Both codes are well calibrated,
- For the phenomenon $x_1 \mapsto y_1$, the accuracy of the calibrated code increases with the number of observations,
- For the phenomenon $x_2 \mapsto y_2$, the accuracy of the calibrated code decreases with the number of observations. This is probably due to an ill-conditioned problem. The space filling of the observations $\mathbf{x_{2,obs}}^{(2)}$ is not good.
- When there are few observations, the uncertainty of the nested phenomenon's predictor mainly comes from the parameters' posterior distribution. The uncertainty lowers with the number of observations. This reduction is particularly significant for the uncertainty coming from the parameters' distribution.

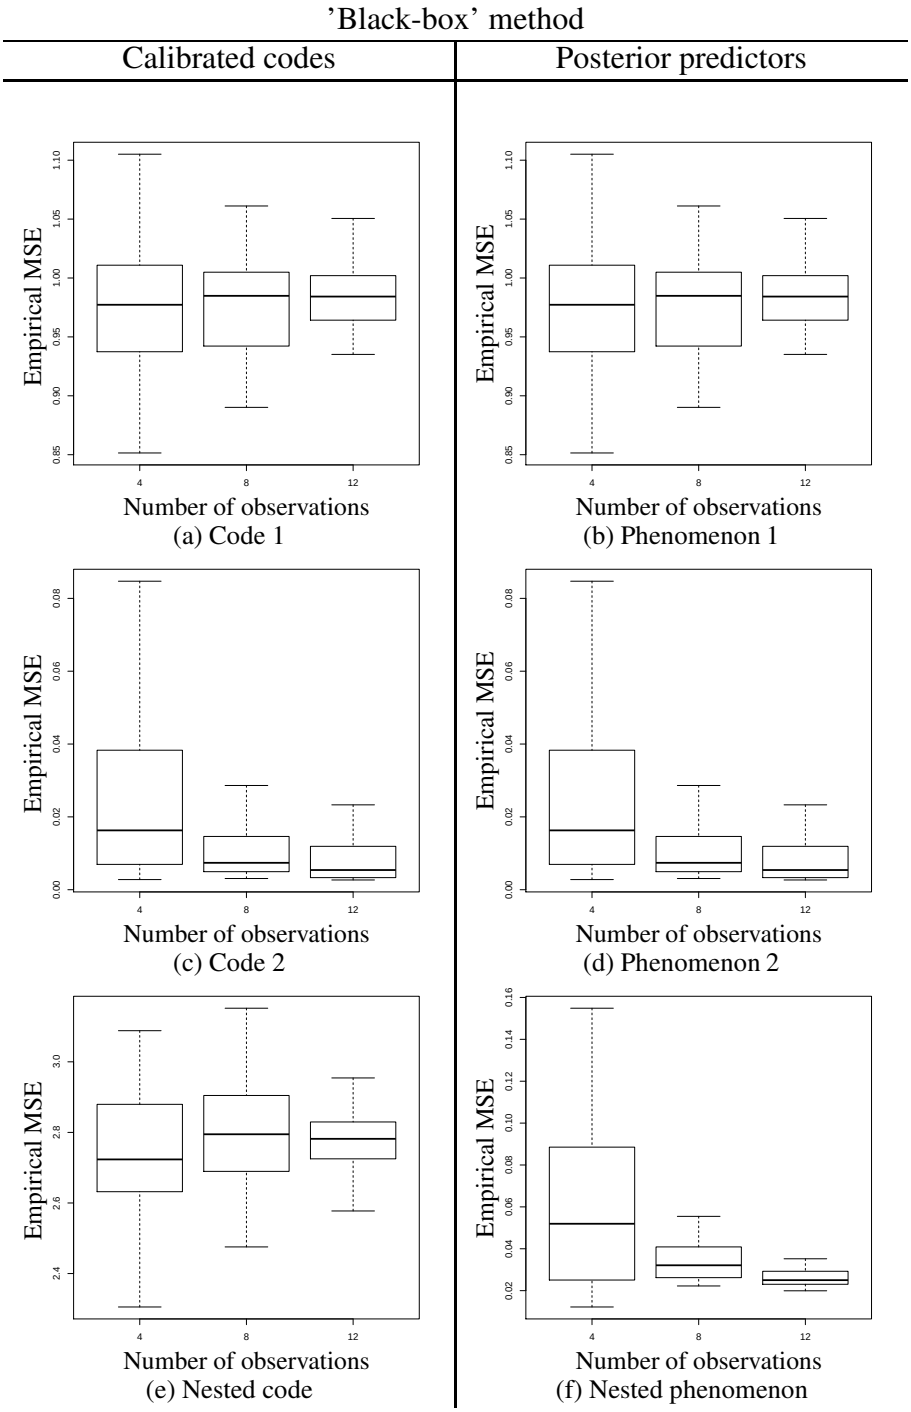


Figure 5: The figures present the empirical MSE (see table 4) of the calibrated codes (5a, 5c, 5e) and the predictors (5b, 5d, 5f) for the "black-box" method. The parameters' calibration and the posterior predictors' construction have been repeated for 50 series of observations. It can be seen that the second code is always better calibrated than the first code. When the number of observations increases, the empirical MSE lowers and is less sensitive to the observations' choice. So the calibrated codes' and predictors' robustness and accuracy increases with the number of observations.

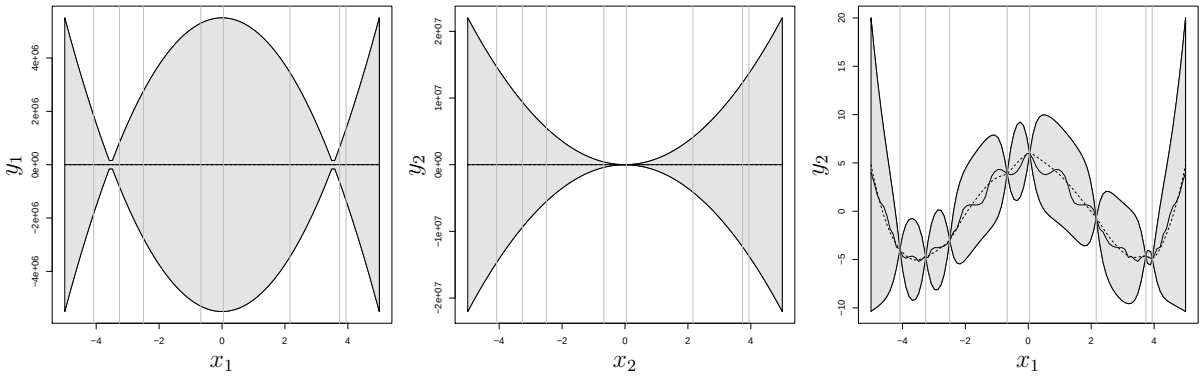
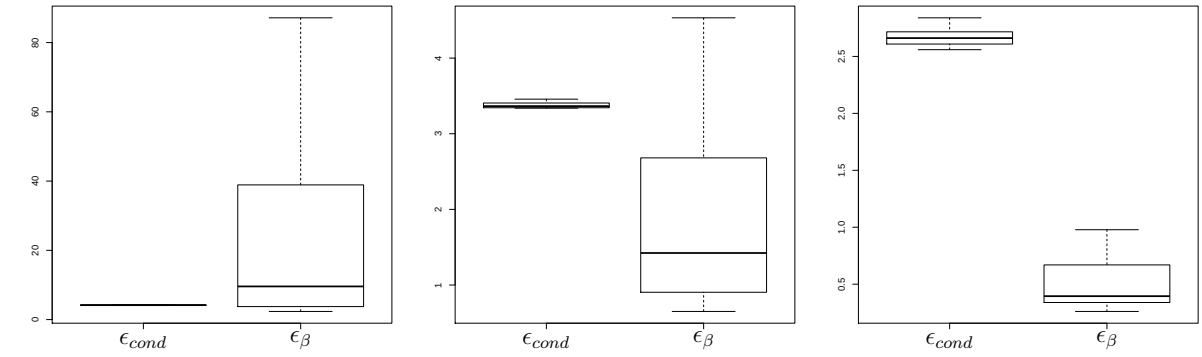
'Black-box' method : Posterior predictors' mean and confidence interval



(a) Phenomenon 1 (b) Phenomenon 2 (c) Nested phenomenon

Figure 6: Each figure presents an example of posterior predictor for each phenomenon. The dotted line represents the predictors' mean, the continuous line the real phenomenon and the grey area the confidence interval of 95%. The predictors are built with a 8-point LHS maximin design. The confidence intervals are relatively high. The predictors of the first and the second phenomena are not interpolating because there is no observation for these phenomena ($\left(\mathbf{x_{1,obs}}^{(1)}, \mathbf{y_{1,obs}}^{(1)}\right) = \emptyset$ and $\left(\mathbf{x_{2,obs}}^{(2)}, \mathbf{y_{2,obs}}^{(2)}\right) = \emptyset$). The predictors for these phenomena are just calibrated codes integrating posterior parameters distribution.

'Black-box' method : sources of uncertainty of the nested phenomenon's predictor



(a) 4 observations (b) 8 observations (c) 12 observations

Figure 7: The figures above present the distribution of the average variance of the nested phenomenon's predictor over a test set of 100 points. We denote by ϵ_{cond} the part of the variance coming from the conditional Gaussian process and by ϵ_β the part of the variance coming from the parameters' posterior distribution. The variance lowers with the number of observations, especially for the part coming from the parameters' distribution (see table 7). The variance coming from the conditional process is relatively high because the error of the nested model is chaotic (see figure 1)

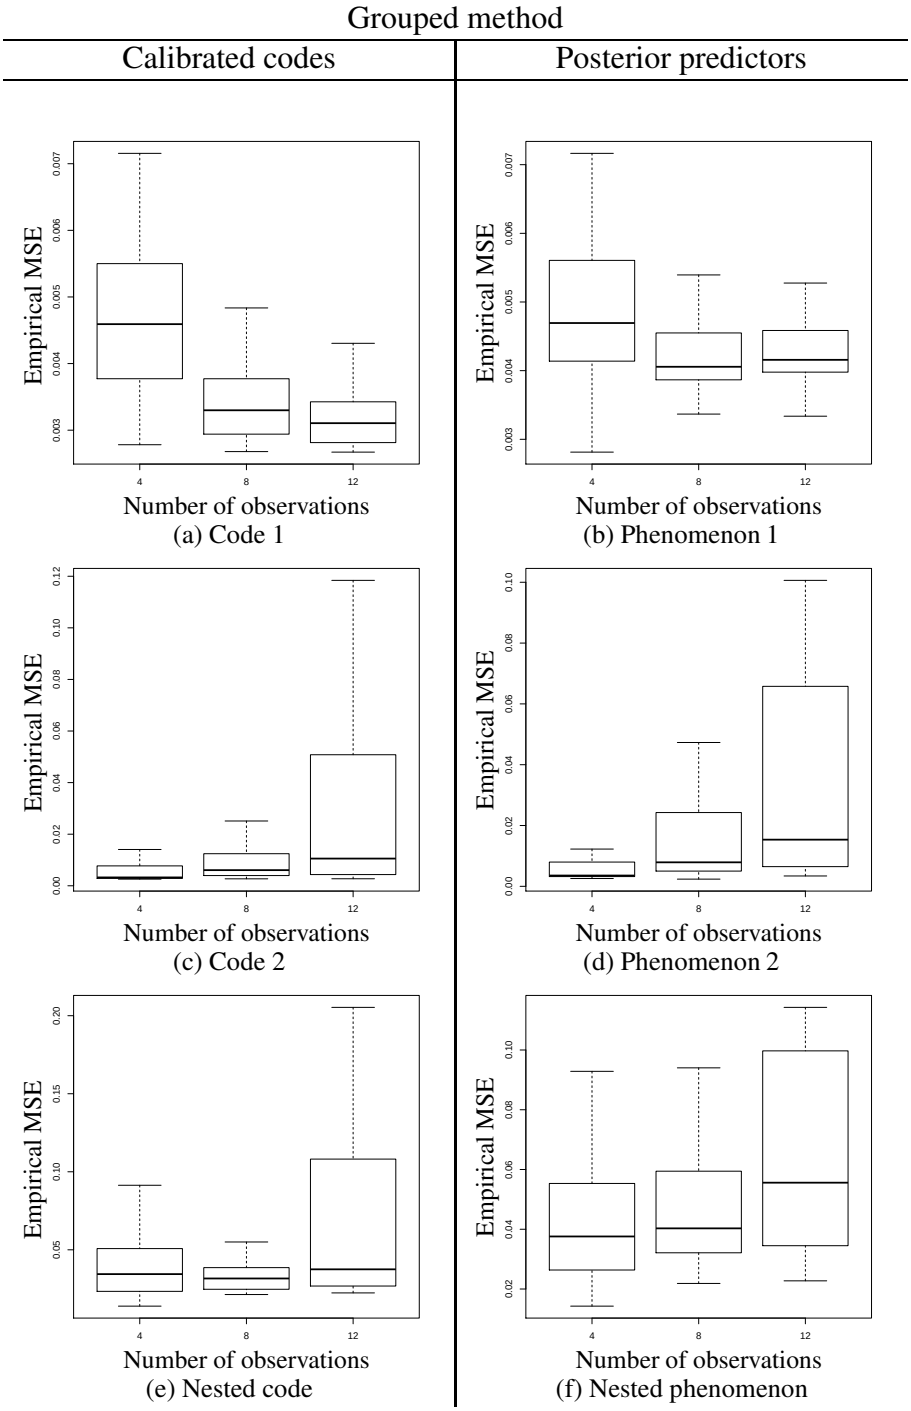


Figure 8: The figures present the empirical MSE (see table 6) of the calibrated codes (8a, 8c, 8e) and the predictors (8b, 8d, 8f) for the "grouped" method. The observations' sampling, the parameters' calibration and the posterior predictors' construction have been repeated 50 times. All codes are well calibrated. The calibrated code's and predictor's accuracy of the phenomenon 1 increases with the number of observations. The calibrated code's and predictor's accuracy of the phenomenon 2 is poorer than for the phenomenon 1 and decreases with the number of observations. This is due to the bad space filling of ${\mathbf{y}_{\mathbf{1},\mathbf{obs}}}^{(1)} = {\mathbf{x}_{\mathbf{2},\mathbf{obs}}}^{(2)}$. Indeed the observations are chosen for phenomenon $x_1 \mapsto x_2 \mapsto y_2$. So even if the observations ${\mathbf{x}_{\mathbf{1},\mathbf{obs}}}^{(1)}$ fill in well the space $[-5;5]$, the observations ${\mathbf{y}_{\mathbf{1},\mathbf{obs}}}^{(1)} = {\mathbf{x}_{\mathbf{2},\mathbf{obs}}}^{(2)}$ are not well distributed in $[-5;5]$. This leads to an ill-conditioned problem.

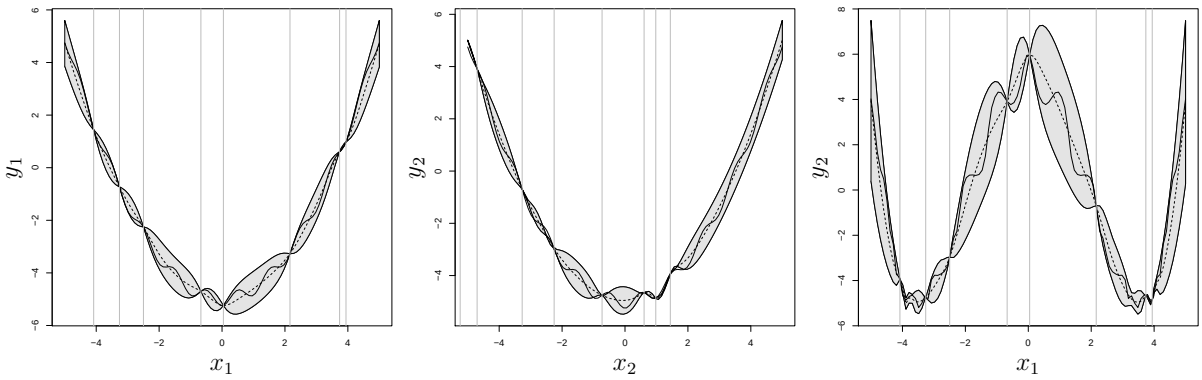
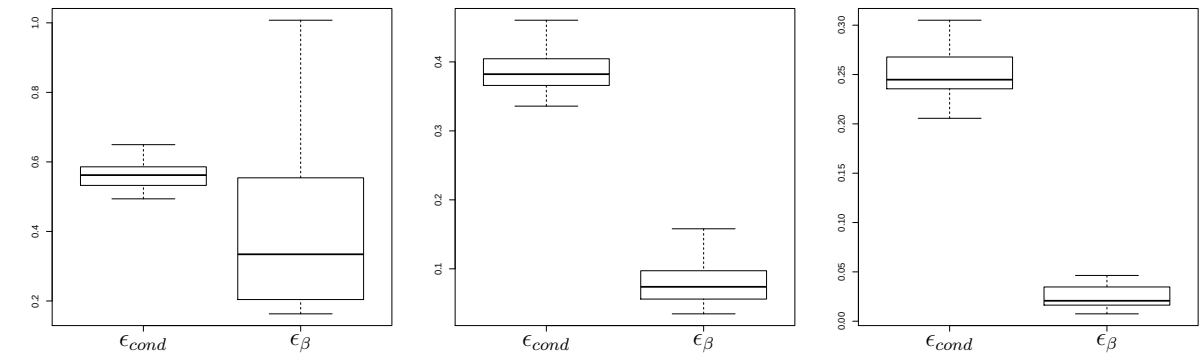
Grouped method : Posterior predictors' mean and confidence interval



(a) Phenomenon 1 (b) Phenomenon 2 (c) Nested phenomenon

Figure 9: Each figure presents an example of posterior predictor for each phenomenon. The dotted line represents the predictors' mean, the continuous line the real phenomenon and the grey area the confidence interval of 95%. The predictors are built with a 8-point LHS maximin design $x_1 \mapsto x_2 \mapsto y_2$. It can be seen that both mean and confidence interval are well estimated. The observations of the phenomenon 2 are not well distributed in $[-5; 5]$. All the predictors are Gaussian and interpolating.

Grouped method : sources of uncertainty of the nested phenomenon's predictor



(a) 4 observations (b) 8 observations (c) 12 observations

Figure 10: The figures above present the distribution of the average variance of the nested phenomenon's predictor over a test set of 100 points. We denote by ϵ_{cond} the part of variance coming from the conditional Gaussian process and by ϵ_β the part of variance coming from the parameters' posterior distribution (see table 7). It can be seen that the variance lowers with the number of observations. This reduction is particularly significant for the uncertainty coming from the parameters' distribution. It can be seen that both part of variance are relatively low even when there are few observations.

7 CONCLUSIONS AND FURTHER WORK

A general framework has been proposed to calibrate nested computer models whatever the type of available observations among the three possibilities $\left(\mathbf{x_{1,obs}}^{(1)}, \mathbf{y_{1,obs}}^{(1)}\right)$, $\left(\mathbf{x_{2,obs}}^{(2)}, \mathbf{y_{2,obs}}^{(2)}\right)$ and $\left(\mathbf{x_{1,obs}}^{(3)}, \mathbf{y_{2,obs}}^{(3)}\right)$. Predictors for all phenomena have been proposed for all possibilities of available observations. Three specific cases of this general method have been presented depending on the available observations. The performance of the codes' calibration and the posterior predictors has been analyzed on a numerical example for these three specific cases.

Questions remain about the choice of the design points. In particular our general framework could enable designs where there are not the same number of observations for the first and the second phenomena. Thus parsimonious or sequential (see [2], [3], [4], [5], [8], [9], [10]) designs could be proposed in order to improve the accuracy of the nested phenomenon's predictor.

Keywords: Sparse polynomial chaos expansion, Uncertainty quantification, Regression, Statistical inference, Curse of dimensionality, Compressive sampling

Abstract. *Over the last years, a lot of effort has been made to make existing uncertainty quantification techniques more efficient in high dimensions. An important class of methods relies on the assumption that the polynomial chaos representation of the model response is sparse. This paper contributes to the validation and assessment of an innovative basis selection technique for building sparse polynomial chaos expansions. A regression approach is used for computing the polynomial chaos coefficients. The technique is based on statistical inference theory which provides information about the true regression model from an estimated regression model based on samples. The latter information is used to build iteratively the sparse polynomial chaos expansion. Using the developed methodology, a more robust and efficient basis selection technique is obtained. For validation purpose, the methodology is applied to high dimensional analytical test cases, including the Oakley & O'Hagan function (d=15) and the Morris function (d=20). The results are compared with those obtained from two state-of-the-art techniques, namely the LARS-based algorithm and compressive sampling. As compared to previous work, more comparisons with the LARS-based method are provided, through the use of UQLab, a MATLAB-based uncertainty quantification framework developed by Sudret and Marelli [1]. It is shown that, with equal settings, the developed methodology results in a more accurate polynomial chaos expansion compared to the aforementioned technique. In addition, a new criterion for building an optimal polynomial chaos expansion is further investigated. The conclusions are in-line with previous findings, i.e. the present criterion always builds a sparser polynomial chaos expansion which is, in addition, at least as accurate as compared to the optimal polynomial chaos expansion obtained from the classical cross validation technique.*

1 INTRODUCTION

In recent years, due to the increase in computational power, the interest in uncertainty quantification (UQ) in computational fluid dynamics (CFD) has drastically increased. This has led to an extensive use of polynomial chaos (PC) methods, which are known for their ability to propagate efficiently uncertainties through complex engineering models.

Initially, the PC applications were highly intrusive in the sense that the PC expansion was inserted in the partial differential equations describing the problem. Some applications of intrusive PC are available in [2, 3]. Though, it turned out that, in addition to being error prone, a lot of effort was required to modify the CFD code. This made intrusive PC less attractive for industry who are relying on their own well-validated CFD code. It is for this reason that a focus was made on non-intrusive techniques, where no change to the CFD software is required.

In non-intrusive PC, the PC coefficients are computed using either a projection or a regression approach [4]. In both cases, the stochastic solution is calculated by running a series of deterministic simulations for different realization of the uncertain input parameters. The exact number of calls to the CFD software, also referred to as the number of samples, depends on the PC expansion order but also, and most importantly, on the number of input random variables. For a given PC order, the number of samples required grows exponentially with the number of dimension. In the literature, this exponential increase of computational cost with the number of random dimensions is often referred to as the *curse-of-dimensionality*. The latter issue constitutes a serious brake in the application of non-intrusive PC to relevant industrial applications, which are inherently characterized by many uncertainties, e.g. uncertainties on operational conditions, geometrical uncertainties, etc. Hence, in order to handle this issue, efficient non-intrusive techniques have been developed in the last few years.

To takle the curse of dimensionality, an important class of methods, which has been proven particularly effective, relies on the assumption that the PC solution is sparse. This means that only a limited number of features will contribute significantly to the modeling of the model response. The most famous techniques relying on such assumption are the sparse regression technique of [5, 6] and the compressive sampling technique [7, 8]. In the former approach, the PC coefficients are calculated using the LARS method while in the later approach, an underdetermined system of equations is solved using ℓ_1 regularization [7].

In this paper, an innovative basis selection technique for building sparse polynomial chaos expansion is further investigated. The methodology combines statistical inference theory with regression-based PC. The use of statistical inference will provide information about the true regression given an estimated regression model based on samples. The latter information is then used to build the sparse PC metamodel iteratively, following a forward-backward strategy. It follows that the developed methodology has two important features, i.e. (i) *robustness* as the dependency with respect to the sampling strategy is removed and (ii) *effectiveness* as most of the terms that are captured will contribute to the true regression model. An extensive comparison with state-of-the-art techniques such as the LARS-based method and the compressive sampling technique is provided.

2 REGRESSION-BASED POLYNOMIAL CHAOS

Suppose Y is the exact model response. Y is function of a set of random variables $\boldsymbol{\xi} = (\xi_1, ..., \xi_d)$, where d is the dimension of the random space. The polynomial chaos theory consists in expanding the exact model response into a series of orthogonal polynomials,

$$Y(\boldsymbol{\xi}) = \sum_{i=0}^{P} u_i \psi_i(\boldsymbol{\xi}) \tag{1}$$

where u_i are the PC coefficients and ψ_i are the PC basis, chosen in accordance with the probability density function of the input random variables following the so-called Askey scheme of polynomials [9]. As an example, if the random variables are uniformly distributed, then the Legendre polynomials are used.

The PC coefficients can be calculated using either a quadrature (projection) or a regression method. In the present work, we focused on the regression approach. The regression method consists in evaluating Equation (1) at different location in the stochastic space and solving the resulting system of equations, i.e.

$$Y\left(\boldsymbol{\xi}^{(j)}\right) = \sum_{i=0}^{P} u_i \psi_i\left(\boldsymbol{\xi}^{(j)}\right), \quad j = 1, ..., n \tag{2}$$

In practice, an overdetermined system of equations is built to avoid the overfitting phenomenon [10]. As a rule of thumb, the number of samples is often chosen as twice the number of PC terms and the system is solved in a least squared sense. The statistical moments are then derived by post-processing the estimated PC coefficients, as detailed in [11].

3 STATISTICAL INFERENCE IN REGRESSION ANALYSIS

In this work, a distinction is made between the population regression model, which is built based on an infinite number of samples, and the estimated regression model, based on a limited number of samples. A convention commonly used is to denote estimated parameters with a "hat" superscript. This convention will be followed throughout this paper. The population regression model is written as

$$Y = \sum_{i=0}^{P} u_i \psi_i + \varepsilon \tag{3}$$

where ε denote the error made by approximating the exact model by the population regression model. In the sequel, it will be assumed that the error is iid. with zero mean and constant variance σ^2. On the other hand, an estimated regression model is given by

$$Y = \sum_{i=0}^{P} \hat{u}_i \psi_i + \hat{\varepsilon} \tag{4}$$

where $\hat{\varepsilon}$, the difference between the exact model and an estimated regression model, is called residual. The primary goal of statistical inference is to derive information about the parameters of the true regression model given the parameters of the estimated regression model. In the following, statistical inference will be used for (i) building confidence intervals on the regression coefficients, (ii) testing the dependency between the exact model response and one specific predictor.

3.1 Confidence intervals

In this section, we build confidence intervals (CIs) on the regression coefficients. A CI always takes the same form, i.e. an estimate $\pm$ critical value $\times$ standard deviation of the estimate. The estimate $\hat{u}_j$ is provided by ordinary least squares (OLS) while it is possible to show that the variance of the regression coefficients can be calculated as [12]

$$\mathbb{V}[\hat{u}] = \sigma^2(\mathbf{\Psi}^T\mathbf{\Psi})^{-1} \tag{5}$$

where $\mathbf{\Psi}$ denotes the design matrix (matrix containing all the features). The variance σ^2 is a population parameter which can be estimated as follows [12]

$$\hat{\sigma}^2 = \frac{1}{\text{DOF}}\sum_{i=1}^{n}(Y_i - \hat{Y}_i)^2 \tag{6}$$

which is nothing else but the residual sum of squares (RSS) divided by the number of degrees of freedom (DOF) [12]. It turns out that the CIs for the regression coefficients can be built as

$$u_j \in \left[\hat{u}_j \pm t_{\text{DOF};\alpha/2}\sqrt{\mathbb{V}[\hat{u}_j]}\right] \tag{7}$$

where $t_{\text{DOF};\alpha/2}$ is the critical value.

3.2 Hypothesis testing

The goal of hypothesis testing in regression analysis is to test the dependency between the exact model response Y and a given predictor. Let consider the following estimated regression model

$$\hat{Y} = \sum_{i=1}^{P}\hat{u}_i\psi_i \tag{8}$$

In order to test the dependency between the response and one specific predictor ψ_i, the null and alternative hypotheses are stated as follows

$$\text{H}_0 : u_i = 0 \tag{9}$$
$$\text{H}_1 : u_i \neq 0 \tag{10}$$

To assess the veracity of H_0 a test statistic is defined

$$t_{\hat{u}_i} = \frac{\hat{u}_i}{\sqrt{\mathbb{V}[\hat{u}_i]}} \sim t_{\text{DOF}} \tag{11}$$

which means that the test statistic follows a Student-t-distribution with DOF degrees of freedom. The decision rule is

$$\text{RH}_0 \text{ : if } |t_{\hat{u}_i}| \geq t_{\text{DOF};1-\alpha/2} \tag{12}$$
$$\cancel{\text{RH}}_0 \text{ : if } |t_{\hat{u}_i}| < t_{\text{DOF};\alpha/2} \tag{13}$$

where RH_0 means the null hypothesis is rejected in favour of the alternative hypothesis and $\cancel{\text{RH}}_0$ the null hypothesis is not rejected. In other words, the test statistic is compared with a critical value. If the test statistic lies inside the critical region, then H_0 is rejected.

4 RESULTS AND DISCUSSION

4.1 Oakley & O'Hagan function (d=15)

First the Oakley & O'Hagan function [13] is considered:

$$Y = \mathbf{a_1}^T \boldsymbol{\xi} + \mathbf{a_2}^T \sin(\boldsymbol{\xi}) + \mathbf{a_3}^T \cos(\boldsymbol{\xi}) + \boldsymbol{\xi}^T \mathbf{M} \boldsymbol{\xi} \tag{14}$$

where $\boldsymbol{\xi} = \{\xi_1, ..., \xi_{15}\}$ are independent random variables, normally distributed with zero mean and variance equals one, i.e. $\xi_i \sim \mathcal{N}(0, 1)$, $i = 1, ..., 15$. The Oakley & O'Hagan function consists of 15 random dimensions, among which 5 variables contribute significantly to the variability of the output, 5 have a smaller effect and the remaining 5 input variables have almost no effect on the output of interest [14]. The vectors $\boldsymbol{a_j}$, $j = \{1, 2, 3\}$ and the matrix $\mathbf{M}$ are reported at `http://www.jeremy-oakley.staff.shef.ac.uk/psa_example.txt`.

The Oakley & O'Hagan function is seen as the expensive model, that will be modeled by a sparse PC expansion using Hermite polynomials. In the sequel, for the sake of comparison, two sparse PC metamodels will be built. The first one is built using the LARS-based method and the second one using the statistic-based approach. On the one hand, the LARS-based calculation of the PC coefficients is provided by UQLab, a MATLAB-based UQ framework developed by Sudret and Marelli [1]. Regarding the settings, the degree-adaptivity is activated, i.e. the calculation of the PCE coefficients is performed for a range of PC degree and the degree with the lowest leave-one-out (LOO) error is selected [REF]. In addition, no truncation to the set of candidates basis has been applied ($q = 1$). On the other hand, the STAT method is also run for a range of PC degree, among which the best PC metamodel is selected. A cut-off level of 20% is applied for the STAT-CI method. In all cases, the PCE-based methods are run with two quasi-random experimental designs of size $n = 500$ and $n = 750$ respectively. The relative ℓ_2 error is used to measure the accuracy of the resulting PC expansions.

Results are reported in Table 1. It turns out that, using the same experimental design, the STAT method results in a metamodel which is almost one order of magnitude more accurate as compared to the accuracy of the best metamodel calculated with the LARS method. Moreover, the level of sparsity of the resulting PCE is significantly much smaller when the STAT-CI method is used (almost 50% less terms are captured). This confirms that the statistic-based method selects the PC terms in a smarter way, which can result in large savings in terms of computational cost.

	LARS-MCV		**STAT-MCV**		**STAT-CI**	
	n=500	n=750	n=500	n=750	n=500	n=750
Relative ℓ_2 error	$2.0 \cdot 10^{-2}$	$4.6 \cdot 10^{-3}$	$3.8 \cdot 10^{-3}$	$7.3 \cdot 10^{-4}$	$3.4 \cdot 10^{-3}$	$4.9 \cdot 10^{-4}$
Level of sparsity	204	341	234	374	135	189
PC order	3	4	4	5	4	5

Table 1: Oakley function - Comparison of different adaptive methods for building sparse PC expansions.

More detailed comparisons are reported in Figure 1. In that Figure, the magnitude of the estimated PC coefficients is plotted against a reference solution. The reference solution is given by a full PCE of order 4 where PC coefficients are computed with regression (requiring 7752 samples). For the sake of comparison only, the LARS algorithm is run using a PC degree of 4 (which is not optimal as shown in Table 1). It is shown that, using only 500 samples, the STAT

method is able to capture exactly the most important contributions while the LARS method also captures lots of irrelevant contributions. It is therefore not surprizing that the STAT method results in better performance as compared to the LARS method.

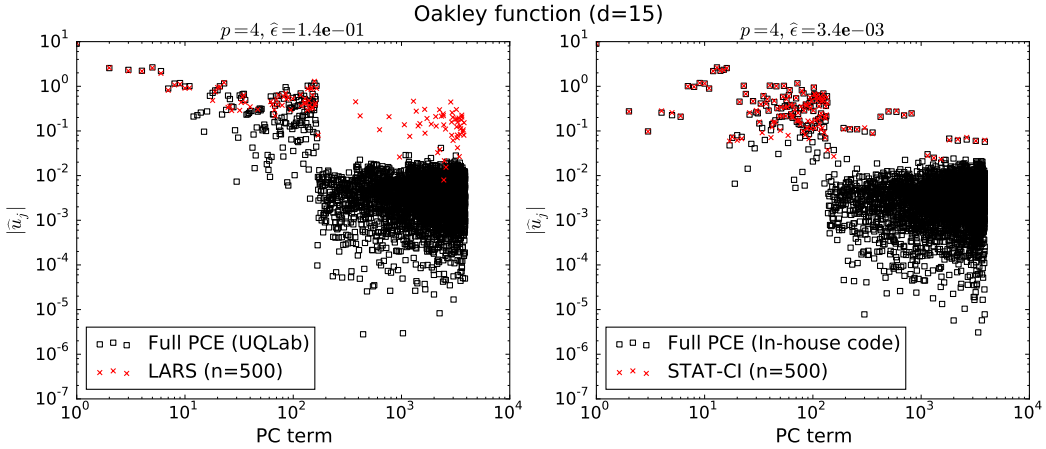

Figure 1: Oakley function - Magnitude of estimated regression coefficients versus a full PCE of order 4 (Left: LARS, Right: STAT)

Eventually, a comparison is made between the STAT method and compressive sampling, using the same experimental design (n=500). Results are reported in Figure 2. It is shown that the compressive sampling technique captures some important contributions. Roughly, the coefficients whose order of magnitude lies in the range $1-10$ are correctly captured. Though CS completely fails in capturing the PC coefficients with lower order of magnitude, resulting in a metamodel of poor quality compared to the one computed with the STAT-CI method.

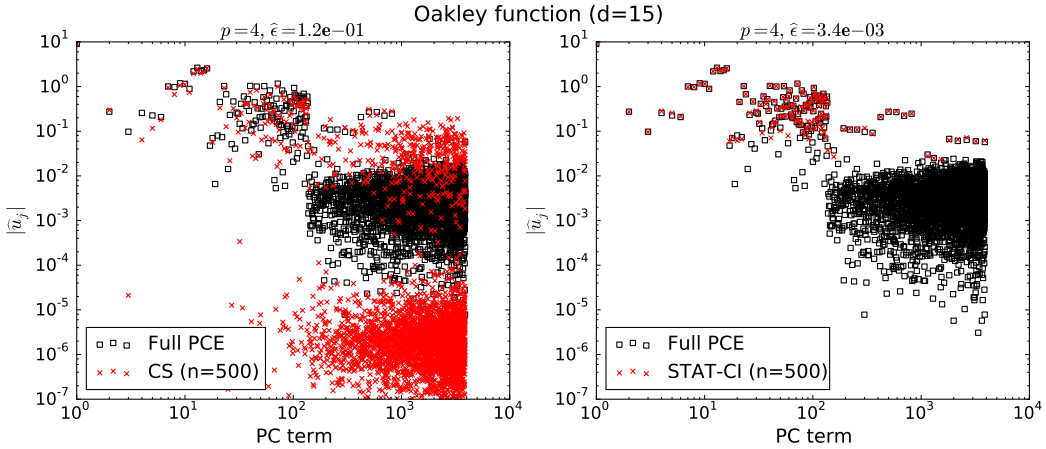

Figure 2: Oakley function - Comparison between the STAT-CI method and compressive sampling

4.2 Morris function (d=20)

The second function considered is another high dimensional function, namely the so-called Morris function [14]:

$$Y = \beta_0 + \sum_{i=1}^{20} \beta_i w_i + \sum_{i<j}^{20} \beta_{ij} w_i w_j + \sum_{i<j<k}^{20} \beta_{ijk} w_i w_j w_k + \sum_{i<j<k<\ell}^{20} \beta_{ijk\ell} w_i w_j w_k w_\ell \tag{15}$$

where

$$w_i = \begin{cases} 2\left(1.1\frac{\xi_i}{\xi_i+0.1} - 0.5\right) & \text{if } i = 3,5,7 \\ 2(\xi_i - 0.5) & \text{otherwise.} \end{cases} \qquad \xi_i \sim \mathcal{U}(0,1) \tag{16}$$

and

$$\begin{cases} \beta_i = 20 & \text{for } i = 1,...,10 & \text{and } \beta_i = (-1)^i & \text{otherwise} \\ \beta_{ij} = -15 & \text{for } i = 1,...,6 & \text{and } \beta_{ij} = (-1)^{i+j} & \text{otherwise} \\ \beta_{ijk} = -10 & \text{for } i = 1,...,5 & \text{and } \beta_{ijk} = 0 & \text{otherwise} \\ \beta_{ijk\ell} = 5 & \text{for } i = 1,...,4 & \text{and } \beta_{ijk\ell} = 0 & \text{otherwise} \end{cases} \tag{17}$$

The Morris function consists of 20 random dimensions, uniformly distributed over [0,1]. A detailed sensitivity analysis of the Morris function is available in [14]. The Morris function is seen as the expensive model which will be replaced by a sparse PC-based metamodel using Legendre polynomials. A similar study is performed as compared to the previous test case. The PC-based methods are run with two quasi random designs of experiments ($n = 500$, $n = 750$). Again, a cut-off level of 20% is applied for the STAT-CI method.

Results are shown in Table 2. In that case, the STAT-CI method still outperforms the LARS method but the gap between both approaches is less significant. The gain in terms of accuracy reaches 27% (resp. 34%) using a design of experiments made of 500 (resp. 750) individuals.

	LARS-MCV		**STAT-MCV**		**STAT-CI**	
	n=500	n=750	n=500	n=750	n=500	n=750
Relative ℓ_2 error	$8.4 \cdot 10^{-2}$	$5.9 \cdot 10^{-2}$	$1.1 \cdot 10^{-1}$	$5.7 \cdot 10^{-2}$	$6.1 \cdot 10^{-2}$	$3.9 \cdot 10^{-2}$
Level of sparsity	52	93	192	195	53	62
PC order	3	3	3	4	3	4

Table 2: Morris function - Comparison of different adaptive methods for building sparse PC expansions.

The resulting sparse PC expansions ($n = 500$) are now faced with a reference solution, namely a full PCE of order 3 whose PC coefficients were calculated with regression (see Figure 3). Those results are in-line with previous findings, i.e. in contrast with the STAT-based method, the terms captured by the LARS method do not exactly correspond to those calculated by the full PC solution. This will inevitably result in a deterioration in the estimation of the statistical moments.

Eventually, the performance of the STAT-CI method is compared with the compressive sampling technique (see Figure 4). Using the same design of experiments ($n = 500$), the performance of compressive sampling is comparable to the performance of the statistic-based method. The main difference with previous test case is that the order of magnitude of the PC coefficients

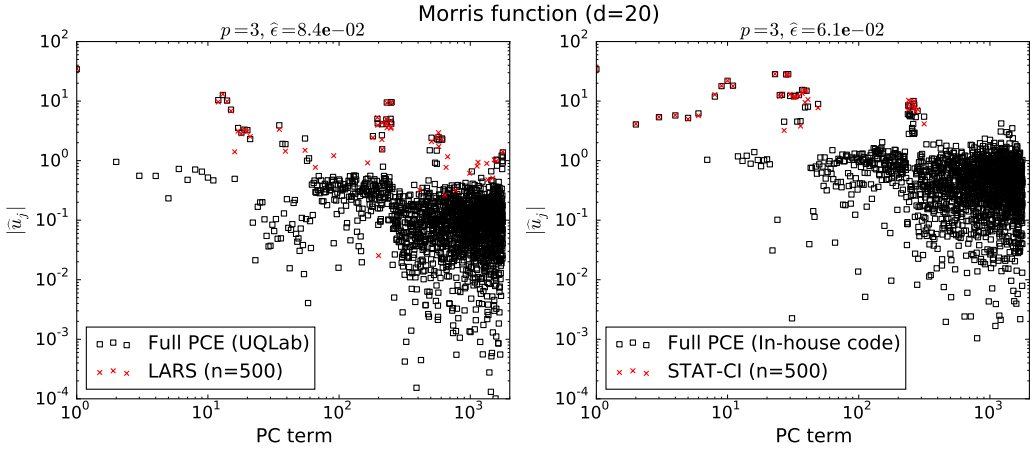

Figure 3: Morris function - Magnitude of estimated regression coefficients versus a full PCE of order 3 (Left: LARS, Right: STAT)

is greater than in the previous test case. Those terms are perfectly capture by the compressive sampling technique.

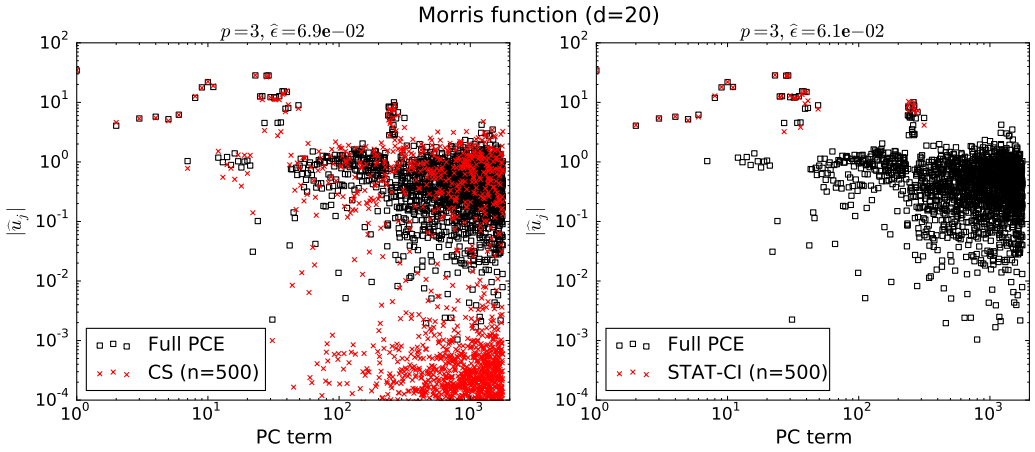

Figure 4: Morris function - Comparison between the STAT-CI method and compressive sampling

5 CONCLUSIONS

In this paper, the performance of a novel basis selection technique are further investigated. The developed methodology shows good potential in building sparse PC expansions at a reduced computational expense. Moreover, it has two essential features, i.e. (i) robustness with respect to the experimental design and (ii) effectiveness in the sense that only terms that truly contribute to the true regression model are captured.

In order to show the effectiveness of the proposed method, two high-dimensional analytical test cases are considered, namely the Oakley & O'Hagan function ($d = 15$) and the more challenging Morris function ($d = 20$). In each case, at equal settings, the accuracy of the sparse PC metamodel shows significant improvement as compared to existing state-of-the-art techniques. Particularly, the results confirm the superiority of the statistic-based approach over the

LARS-based approach. In addition, it is confirmed that the terms captured by the statistic-based method correspond exactly to the most important features calculated by a full PC expansion.

In the future, the method will be applied to relevant industrial applications.

Abstract. *The necessity for more detailed descriptions of both structural geometry and mechanical properties, renders the use of highly detailed finite element (FE) models almost prohibitive for complex, large structures. This becomes even more challenging when taking into account that structural systems and their excitations are often characterized by parameter uncertainty. To this end, this study addresses the problem of estimating reduced order metamodels for the accurate representation of computationally costly numerical models. A substructuring approach is adopted for segregating the modeled system into a series of smaller components, by separating the parts with exclusively linear characteristics from the uncertain ones. Each of these components is then approximated by corresponding ARX representations, the parameters of which are functionally dependent on uncertain input parameters, also accounting for uncertainty propagation through the FE model. These functional models are coupled in the time domain to formulate a complete metamodel of the system. The effectiveness of the proposed method is illustrated through its application on the metamodeling of a vehicle frame with uncertain suspension. The results demonstrate the efficiency of the proposed methodology for accurate prediction and simulation of the numerical model dynamics.*

1 INTRODUCTION

FE modeling has nowadays become a standard tool for the numerical simulation of civil, mechanical and aeronautical engineering structures [1, 2, 3] and is extensively used for design optimization [4], reliability analysis [5, 6], as well as for the simulation of hysteretic behaviour [7, 8] and damage [9, 10]. When dynamic loading is involved, however, the increased complexity of FE models renders the efficient characterization of the structural response a quite difficult task, especially for large structures, despite the rapidly growing computational power and the continuous development of increasingly efficient algorithms [11, 12]. A common strategy in such cases is to apply less refined macro-models to the simulation of the global behaviour using, for example, model reduction methods [13], and then implement more detailed local FE micro-models for the description of complex parts of the structure.

Alternatively, substructuring techniques [14] can be considered, under which the total structure is disassembled into several subcomponents that can be analysed separately. This framework retains many advantages over other approaches, since it allows isolation of areas, in which more detail is required, it can be successfully implemented in parallel computing and software–in–the–loop schemes, while it allows for flexible usage of the subcomponents in other structures. This latter advantage is one of the most significant aspects of substructuring, taking under consideration modern challenges of production engineering [15], where coupling of numerical models with fabricated subcomponents (e.g., in the form of experimental prototypes [16]) is a common practice, using hybrid testing and hardware–in–the–loop methods [17].

Another important aspect that must be taken into consideration during the simulation process corresponds to the inherent uncertainty that characterizes critical parameters of the available FE model, such as its associated mechanical properties, the range of operational and environmental conditions under which the structure is designed to operate and, of course, the diverse nature and levels of all possible excitations. In dealing with this issue, Monte Carlo–based methods have been widely applied, despite the necessity for a large number of simulations, with each one demanding excessive computational cost. In contrast to these, simpler representations of the numerical model are formulated using metamodelling techniques, which essentially build a parametric model of the original FE one, termed as *metamodel* or *surrogate model* [18, 19]. This metamodel must be able to predict the dynamic response in a computationally inexpensive way and with sufficient accuracy [20, 21].

Under this perspective, the problem faced in the current study pertains to the determination of the structural response in critical points of the structure using a *small number* of *computationally inexpensive* simulations, which take into account the whole operational range of inherent uncertainties and provide a representative behavioral map of the structure. A special case to this problem corresponds to the availability of physically available parts of the structure, for which experimental data, rather than an analytical model, are available. To address this problem, a process that consists of three overlapping and interrelated stages, namely, (i) the *substructuring* stage, (ii) the *model reduction* stage and (iii) the *metamodeling* stage, is proposed and outlined in the following.

The paper is organized as follows: Section 2 outlines the proposed methodology and describes the associated substructuring, model reduction and metamodeling stages. Section 3 contains a numerical study pertaining to a "vehicle"–like prototype that consists of a frame substructure and one linear suspension with uncertain stiffness. Finally, in Section 4 the results are summarized and remarks for further research are given.

2 THE PROPOSED FRAMEWORK

2.1 Problem formulation

Let us consider an n–DOF FE model of a damped structural system that can be mathematically represented by a second–order vector differential equation of the form

$$\mathbf{M}(\boldsymbol{\xi})\ddot{\mathbf{q}}(t) + \mathbf{D}(\boldsymbol{\xi})\dot{\mathbf{q}}(t) + \mathbf{K}(\boldsymbol{\xi})\mathbf{q}(t) = \mathbf{f}(t) \tag{1}$$

where $\mathbf{M}(\boldsymbol{\xi})$, $\mathbf{D}(\boldsymbol{\xi})$ and $\mathbf{K}(\boldsymbol{\xi})$ are the real $[n \times n]$ mass, viscous damping and stiffness matrices, $\mathbf{q}(t)$ is the $[n \times 1]$ vibration displacement vector and $\mathbf{f}(t)$ is the $[n \times 1]$ vector of excitations.

The dependence of the structural matrices to $\boldsymbol{\xi}$ is herein used to notate their variability due to a number of uncertain parameters related with either inherent properties of the structure, or exogenous random variables, e.g. geometry, mass distribution, environmental conditions and so on. For a number of L such uncertain parameters it follows that $\boldsymbol{\xi}(t) = [\xi_1, \xi_2, \ldots, \xi_L]$. In its most general statistical representation, the parameter vector $\boldsymbol{\xi}$ may be considered as a realization of the vector random process $\boldsymbol{\Xi}$ with joint PDF $f_{\boldsymbol{\Xi}}(\boldsymbol{\xi})$. Simpler realizations are possible if it is assumed that each parameter ξ_k is a realization of an independent random process Ξ_k with PDF $f_{\Xi_k}(\xi_k)$.

In this setting, the problem addressed herein aims at simulating the structural response, in the form of vibration displacement, velocity, or acceleration, under the following conditions:

- The size n of the FE model of the structure is prohibitely large for computationally efficient direct simulation.
- The structure can be split into a number of smaller substructures and all the associated boundaries can be adequately described.
- A statistical description of the uncertain parameters and the excitations is available for the whole operating range of the structure.

2.2 Substructuring

Assume that the total structure, described by Eq. 1, is constructed by the proper assembly of two substructures, $A(\boldsymbol{\xi})$ and $B(\boldsymbol{\xi})$. Then, instead of attempting to simulate the whole structure, it is possible to carry out distributed simulations for each substructure, provided that the common interface among the subdomains is appropriately defined. Indeed, the equations of motion that describe each substructure are

$$\mathbf{M}_A(\boldsymbol{\xi})\ddot{\mathbf{q}}_A(t) + \mathbf{D}_A(\boldsymbol{\xi})\dot{\mathbf{q}}_A(t) + \mathbf{K}_A(\boldsymbol{\xi})\mathbf{q}_A(t) = \mathbf{f}_A(t) + \mathbf{h}_A(t) \tag{2}$$

and

$$\mathbf{M}_B(\boldsymbol{\xi})\ddot{\mathbf{q}}_B(t) + \mathbf{D}_B(\boldsymbol{\xi})\dot{\mathbf{q}}_B(t) + \mathbf{K}_B(\boldsymbol{\xi})\mathbf{q}_B(t) = \mathbf{f}_B(t) + \mathbf{h}_B(t) \tag{3}$$

with all the associated quantities previously defined, with the exception of $\mathbf{h}_*(t)$, which corresponds to the vector of connecting forces. Then, from de Klerk *et al.* [14], recovery of Eq. 1 proceeds by first stacking the substructures as

$$\underbrace{\begin{bmatrix}\mathbf{M}_A & \mathbf{O}\\ \mathbf{O} & \mathbf{M}_B\end{bmatrix}}_{\overline{\mathbf{M}}}\begin{bmatrix}\ddot{\mathbf{q}}_A(t)\\ \ddot{\mathbf{q}}_B(t)\end{bmatrix} + \underbrace{\begin{bmatrix}\mathbf{D}_A & \mathbf{O}\\ \mathbf{O} & \mathbf{D}_B\end{bmatrix}}_{\overline{\mathbf{D}}}\begin{bmatrix}\dot{\mathbf{q}}_A(t)\\ \dot{\mathbf{q}}_B(t)\end{bmatrix} + \underbrace{\begin{bmatrix}\mathbf{K}_A & \mathbf{O}\\ \mathbf{O} & \mathbf{K}_B\end{bmatrix}}_{\overline{\mathbf{K}}}\underbrace{\begin{bmatrix}\mathbf{q}_A(t)\\ \mathbf{q}_B(t)\end{bmatrix}}_{\overline{\mathbf{q}}(t)} = \underbrace{\begin{bmatrix}\mathbf{f}_A(t)\\ \mathbf{f}_B(t)\end{bmatrix}}_{\overline{\mathbf{f}}(t)} + \underbrace{\begin{bmatrix}\mathbf{h}_A(t)\\ \mathbf{h}_B(t)\end{bmatrix}}_{\overline{\mathbf{h}}(t)} \tag{4}$$

and then by specifying the compatibility (identical displacements of the coupled DOFs) and equilibrium (action–reaction forces) conditions as,

$$\mathbf{C}\overline{\mathbf{q}}(t) = \mathbf{0} \quad \text{and} \quad \mathbf{E}^T\overline{\mathbf{h}}(t) = \mathbf{0} \tag{5}$$

respectively, with $\mathbf{C}$ and $\mathbf{E}$ denoting signed Boolean and Boolean matrices, respectively. Accordingly, by defining a unique set of structural DOFs, $\mathbf{q}(t)$, through

$$\overline{\mathbf{q}}(t) = \mathbf{E}\mathbf{q}(t) \tag{6}$$

it follows from Eq. 5 that $\mathbf{C}\overline{\mathbf{q}}(t) = \mathbf{C}\mathbf{E}\mathbf{q}(t) = \mathbf{0}$, from which $\mathbf{E} = \text{null}\{\mathbf{C}\}$. Substituting Eq. 6 to Eq. 4 implies

$$\overline{\mathbf{M}}\mathbf{E}\ddot{\mathbf{q}}(t) + \overline{\mathbf{D}}\mathbf{E}\dot{\mathbf{q}}(t) + \overline{\mathbf{K}}\mathbf{E}\mathbf{q}(t) = \overline{\mathbf{f}}(t) + \overline{\mathbf{h}}(t) \tag{7}$$

thus, multiplication by $\mathbf{E}^T$ leads to the representation of the total structure by Eq. 1 with

$$\mathbf{M} = \mathbf{E}^T\overline{\mathbf{M}}\mathbf{E}, \;\; \mathbf{D} = \mathbf{E}^T\overline{\mathbf{D}}\mathbf{E}, \;\; \mathbf{K} = \mathbf{E}^T\overline{\mathbf{K}}\mathbf{E}, \;\; \mathbf{f}(t) = \mathbf{E}^T\overline{\mathbf{f}}(t) \tag{8}$$

2.3 Model reduction

When the substructures still retain a large number of DOFs, model reduction can be used to further suppress the DOFs. While several other alternatives are possible (the interested reader is referred to Antoulas [13] for an authoritative treatment) the Ritz transformation is currently implemented. Following the previous discussion and if only the substructure $A(\boldsymbol{\xi})$ requires reduction, a new set of coordinates is provided by

$$\mathbf{q}_A(t) = \boldsymbol{\Psi}_A\mathbf{q}_{AR}(t) \tag{9}$$

where $\boldsymbol{\Psi}_A$ is a subset of the normal modes of Eq. 2, the selection of which depends on the frequency range examined. Applying this transformation to Eq. 2 and pre–multiplying by $\boldsymbol{\Psi}_A^T$ implies

$$\mathbf{M}_{AR}(\boldsymbol{\xi})\ddot{\mathbf{q}}_{AR}(t) + \mathbf{D}_{AR}(\boldsymbol{\xi})\dot{\mathbf{q}}_{AR}(t) + \mathbf{K}_{AR}(\boldsymbol{\xi})\mathbf{q}_{AR}(t) = \mathbf{f}_{AR}(t) + \mathbf{h}_{AR}(t) \tag{10}$$

for

$$\begin{aligned} \mathbf{M}_{AR} = \boldsymbol{\Psi}^T\mathbf{M}_A\boldsymbol{\Psi}, \;\; \mathbf{D}_{AR} = \boldsymbol{\Psi}^T\mathbf{D}_A\boldsymbol{\Psi}, \;\; \mathbf{K}_{AR} = \boldsymbol{\Psi}^T\mathbf{K}_A\boldsymbol{\Psi} \\ \mathbf{f}_{AR}(t) = \boldsymbol{\Psi}^T\mathbf{f}_A(t), \;\; \mathbf{h}_{AR}(t) = \boldsymbol{\Psi}^T\mathbf{h}_A(t) \end{aligned} \tag{11}$$

and corresponds to a reduced representation of the substructure $A(\boldsymbol{\xi})$.

2.4 Metamodeling

The third stage of the proposed methodology aims at estimating a reduced model of Eq. 3. Consider the case where the substructure $B(\boldsymbol{\xi})$ contains one DOF, a single excitation and a single uncertain parameter, so that Eq. 3 corresponds to a scalar nonlinear differential equation and $\boldsymbol{\xi} = \xi$. Then the structural output can be approximated using Adaptable Functional Series Autoregressive with eXogenous input (AFS-ARX) models of the form [22]

$$y[t,\xi] + \sum_{i=1}^{na}\alpha_i(\xi)y[t-i] = \sum_{i=0}^{nb}\beta_i(\xi)u[t-i] + e[t] \tag{12}$$

where $y[t]$ and $u[t]$ denote the model's output and input, respectively, $\alpha_i(\xi)$ and $\beta_i(\xi)$ are the coefficients of the AR and exogenous polynomials, of orders na and nb, respectively, and $e[t] \sim \mathcal{N}(0, \sigma_e^2)$ is the model's zero-mean Gaussian residual sequence.

The AFS-ARX(na, nb) model of Eq. 12 accounts for the uncertainty of $B(\boldsymbol{\xi})$ through the regression parameters $\theta_i(\xi)$, which are currently admitting a representation based on B–spline functions

$$\alpha_i(\xi) = \sum_{j=1}^{p} \alpha_{ij} S_{j,k}(\xi, \boldsymbol{\delta}_\alpha) \tag{13a}$$

$$\beta_i(\xi) = \sum_{j=1}^{p} \beta_{ij} S_{j,k}(\xi, \boldsymbol{\delta}_\beta) \tag{13b}$$

with $S_{j,k}(\xi, \boldsymbol{\delta})$ denoting the sequence of B-splines of order k and of functional subspace parameter vector $\boldsymbol{\delta} \equiv [\tau_{k+1}, \dots, \tau_p]^T$, henceforth referred to as the vector of free knots, of dimension $\dim(\boldsymbol{\delta}) = p - k$, consisting of the non-decreasing sequence of the free internal knots. Given a realization ξ, a particularly convenient way for defining $S_{j,k}(\xi, \boldsymbol{\delta})$ is obtained by means of the Cox-de Boor recursion formula for the normalized B-splines [23, p. 90], according to which

$$S_{j,1}(\xi, \boldsymbol{\delta}) = \begin{cases} 1 & \text{if } \tau_j \leq \xi < \tau_{j+1} \\ 0 & \text{otherwise} \end{cases} \tag{14a}$$

$$S_{j,i}(\xi, \boldsymbol{\delta}) = w_{j,i}(\xi) S_{j,i-1}(\xi, \boldsymbol{\delta}) + (1 - w_{j,i}(\xi)) S_{j+1,i-1}(\xi, \boldsymbol{\delta}), \quad \text{for } 1 < i \leq k \tag{14b}$$

where

$$w_{j,i}(\xi) = \begin{cases} \frac{\xi - \tau_j}{\tau_{j+i-1} - \tau_j} & \text{if } \tau_j < \tau_{j+i-1}, \\ 0 & \text{otherwise.} \end{cases} \tag{14c}$$

It is noted that since the internal free knots form a non decreasing sequence of real numbers, they have to satisfy proper constraints in relation to their bounds and order [24].

The efficient representation of $B(\xi)$ through AFS-ARX(na, nb) models is succeeded through the establishment and the solution of an associated identification problem, in which all the unknown parameters of the model are estimated, that is, the integers na, nb, p and k, the parameters α_{ij} and β_{ij} in Eq. 13, the vectors of free knots $\boldsymbol{\delta}_\alpha$ and $\boldsymbol{\delta}_\beta$, as well as the residual variance σ_e^2. To this end, the original AFS-ARX(na, nb) model of Eq. 12 is transformed into a linear regression form as

$$y[t] = \boldsymbol{\phi}[t, \boldsymbol{\delta}]\boldsymbol{\theta} + e[t] \tag{15}$$

for $\boldsymbol{\delta} = [\boldsymbol{\delta}_\alpha \;\; \boldsymbol{\delta}_\beta]^T$ and

$$\boldsymbol{\phi}[t, \boldsymbol{\delta}] = \big[-y[t-1] S_{1,k}(\xi, \boldsymbol{\delta}_\alpha) \;\; -y[t-1] S_{2,k}(\xi, \boldsymbol{\delta}_\alpha) \;\; \dots \;\; x[t-nb] S_{p,k}(\xi, \boldsymbol{\delta}_\beta) \big] \tag{16}$$

and

$$\boldsymbol{\theta} = [\alpha_{1,1} \; \alpha_{1,2} \; \dots \; \alpha_{na,p}]^T \tag{17}$$

If input–output data are available over $t = 1, \dots, N$ then Eq. 15 yields

$$\mathbf{y} = \boldsymbol{\phi}(\boldsymbol{\delta})\boldsymbol{\theta} + \mathbf{e} \tag{18}$$

where $\mathbf{y} = [y[1] \ \dots \ y[N]]^T$, $\boldsymbol{\phi}(\boldsymbol{\delta}) = [\boldsymbol{\phi}[1,\boldsymbol{\delta}] \ \dots \ \boldsymbol{\phi}[N,\boldsymbol{\delta}]]^T$ and $\mathbf{y} = [e[1] \ \dots \ e[N]]^T$. Notice that the AFS-ARX(na, nb) model must include all available statistical information of ξ. Thus, a number of simulations (or experiments, if the substructure $B(\xi)$ is experimental) is performed, say L, given a set of uncertainty parameter realizations, ξ_l, and the corresponding input–output data sets are obtained, $\mathbf{x}_l = [x_l[1] \ \dots \ x_l[N]]^T$ and $\mathbf{y}_l = [y_l[1] \ \dots \ y_l[N]]^T$, respectively, for $l = 1, 2, \dots, L$. Each one of these sets must satisfy Eq. 18, so that

$$\mathbf{y}_l = \boldsymbol{\phi}_l(\boldsymbol{\delta})\boldsymbol{\theta} + \mathbf{e}_l \tag{19}$$

By pooling Eq. 19 for all available experiments it follows that

$$\begin{bmatrix} \mathbf{y}_1 \\ \vdots \\ \mathbf{y}_l \end{bmatrix} = \begin{bmatrix} \boldsymbol{\phi}_1(\boldsymbol{\delta}) \\ \vdots \\ \boldsymbol{\phi}_l(\boldsymbol{\delta}) \end{bmatrix} \theta + \begin{bmatrix} \mathbf{e}_1 \\ \vdots \\ \mathbf{e}_l \end{bmatrix} \Rightarrow \mathbf{Y} = \boldsymbol{\Phi}(\boldsymbol{\delta})\boldsymbol{\theta} + \mathbf{E} \tag{20}$$

and the parameter vector $\boldsymbol{\theta}$ can be recovered by the least squares estimate

$$\boldsymbol{\theta} = \left[\boldsymbol{\Phi}(\boldsymbol{\delta})^T\boldsymbol{\Phi}(\boldsymbol{\delta})\right]^{-1}\boldsymbol{\Phi}(\boldsymbol{\delta})^T\mathbf{Y} = \boldsymbol{\Phi}(\boldsymbol{\delta})^\dagger\mathbf{Y} \tag{21}$$

with $\boldsymbol{\Phi}(\boldsymbol{\delta})^\dagger$ denoting the pseudo-inverse of $\boldsymbol{\Phi}(\boldsymbol{\delta})$. Since the parameter vector $\boldsymbol{\theta}$ depends on the vector of free knots $\boldsymbol{\delta}$, the latter must be estimated prior to the implementation of Eq. 21. Notice that the prediction error sequence $\mathbf{E}$ can be expressed as

$$\begin{aligned} \mathbf{E} &= \mathbf{Y} - \boldsymbol{\Phi}(\boldsymbol{\delta})\boldsymbol{\theta} \Rightarrow \\ &= \mathbf{Y} - \boldsymbol{\Phi}(\boldsymbol{\delta})\boldsymbol{\Phi}(\boldsymbol{\delta})^\dagger\mathbf{Y} \Rightarrow \\ &= \left[\mathbf{I} - \boldsymbol{\Phi}(\boldsymbol{\delta})\boldsymbol{\Phi}(\boldsymbol{\delta})^\dagger\right]\mathbf{Y} \end{aligned} \tag{22}$$

Thus, $\boldsymbol{\delta}$ can be estimated by the solution of the following nonlinear optimization problem [24]

$$\hat{\boldsymbol{\delta}} = \arg\min_{\boldsymbol{\delta}} V_{\text{VP}}(\boldsymbol{\delta}) \doteq \arg\min_{\boldsymbol{\delta}} \|(\mathbf{I} - \boldsymbol{\Phi}(\boldsymbol{\delta})\boldsymbol{\Phi}(\boldsymbol{\delta})^\dagger)\mathbf{Y}\|^2 \tag{23}$$

A final note in metamodeling refers to the cases of large data: observe that from Eqs. 18–20 the involved matrices, $\mathbf{Y}$ and $\boldsymbol{\Phi}(\boldsymbol{\delta})$, can become quite large even for small values of na, nb, p, L and N. Indicatively, for an AFS-ARX(2,3) model with B–spline basis of second order, $p = 3$, $L = 20$ and $N = 500$, their sizes are $[10000 \times 1]$ and $[10000 \times 15]$, respectively. In such cases, and in order to avoid numerical inconsistencies, it may be preferable to model directly the parameters $\alpha_i(\xi)$ and $\beta_i(\xi)$ from Eq. 13, in a process that can be easily realized in parallel. Such an estimation problem turns out to be a typical data–driven uncertainty quantification one that can be solved using, for example, the method described in Spiridonakos *et al.* [24]. This alternative is adopted for the analysis presented in the next section.

3 IMPLEMENTATION

The method's performance and effectiveness is assessed via the metamodeling of a "vehicle"–like prototype that consists of a frame substructure, displayed in Fig. 1, which is connected to four wheelsets through corresponding primary linear suspensions. Each wheelset is modeled as a mass with one degree of freedom and with equivalent stiffness and damping, while all suspensions are identical, except from the front right one that is characterized by uncertain stiffness. The associated parameters of the model are displayed in Tab. 1.

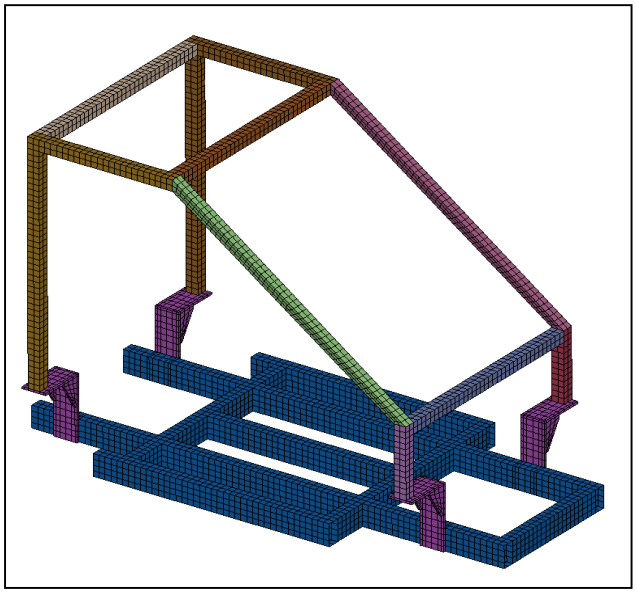

Figure 1: The frame substructure.

Quantity	**Symbol**	**Value**	**Unit**
Frame material density	E	2.1×10^{11}	N/m
Frame material modulus	ρ	7850	kg/m^3
Wheelset mass	m_w	16	kg
Wheelset stiffness	k_w	35	N/m
Wheelset damping	c_w	0	Ns/m
Suspension stiffness	k_s	22	N/m
Suspension damping	c_s	5	Ns/m
Uncertain stiffness	k_{fr}	$\sim \mathcal{N}(22, 6)$	N/m
Road profile	r_{fr}	$\sim \mathcal{N}(0, 7 \times 10^{-3})$	m

Table 1: Parameters of the simulated vehicle.

The FE model of the frame is constructed using quadrilateral shell and hexahedral solid elements, resulting in 45564 DOFs. Model reduction is accordingly applied using the method outlined in Section 2.3, leading to a reduced model of only 54 DOFs. The latter is then connected to the wheelset–suspension subsystems and the total structure is simulated by assuming excitation only in the front right position, which consists of a zero mean Gaussian process that is filtered using a 10th order digital Butterworth filter with low-pass frequency at 30 Hz. A number of $L = 50$ simulations is performed at a sampling period $T_s = 1$ ms and for $t = 5$ s, each one under a specific realization of k_{fr}, drawn using the latin hypercube sampling (LHS) method and illustrated in Fig. 2. The substructure $B(\xi)$ is herein selected to be the subsystem that has the road-induced force applied to the wheelset mass as an input and the vertical acceleration of the common boundary between the frame and the front right suspension as an output. Vibration excitation-response pairs of $N = 5000$ data are thus stored after every simulation. Figure 3 displays an indicative data pair that corresponds to $L = 20$.

To examine the consistency of the method under the availability of limited simulations and /or data, estimation of $B(\xi)$ is conducted using only simulations $\#$ 16 until $\#$ 30 (see Fig. 2). In

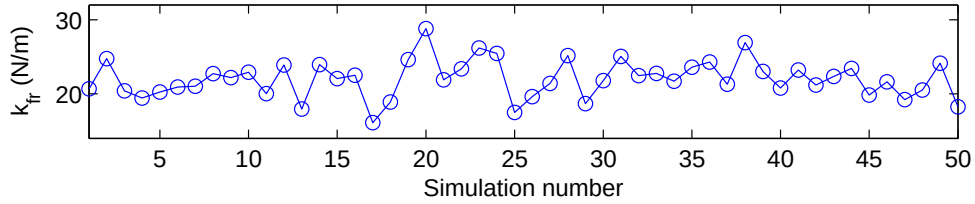

Figure 2: The uncertain stiffness k_{fr} for the 50 simulations conducted.

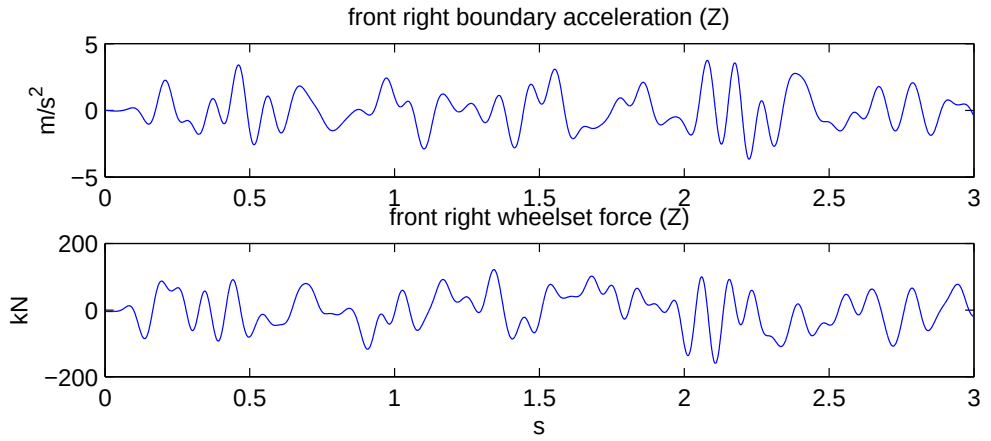

Figure 3: Vibration acceleration response at the front right boundary and road induced force for $L = 20$.

every case, the first 2000 values are extracted from the input–output data set, in order to avoid modeling transient effects, and the set used for identification consists of only the next 1000 data. In order to get an initial insight some initial trial-and-error modeling attempts were performed, revealing that AFS-ARX(2,3) are potentially adequate for representing the substructure $B(\xi)$. This results in five parameters, α_1, α_2, β_0, β_1 and β_2, which must be expressed in respect to the uncertain stiffness. A two–stage procedure is utilized to this purpose:

[S1] Simple ARX(2,3) models are estimated for every simulation and five new (compressed) data sets are formulated, with the uncertain stiffness as input and the AR/X parameter as output.

[S2] Models in the form of Eq. 13 are fitted to each parameter, for $p = 1, \ldots, 10$ and $k = 1, \ldots, 4$.

Figure 4 illustrates the results of this procedure. All examined models returned almost perfect match, as can be seen by the percentage fitness to the data, calculated by

$$\text{fit} = 100\left(1 - \frac{\|q - \hat{q}\|}{\|q - \bar{q}\|}\right)\ (\%) \tag{24}$$

where q and $\hat{q}$ denote true and estimated quantity, respectively, and $\bar{q}$ denotes mean value, with only $S_{j,1}$ exhibiting slightly lower performance. Thus, a model with B-spline basis functions of second order, $S_{j,2}$, and of $p = 3$ was selected for the uncertainty quantification of the AFS-ARX(3,2) parameters. For this model, Fig. 4 further displays the true (e.g., the ones estimated during step **[S1]** above) parameter values versus the model calculated ones.

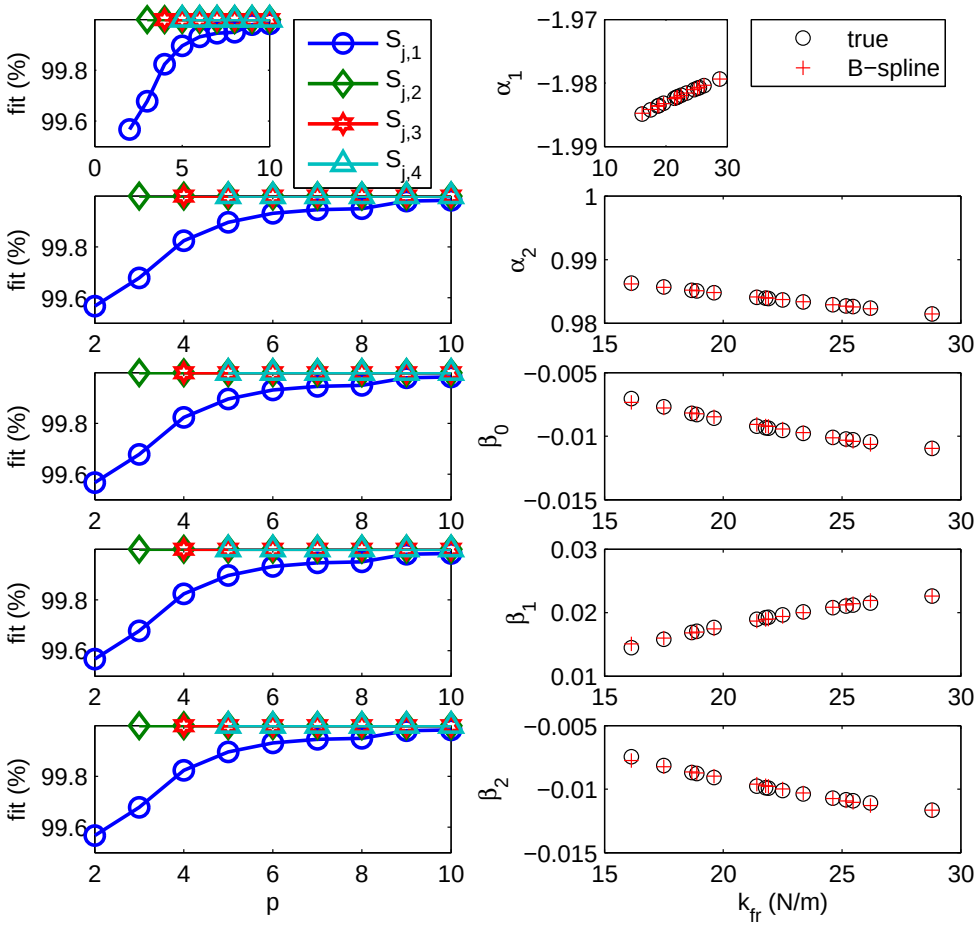

Figure 4: Results of the uncertainty quantification process for each parameter of the AFS-ARX(2,3) model. Left side: percentage fitness to data of every estimated model. Right side: true versus model-based outputs, using Eq. 13 with $p = 3$ and $k = 2$.

The identified AFS-ARX(3,2) model is finally validated against its applicability to the whole spectrum of possible uncertain values. To this end, the data from four simulations that were not used in the estimation process (randomly selected, with two realizations among $\#1, \ldots, \#15$ and two among $\#31, \ldots, \#50$) are forwarded into the model and the predicted output is plotted over the one simulated from the total structure in Fig. 5. Excellent matching is confirmed, implying that the AFS-ARX(3,2) model can adequately replace substructure $B(\xi)$.

4 CONCLUSION

A process for the effective simulation of large–scale, uncertain FE models was outlined in this study, consisting of three interrelated stages that take on the substructuring, the model reduction and the metamodeling steps. The illustrated results provide significant indication of effectiveness and suggest further investigation in this path, with respect to a number of issues that remain active challenges in the field of structural modeling and simulation. Automation of the proposed process, by focusing on the smart interpretation of boundary constraints, the extension to simultaneous substructuring and metamodeling of nonlinear models, as well as the implementation to real-time hybrid testing techniques are issues that are currently being investigated by the authors.

Keywords: Collision Detection, Unilateral Contact, Friction, Multibody Dynamics, Computational Methods.

Abstract. *In this work, some new results are presented on the dynamics of multibody mechanical systems involving contact and friction. The main contribution refers to the development of a new, systematic and accurate method for detecting contact among the components of the system. For simple geometries, this task is achieved by employing analytical means. For systems with components involving complex geometric shapes a more involved numerical methodology is developed. In both cases, once contact is detected, the common normal vector and the penetration depth is also calculated, leading to determination of the contact force and moment arising between the contacting bodies. This information is then passed to a solver, providing the full dynamic response of the system. The validity and numerical efficiency of the methodology developed is first demonstrated by considering a number of examples with relatively small geometric complexity but large traditional value and interesting dynamic response. Some new results are obtained on the dynamics of these systems. Finally, the same methodology is also tested and found to give more realistic results in more complicated mechanical applications.*

1. INTRODUCTION

Accurate and efficient prediction of dynamics of a multibody system subject to unilateral constraints is necessary in a large number of modern engineering applications [1-4]. This prediction is based heavily on suitable algorithms, leading to a fast and accurate prediction of the contact points and the forces developed there during motion. As a result, there is a continuous effort to improve the available techniques in both the contact detection and the prediction of the overall dynamics, as reflected by the vast amount of the literature devoted to the subject. The present research work belongs to this general category of investigations.

In general, the contact detection methods rely heavily on the type of geometric modeling. There are two major categories of geometric models employed currently, the polygonal and the non-polygonal. According to the first category, a solid body is divided into polygon soups (the solid is represented by a set of connected triangles) and conventional polyhedra (the geometry is represented with a polyhedron). These polyhedra may be convex or non-convex. In the category of the non-polygonal models, the body is divided into constructive solid geometry, implicit surfaces and parametric surfaces. Using the constructive solid geometry method, one can create objects from basic primitives such as spheres, blocks, cones and others, by combining them with set theoretical operations. The contact detection methods developed in the present research work use conventional convex polyhedra and basic primitives. These methods have found wide application in many diverse areas such as robotic simulations and computer games [5-8].

In particular, a two step approach has been developed in this work for the contact detection problem, referring to the computational problem of detecting intersection of two or more rigid bodies. In brief, a broad phase detection is considered first, which is typically a computationally efficient operation that yields pairs of objects that may intersect. This involves either the bounding volume approach (more specifically the axis aligned bounding boxes (AABB) for the cases of simple primitives) or the more elaborate approach of an AABB tree for the cases where a triamesh construction of a surface is involved. Next, a narrow phase detection is considered, where the individual pairs of bodies identified in the previous strep as potentially intersecting are checked in a more elaborate manner. This includes simple analytical relations (as in the case of sphere to sphere or sphere to box) or more complex approaches for the general convex polytope cases. In the latter case, intersection is tested using the Gilbert-Johnson-Keerthi's algorithm, which relies on support functions to measure the shortest directed distance for the two bodies of interest by creating and iteratively updating a simplex inside the Minkowski difference. As soon as contact is detected, the corresponding contact response is resolved. This includes evaluation of the penetration depth and the contact normal as well as identification of the contact manifold. For the non trivial cases, the penetration depth and the contact normal are resolved by employing the expanding polytope algorithm. According to this algorithm, a polytope is created inside the Minkowski difference and is iteratively expanded until an edge of the Minkowski difference is hit, thereby yielding the penetration depth and the contact normal vector. Finally, for the non trivial cases a clipping algorithm is used, where the two objects are clipped in the direction of the contact normal generating the contact manifold. The geometric center of the contact manifold is assumed to be the contact point.

In the present paper, a collection of contact detection methods between bodies of specific shape are presented. This includes a two part combination of canonical shapes, like a sphere, an orthogonal parallelepiped, an ellipsoid, a conical frustum and a triangle. The algorithms used are analytical in some cases and numerical in others. In all cases, the algorithm comprises of three parts. At first, it is determined whether there is contact between two bodies. Then, the contact point, the common normal vector and the penetration depth are calculated. Finally, the contact force and moment are applied on both bodies taking into account the penetration depth,

the relative velocities of the bodies and the contact point. The last part of the algorithm is the same for all the above cases. The first two parts are different for each case and they are presented thoroughly in Sections 2 and 3 below.

Employing the aforementioned contact detection algorithm, a number of characteristic example problems was solved by using existing numerical codes for predicting the dynamic response [9, 10]. The first set of examples chosen are of academic interest and well-known in previous literature [4, 11-17]. This includes the rattleback, the Euler disk, the sphere on a turntable, the tippe–top and the woodpecker toy. A selected set of numerical results are first presented for these systems, throwing some new light into special features of their dynamics, which were not examined before. In addition, results for a more involved mechanical system [18-20], taken from an industrial application, are also obtained by using the same methodology and presented.

The organization of this paper is as follows. First, in Section 2, some simple cases of contact detection are briefly summarized. In particular, these cases refer to contact of bodies with a canonical geometric shape, which can be solved in an analytical manner,. Then, in Section 3, a general contact detection methodology is presented, referring to bodies with arbitrary geometrical shapes. Next, in Section 4 some numerical results are presented for two selected mechanical systems. Finally, the most important findings of this work are summarized in the last section.

2. CONTACT DETECTION BETWEEN BODIES OF CANONICAL SHAPE

In the present section, a collection of results on contact detection between bodies with a specific canonical shape are presented. These shape combinations include the following: sphere to sphere, sphere to orthogonal parallelepiped (or simply box), sphere to ellipsoid, sphere to conical frustum and sphere to triangle.

2.1 Sphere to Sphere

This case is trivial. Let $\mathbf{c}_1$ and $\mathbf{c}_2$ be the position vectors of the two spheres' centers, while r_1 and r_2 are the corresponding radii. Then, the two spheres intersect when the distance between their centers is less than or equal to the sum of the radii. This means that $\|\mathbf{c}_1-\mathbf{c}_2\| \leq r_1+r_2$. In addition, the penetration depth is $d = (r_1+r_2) - \|\mathbf{c}_1-\mathbf{c}_2\|$, as shown in Fig. 1. Moreover, the contact point $\mathbf{x}$ is defined by the intersection of the line that connects the centers and an arbitrarily chosen sphere. The common normal vector $\mathbf{n}$ defines the line of impact and its direction is defined from the contact point to the sphere's center which was arbitrarily chosen.

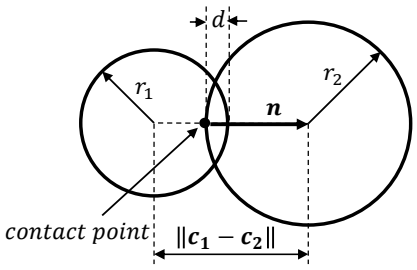

Fig. 1. Geometry of sphere to sphere contact.

2.2 Sphere to box

The intersection test is done by computing the point in the parallelepiped (or box, for brevity) which is closest to the sphere. Let the box be centered at the origin and aligned with the axes,

as shown in Fig. 2. The dimensions of the box in the x, y and z axes are $2n_1$, $2n_2$ and $2n_3$, respectively. The sphere's center is at $\mathbf{c} = (c_1 , c_2 , c_3)$. The point in the box closest to the sphere's center is given by

$$\mathbf{x} = (\text{clamp}(c_1,-n_1,n_1),\text{clamp}(c_2,-n_2,n_2),\text{clamp}(c_3,-n_3,n_3)) \quad (1)$$

where

$$\text{clamp}(c,a,b)=\begin{cases} a, \text{ if } c<a \\ b, \text{ if } c>b \\ c, \text{ otherwise} \end{cases} \quad (2)$$

The sphere intersects the box if the point **x** is contained in the sphere $\|\mathbf{x}-\mathbf{c}\| \leq r$, where r is the sphere's radius. The contact point is **x**. The penetration depth is given by $d = r - \|\mathbf{x}-\mathbf{c}\|$. The common normal vector **n** is a vector starting from the contact point **x** and ending at the sphere's center **c**.

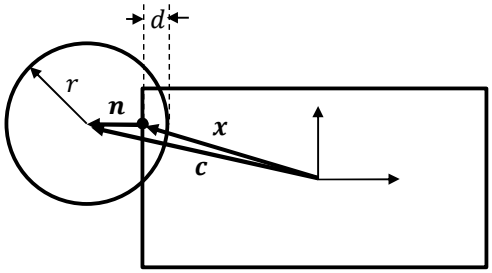

Fig. 2. Geometry of sphere to orthogonal parallelepiped contact.

2.3 Sphere to ellipsoid

For testing the intersection of a sphere with radius R and an ellipsoid with semi–principal axes a, b and c, the point of the ellipsoid closest to the sphere is calculated. Let the axes' origin be centered at the ellipsoid center, as depicted in Fig. 3. Also, let $\mathbf{p} = (p_x , p_y, p_z)$ be the sphere's center and $\mathbf{r} = (x, y, z)$ be the point in the ellipsoid closest to the sphere. In order to determine this point, the following constrained minimization problem needs to be solved

$$\min \ (p_x - x)^2 + \left(p_y - y\right)^2 + (p_z - z)^2 \quad (3)$$

such that

$$\left(\frac{x}{a}\right)^2 + \left(\frac{y}{b}\right)^2 + \left(\frac{z}{c}\right)^2 - 1 = 0. \quad (4)$$

For this, a Lagrange multiplier λ and a function L(x,y,z,λ) are introduced by

$$L(x, y, z, \lambda) = (p_x - x)^2 + \left(p_y - y\right)^2 + (p_z - z)^2 + \lambda\left(\left(\frac{x}{a}\right)^2 + \left(\frac{y}{b}\right)^2 + \left(\frac{z}{c}\right)^2 - 1\right). \quad (5)$$

Then, the minimum of the above function is calculated by solving the following equations

$$\frac{\partial L}{\partial x} = 0, \frac{\partial L}{\partial y} = 0, \frac{\partial L}{\partial z} = 0, \frac{\partial L}{\partial \lambda} = 0 \quad (6)$$

The resulting set of nonlinear algebraic equations is solved with the Newton–Raphson method.

The sphere intersects the ellipsoid if the point **r** is contained in the sphere $\|\mathbf{r}-\mathbf{p}\| \leq R$. The contact point is **r**. The penetration depth is given by $d = R - \|\mathbf{r}-\mathbf{p}\|$. The common normal **n** vector is a vector starting from the contact point **r** and ending to the sphere's center **p**.

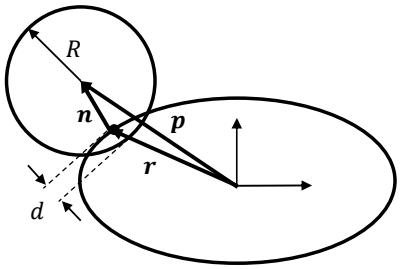

Fig. 3. Geometry of sphere to ellipsoid contact.

2.4 Sphere to conical frustum

This case leads to an axisymmetric problem with axis being the frustum's axis, as shown in Fig. 4. By taking the plane which is defined by the frustum's axis and the sphere's center, the problem becomes equivalent to determining the intersection between a trapezoid and a circle. The coordinate system origin is placed at the center of the bottom face of the frustum. For testing the intersection, a point **x** in the trapezoid which is closest to the sphere is calculated. The space outside the trapezoid is divided into five sections and according to which section the sphere's center **p** belongs to, a different analytical method of calculating the closest point is applied. Then, the sphere intersects the frustum if the point **x** is contained within the sphere $\|\mathbf{x}-\mathbf{c}\| \leq r$, where r is the sphere's radius. The contact point is **x**. The penetration depth is given by $d = r - \|\mathbf{x}-\mathbf{c}\|$. The common normal vector **n** is a vector starting from the contact point **x** and ending to the sphere's center **c**.

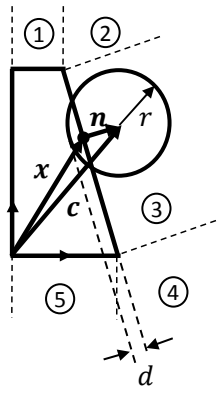

Fig. 4. Geometry of sphere to conical frustum contact.

2.5 Sphere to triangle

The intersection test is done by computing the point **x** in the triangle which is closest to the sphere. Let the coordinate system origin be placed at the center of the sphere, as shown in Fig. 5. Let $\mathbf{p}_0$, $\mathbf{p}_1$ and $\mathbf{p}_2$ be the vertices of the triangle. The sphere's center is projected on the triangle's plane. This plane is divided into seven sections and according to which section the sphere's projected center belongs to, a different analytical method of calculating the closest point is applied. Then, the sphere intersects the triangle if the point **x** is contained in the sphere

$||\mathbf{x}|| \leq r$, where r is the sphere's radius. The contact point is **x**. The penetration depth is given by $d = r - ||\mathbf{x}||$. The common normal vector **n** is a vector starting from the contact point **x** and ending to the sphere's center.

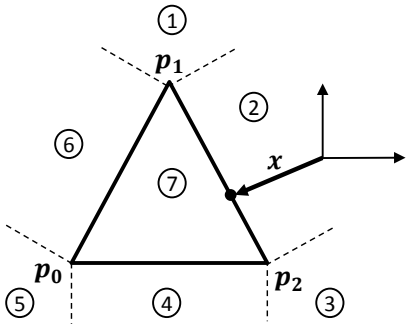

Fig. 5. Geometry of sphere to triangle contact.

3. CONTACT DETECTION BETWEEN BODIES OF GENERAL SHAPE

For the general case of two convex polytopes, the contact detection problem is resolved by following the algorithmic treatment presented in this section. The computational problem is assumed to be defined given a pair of convex shapes and the spatial relation between them. The above treatment is currently employed for cases including the rectangular cuboid (or simply box), the conical frustum and the ellipsoid, giving a total of six different contact combinations. The proposed approach is split into the following three steps.

1. The *intersection testing*, which refers to a Boolean query that is true if and only if the intersection of two shapes is nonempty [8]. The intersection is tested within this work, using the Gilbert-Johnson-Keerthi's algorithm [5, 6].
2. The *evaluation of the penetration depth and the contact normal*. As soon as the intersection testing query yields true, the corresponding penetration depth and the contact normal are evaluated using the Expanding Polytope Algorithm (EPA) [5]. The penetration depth and the contact normal can then be used for the estimation of the corresponding contact force/moment vector.
3. The generation of the contact manifold, i.e., the set of contacting points [6], which can be used for the contact force/moment vector application. An implementation based on clipping is proposed for all cases except those employing an ellipsoid. For the latter, the geometric properties of the ellipsoid are exploited.

3.1 Intersection testing

The intersection is tested using the Gilbert-Johnson-Keerthi's (GJK) algorithm. GJK is an iterative method, initially proposed for computing the distance between complex objects in three-dimensional space [5]. It can, however, be also employed to solve different proximity queries including ones that are of interest in the collision detection problem. GJK is quite popular in this field, mainly because it is very versatile (only a set of vertices describing the convex polytope can be used) and is extremely efficient [6].

Overall, GJK relies on support functions to measure the shortest directed distance between the two convex polytopes of interest, say A and B. It does so, by creating and iteratively updating a simplex inside the Minkowski difference set A–B, with $A–B=\{\mathbf{a}–\mathbf{b} \mid \mathbf{a} \in A, \mathbf{b} \in B\}$. A simplex is defined as the convex hull of an affinely independent set of vertices. Up to four vertices can be employed, so a simplex can be a single point, a line, a triangle or a tetrahedron.

In each iteration, the updated simplex lies closer to the origin than the previous one. When the origin of the Minkowski difference is included in the simplex, the two shapes are determined to intersect.

```
function EPA:
  D ← arbitrary vector
  v ← A.Support(d) – B.Support(-d)
  W ←{v}
  do:
    w ← A.Support(v) – B.Support(-v)
    if v·w > 0:
      return false
    W ←ProjectOrigin(W ∪ v)
  until |W| = 4 or ||v|| < tol
  return true
```

Table 1. The basic steps of the GJK algorithm

In the above, `Support` provides the support mapping

$$S_A(\boldsymbol{v}) = \{\mathbf{p}: \max\{\boldsymbol{v}\cdot\boldsymbol{a}: \boldsymbol{a} \in A = \boldsymbol{v}\cdot\boldsymbol{p}, \boldsymbol{p} \in A\}\}.$$

Given a direction $\boldsymbol{v}$ this returns the points $\mathbf{p}$ in the shape A that would be the first to come in contact with a plane with normal $\boldsymbol{v}$ that moves from infinitely far away towards the center of A. Furthermore, `ProjectOrigin` returns the point on a point (obvious solution), line or triangle which is the closest to the origin.

3.2 Penetration depth and contact normal

The penetration depth and the contact normal are found using the Expanding Polytope Algorithm (EPA). EPA is an accurate algorithm used for computing the penetration depth between a pair of shapes A and B, having a non-empty intersection. Similar to the GJK, EPA employs only the support mappings of the corresponding shapes, further contributing to the versatility of the overall approach.

Starting point for the EPA is a polytope that contains the origin of the Minkowski difference. The simplex provided by GJK is used to generate the polytope required. The GJK may consist of only a point, a line or a triangle. In this case, proper initialization of the polytope is performed, following the approach described in [6].

As soon as a valid simplex is build inside the Minkowski difference set, then this is iteratively expanded into a convex polytope. The algorithm proceeds in each step so that the face closest to the origin is the one that is expanded. The iterations stop when an edge of the Minkowski difference is recovered during expansion (within some numerical accuracy), thereby yielding the penetration depth (and the corresponding normal vector), as equal to the distance from the origin to this face.

```
function EPA:
  P ← A convex polytope containing the origin
  Q ← ∅
  for each face f in P:
    e ← construct(f)
    if e.closest_internal():
      Q.push(e)
```

```
    μ ← infinity
    do:
      e = Q.pop()
      if not e.obsolete:
        v ← e.v
        w ← A.Support(v) – B.Support(-v)
        μ ← min(μ, (v·w)² / ||v||²)
        close_enough ← μ ≤ (1 + tol)²||v||²
        if not close_enough:
          e.obsolete = true
          E ← ∅
          for i ← 0, 1, 2:
            sihlouette(e.adjᵢ, e.jᵢ, w, E)
            for se, i ∈ E:
              ne ← construct(se.yᵢ⊕₁, se.yᵢ, w)
              if ne.affinely_dependent:
                return ||v||
              if ne.closest_internal()
                 and ||v||²≤|ne· v|≤μ:
                   Q.push(ne)
    until close_enough or Q.empty() or ||Q.pop().v||² > μ
    return ||v||
```

Table 2. The algorithm in [6]

In the above `Q` is a priority list and μ is an upper bound for the squared penetration depth. Entry is a structure for the polytope face, that holds the vertices (`y`), the adjacent entries (`adj`), the indices of the corresponding adjoining edges (`j`) and `obsolete` which is a boolean that identifies if this face has become obsolete during a previous iteration. Furthermore $\oplus$ denotes the addition modulo 3.

Once an entry `e` that contains the point closest to the origin, point `w` is calculated as described above. The front side of entry `e` can always be seen from the `w`, so that `e` is marked `obsolete`. Then, the polytope is recursively traversed starting with each entry adjacent to `e`. All the entries that can be seen from e are further marked as `obsolete`. This procedure is provided by function `sihlouette`, which is based on a recursive flood filling algorithm.

```
function sihlouette(e, i, w, E):
  if not e.obsolete:
    if e.v·w < ||e.v||²:
      E ← {E, (e, i)}
    else:
      e.obsolete ← true
      sihlouette(e.adji⊕1, e.ji⊕1, w, E)
      sihlouette(e.adji⊕2, e.ji⊕2, w, E)
```

Table 3. Pseudocode for function `sihlouette`

3.3 Contact manifold generation

The contact manifold, which usually is further reduced to a single point where the contact force is to be applied, is generated using a clipping algorithm. For this case, the faces of the shapes A and B should be explicitly defined. This is a major difference from the algorithmic

treatment described so far, that required only the corresponding support mappings. Furthermore, this procedure may introduce accuracy issues when the shape is not defined from flat faces only. This is the reason why the contact point in the ellipsoid is not generated by this method, but by exploiting its geometric property of the normal uniqueness.

As a first step, the reference face is identified, which is the face normal to the contact vector (or its opposite), as returned by the EPA. An incident face is then identified on the other shape, which is the one that is closer to the opposite of the vector used for the reference face. Then, a set of clippings is performed between the incident face and the faces that are adjacent to the reference one. Each clipping reduces the size of the contact manifold, which is initially set equal to the incident face. A final clipping is performed in the remaining area by the reference face.

```
function clipping:
  reference ← A.find_reference(v)
  incidence ← B.find_incidence(v)
  if not reference:
    reference ← B.find_reference(-v)
    incidence ← A.find_incidence(-v)
  manifold ← incidence.vertices()
  for f ← reference.faces():
    manifold ← manifold.clip(f)
  manifold ← manifold.translate(||v||)
  manifold ← manifold.clip(reference)
```

Table 4. Pseudocode for the clipping function

The contact point can then be assumed as the geometrical center of the contact manifold.

4. NUMERICAL RESULTS

Employing the aforementioned contact detection algorithms, a number of characteristic example problems was solved by using an existing numerical codes for predicting the dynamic response [9]. The first example chosen is of academic interest and is known in literature as the woodpecker toy [15-17]. In addition, results for a more complex mechanical system, involving ball bearings, were also obtained by using the same methodology [18-20].

4.1 Results for the woodpecker toy

The woodpecker toy shown in Fig. 6 consists of a pole fixed to the ground, a sleeve, a torsional spring and a woodpecker. The sleeve and the woodpecker are connected with a revolute joint and a torsional spring. The hole in the sleeve is slightly larger than the diameter of the pole. The toy's response is heavily affected by friction and impact phenomena. The woodpecker moves down due to gravity with a pitching motion and impacts the pole while the sleeve acts as a jamming mechanism with the presence of friction. The system oscillates and may end up in a stable limit cycle.

The first scientific studies on the dynamics of this toy, based on application of non–smooth and contact mechanics theory, was presented in [15-17]. The model is planar and consists of three rigid bodies: the woodpecker, the sleeve and the pole. The sleeve's lateral movement is small so it is neglected. Another major assumption is that both the woodpecker and the sleeve rotate with small angle, so the gap functions are calculated with linearized kinematics.

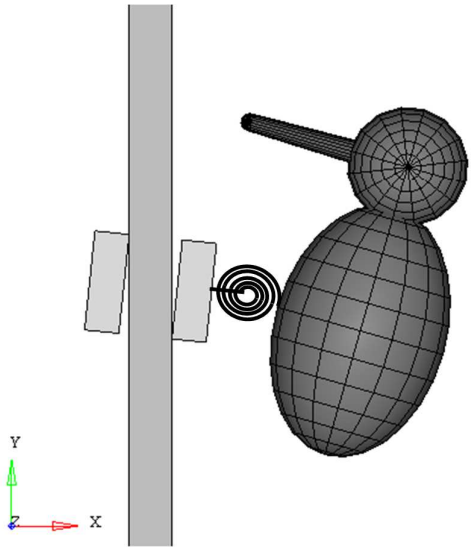

Fig. 6. The woodpecker toy.

In the present paper, the model is created using basic solids. Specifically, the pole is represented by an orthogonal parallelepiped, the sleeve by two orthogonal parallelepipeds, the body of the woodpecker by an ellipsoid, its head by a sphere, its beak by a conical frustum and a sphere at the tip (see Fig. 6). There exist also a revolute joint and a torsional spring between the sleeve and the woodpecker. Contact is taken into account between the beak's tip and the pole (sphere to box) and between the sleeve and the pole (box to box). Values for the geometry, masses, moments of inertia and contact parameters are taken from [16]. Here, the model is also planar. However, the sleeve's lateral movement is taken into account, although it does not make any significant difference. The major difference with [16] is that the rotations of both the sleeve and the woodpecker are not assumed to be small, hence the kinematics is nonlinear. The above assumptions are critical and play a significant role to the system's response. By examining the results of [5], it can be seen that the woodpecker's and sleeve's extremum angles are 30 and 6 degrees respectively. The woodpecker's rotation is far too large to be linearized, whereas the sleeve's angle just passes the limit.

Comparing the results obtained here with those presented in [16] it is concluded that the linearization based on small rotations influences the results especially in the woodpecker's angle where the upper and lower limits are slightly greater and smaller respectively (see Fig. 7a). Regarding the sleeve's angle there are no significant differences because for such an angle range the linearization is a good approximation (Fig. 7d). Similar bevahior is evident concerning the angular velocities. Examining these quantities, it is evident that a slight variation appears at the upper and lower limits for both the woodpecker and the sleeve (Figs. 7c and 7d).

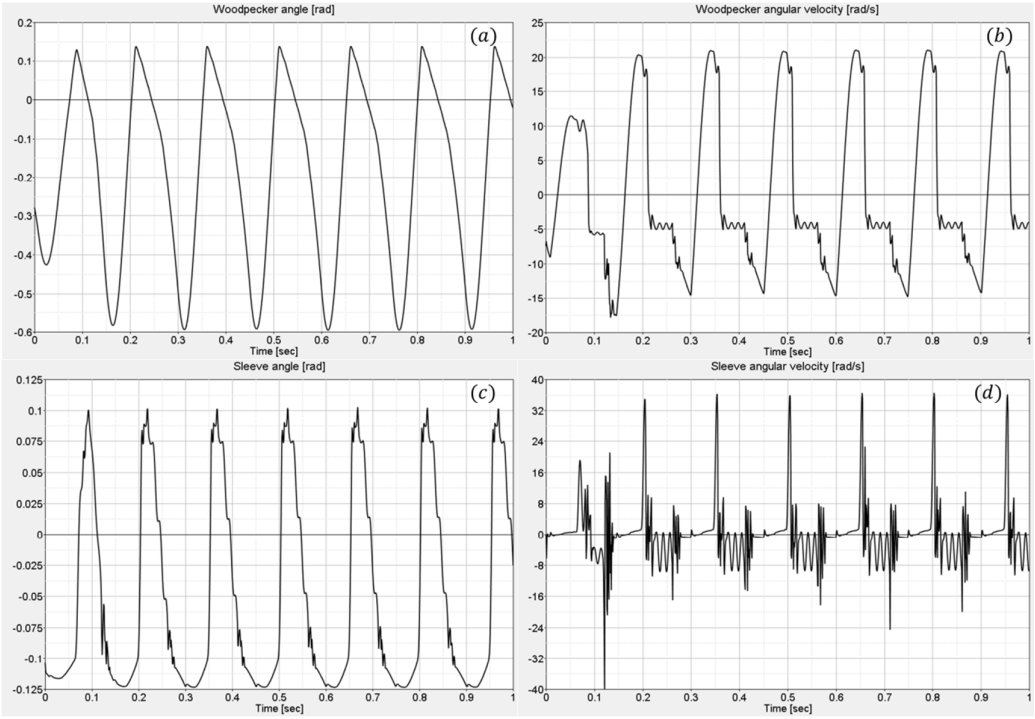

Fig. 7. Numerical results for the woodpecker toy. Time history of the woodpecker: (a) rocking angle, (b) angular speed, (c) sleave angle and (d) sleave angular speed.

4.2 Results for a mechanism with a rolling bearing

Dynamics of ball bearings has been studied from many different angles of view, including lubrication, wear, vibration and sound. In some cases, a multibody model was used. The most preferred modeling assumptions are the following: no slipping of the balls during rolling on the surface (the ball motion is defined by a kinematic constraint), no friction between the balls and the bearing's rings, planar motion and negligible mass of the balls [18, 19]. To investigate whether these assumptions are reasonable, development and consideration of more realistic models that remove the above assumptions is needed.

In the present paper, a model for a ball bearing (SKF BB1B420205) is first developed. Then, this is used in a crank-rod-slider mechanism to represent the revolute joint between the crank and the rod, as shown in Fig. 8a. Regarding the ball bearing modeling, the balls are modeled by eight spheres, while the inner and outer rings and the cage are modeled by triangle meshed solids (see Fig. 8b). Moreover, contact is enabled between each sphere and both rings, while sphere to sphere and inner to outer ring contact is not taken into account. Although contact between the cage and the balls could also be studied, it was choosen not to do it here because the loads arising between the cage and the balls are not significant. Another reason for this is that the model becomes much more complicated, resulting in additional computer simulation time with no significant gain. To prevent the balls from coming into contact, eight inline constraints are added between each ball's center and a specific coordinate system on the cage (see Fig. 8c). Concerning other major connections, the cage is connected to the inner ring's center with a revolute joint, the outer ring is fixed to the crank, while the inner ring is fixed to the rod. Values for the geometry, masses, moments of inertia and contact parameters are taken from [19]. The evaluation of the contact forces is based on Herzian contact deformation theory that

takes into account the geometry and the material properties. The methodology for calculating the stiffness values for the contact is described thoroughly in [20].

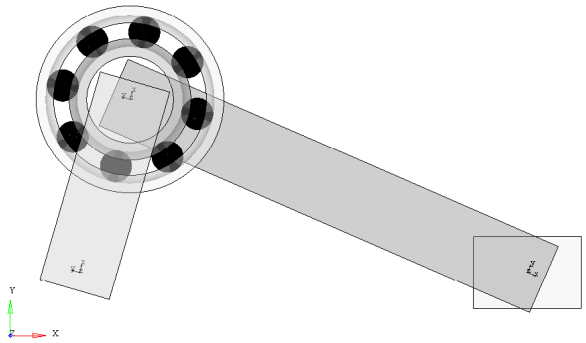

Fig. 8a. Mechanism

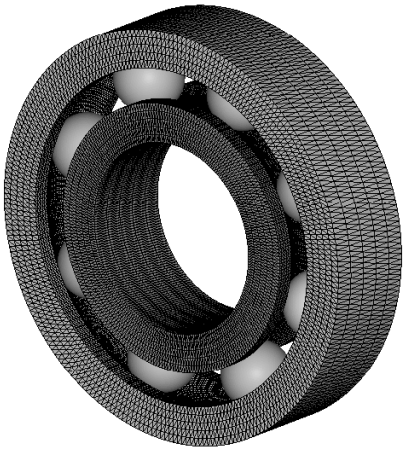

Fig. 8b. Ball bearing model

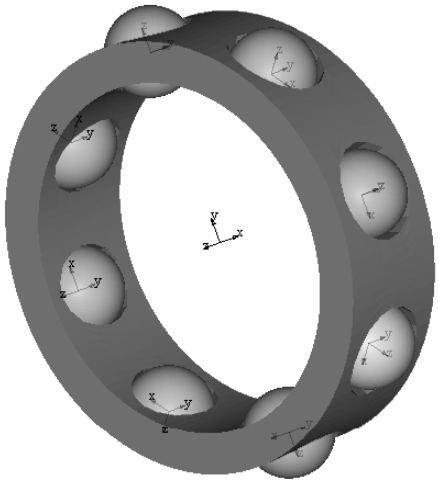

Fig. 8c. Cage model

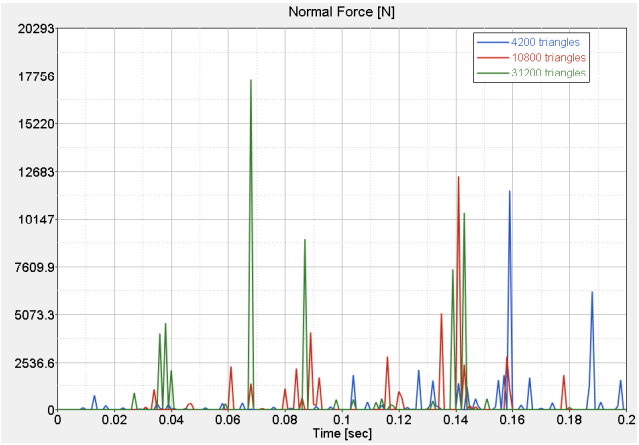

Fig. 8d. Normal force on a ball

By implementing the contact detection algorithm between sphere and triangle presented in Section 2, the mechanical model developed was simulated, assuming that the crank rotates with a constant angular speed of 300 rpm. In Fig. 8d is depicted the normal force acting from the outer ring to a ball for three different meshes. Although the maximum force is congruent with that presented in [19], the time history is completely different. This is believed to be due to the lack of friction in the model employed in [19], where the balls movement is induced by imposing a kinematic constraint, taking into account that the balls roll without sliding. In reality, this is not true and causes the balls to be at a different position.

5. SYNOPSIS

A new contact detection methodology was presented, leading to an accurate and numerically efficient determination of the dynamic response of a class of multibody engineering systems involving contacts and friction. The methodology developed allows solution to general

mechanical problems, without having to formulate the equations of motion and the gap functions in each case, separately. Furthermore, the new algorithm takes into account large relative rotations between two solid bodies and does not suffer from restrictions caused by kimenatic linearization. In particular, the contact detection algorithm between a sphere and a triangle allows to create more detailed and realistic models for ball bearings or any machine element involving contact between a sphere and a general surface (e.g., constant velocity joint). Furthermore, it allows incorporation of friction using either Amontons–Coulomb or even more sophisticated friction laws. Therefore, it is expected that this tool can prove usefull to engineers who want to study various phenomena arising in complex mechanical systems with components involving contact and friction. Some of these advantages were illustrated in this work by presenting results for the classical woodpecker toy and a more complex systems involving ball bearings.

Keywords: Analytical dynamics; Newton's law of motion; Rheonomic constraint; Acatastatic constraint; Foliated manifold; Scleronomic manifold.

Abstract. *This study is focused on a class of discrete mechanical systems subject to equality motion constraints involving time and acatastatic terms. In addition, their original configuration manifold possesses time dependent geometric properties. The emphasis is placed on a proper application of Newton's law of motion. A first step is to consider the corresponding event manifold by adding time to the set of coordinates and then determine its geometric properties. Next, the way of introducing time dependence in these properties through a coordinate transformation in the event manifold or the motion constraints is also investigated. Also, foliation theory is used to clarify some key concepts and provide an accurate definition of a scleronomic manifold, leading to a set of coordinate invariant conditions. The analysis is completed by an appropriate set of equations of motion on the original configuration manifold, appearing as a system of second order ordinary differential equations. Finally, the analytical findings are enhanced and illustrated further by considering selected examples.*

1 INTRODUCTION

Among the many subjects of analytical dynamics, a central place is occupied by those referring to the derivation of the equations of motion of systems subject to equality constraints (e.g., [8, 21, 23]). Over the last decades, it has become apparent that many of the theoretical questions in this area of dynamics can be answered in an illustrative and complete way by employing fundamental concepts of differential geometry [4, 17, 18]. This in turn provides a stronger foundation in solving difficult engineering problems by employing new, more accurate and robust numerical techniques (e.g., [2, 6, 11]). Based on these observations, the main objective of this work is to use such concepts in order to treat a class of mechanical systems. These systems are described by configuration manifolds possessing time dependent geometric properties (i.e., metric and connection) and are subject to equality motion constraints involving an explicit time dependence and acatastatic terms. Besides providing a new and clear interpretation of the key concepts, the theoretic framework chosen allows a systematic derivation of the equations of motion for the class of systems examined.

The present study is an extension of recent work of the authors on scleronomic systems [15, 19]. Again, the emphasis is put on explaining several demanding theoretical aspects, which are of keen interest to the engineering community. In addition, the main philosophical approach adopted is that the safest and deepest principle of Mechanics is Newton's law of motion [7, 9]. Specifically, the new contributions of this work can be summarized as follows. First, the central issue is the consistent application of Newton's law to the class of mechanical systems examined. Due to the presence of time in the properties of the configuration manifold, the need to express Newton's law in an invariant form leads naturally to its application to the event configuration manifold of the system [12, 23]. This step is performed first in a geometrically consistent manner. Moreover, another issue clarified in this work is the way time effects are introduced into the properties of a configuration manifold in an explicit manner. It is shown that these effects appear either by performing a time dependent transformation in the event manifold or by enforcing additional time dependent motion constraints. In addition, it is demonstrated that the former effects are in fact removable. Furthermore, the geometrical picture built by employing the classical engineering approach is enhanced in a remarkable way by utilizing some ideas of foliation theory [3, 14, 22]. Among other things, this theory provides a coordinate invariant way of stating the conditions for a configuration manifold to be scleronomic, even though its geometric properties may exhibit a spurious time dependence. Another important new contribution of the present work is the derivation of the equations of motion for the class of systems examined as a set of second order ordinary differential equations in the original configuration manifold. This presents certain advantages when compared to classical approaches leading to a set of differential algebraic equations, instead. It also exhibits better characteristics than previous methods leading to sets of ordinary differential equations through elimination of motion constraints or Lagrange multipliers [2, 15]. Finally, for the special case of scleronomic systems, the equations of motion derived are shown to become identical with a similar set of equations obtained earlier [15].

The organization of this paper is as follows. First, some useful concepts of differential geometry are briefly summarized in Section 2. In Section 3, the idea of the event manifold is employed and its geometric properties are set up. Then, the equations of motion are derived, firstly on the event and subsequently on the configuration manifold. In Section 4 are discussed effects caused by a special change of coordinates in the event manifold. Likewise, in Section 5 is investigated the effect caused by the presence of time dependent and acatastatic terms in the motion constraints. The results of these effects are identified and separated in Section 6, where a set of scleronomicity conditions is presented by employing basic ideas of

foliation theory on manifolds. Then, the equations of motion for the general class of systems examined are derived and presented in Section 7. Finally, results are presented for two mechanical examples, illustrating basic features of the class of systems examined.

2 SOME GEOMETRIC PRELIMINARIES

This work focuses on the dynamics of mechanical systems, whose spatial configuration can be determined at any time by a finite set of local coordinates, say $q^1,\ldots,q^n$ [12, 21]. The motion of such a system can be represented by the motion of a fictitious point p moving along a curve $\gamma=\gamma(s)$ on an n-dimensional manifold M, the configuration space of the system [23]. Then, if φ is a coordinate map acting from a neighborhood of point p to the classical space $\mathbb{R}^n$, the coordinates of p are

$$q=\varphi(p), \tag{1}$$

with $q=(q^1,\ldots,q^n)$. Usually, the parameter s coincides with time t and the quantity $\underline{v}=d\gamma/dt$ represents the velocity vector at p. This vector is tangent to γ and belongs to an n-dimensional vector space T_pM, the tangent space of the manifold at p [4, 10], with components $v^i=\dot{q}^i$ in the holonomic basis $\mathfrak{B}_g=\{\underline{g}_1 \ \ldots \ \underline{g}_n\}$ [5]. Adopting the usual summation convention for repeated indices [24], the velocity vector can be written as

$$\underline{v}=\sum_{i=1}^{n} v^i \underline{g}_i = v^i \underline{g}_i .$$

In general, any element $\underline{u}$ of the vector space T_pM can be expressed in the form $\underline{u}=u^i \underline{e}_i$, where $\mathfrak{B}_e=\{\underline{e}_1 \ \ldots \ \underline{e}_n\}$ is an arbitrary basis of T_pM. Also, one needs often to establish a relation between two different bases, say between $\mathfrak{B}_g$ and $\mathfrak{B}_e$, through equations of the form

$$\underline{e}_i=A_i^j \underline{g}_j \quad \text{or} \quad \underline{g}_i=B_i^j \underline{e}_j \quad (i,j=1,\ldots,n), \tag{2}$$

where A_i^j and B_i^j are elements of $n\times n$ matrices, satisfying the conditions

$$A_i^j B_k^i = A_k^i B_i^j = \delta_k^j , \tag{3}$$

which involve Kronecker's delta δ_k^j [17]. Moreover, any basis of T_pM is characterized by its structure constants c_{jk}^i, defined through the Lie bracket in the form

$$[\underline{e}_j,\underline{e}_k]=c_{jk}^i \underline{e}_i .$$

A complete description of the motion of a dynamical system can be achieved by introducing the dual space to T_pM at any point of the manifold, denoted by T_p^*M. Its elements are called convectors. Then, for any vector $\underline{u}$, a covector $\underset{\sim}{u}^*$ may be found through the dual product. For example, to each basis $\mathfrak{B}_e$ of T_pM, a dual basis $\mathfrak{B}_e^*$ can be constructed for T_p^*M, with elements $\{\underset{\sim}{e}^i\}$ satisfying

$$\underset{\sim}{e}^i(\underline{e}_j)=\delta_j^i , \tag{4}$$

Apart from the set of points, a manifold used in dynamics should possess two additional geometrical objects. One of them is the metric tensor, with components in the basis $\mathfrak{B}_e^*$ given by

$$g_{ij} = \langle \underline{e}_i, \underline{e}_j \rangle \,, \tag{5}$$

where $\langle \cdot, \cdot \rangle$ denotes the inner product of the tangent space $T_p M$. This provides a dual product by

$$\underset{\sim}{u}^*(\underline{w}) \equiv \langle \underline{u}, \underline{w} \rangle, \quad \forall \underline{w} \in T_p M \,. \tag{6}$$

If the components of the metric tensor are identified with those of mass matrix, through the kinetic energy, then the covector corresponding to the velocity vector $\underline{v}$ is the generalized momentum $\underset{\sim}{p}^*$.

Another geometrical tool which is essential in dynamics is the affine connection, represented by symbol ∇ . Its components Λ^i_{jk} in a basis $\mathfrak{B}_e$ of space $T_p M$, known as affinities, are defined by

$$\nabla_{\underline{e}_j} \underline{e}_k = \Lambda^i_{jk} \underline{e}_i \,. \tag{7}$$

Then, the covariant differential of a covector $\underset{\sim}{u}^*$ along a curve on M with tangent vector $\underline{v}$ is

$$\nabla_{\underline{v}} \underset{\sim}{u}^* = (u_{i,j} - \Lambda^{\ell}_{ji} u_{\ell}) v^j \underset{\sim}{e}^i \,, \tag{8}$$

with $u_{i,j} = \partial u_i / \partial q^j$. Then, M is a Newton manifold if determination of the true path of motion on M due to a given set of applied forces $\underset{\sim}{f}^*$ is based on application of Newton's second law with form

$$\nabla_{\underline{v}} \underset{\sim}{p}^* = \underset{\sim}{f}^* , \tag{9}$$

Next, consider a new manifold M_A, with a dimension m smaller than n, generated after imposing a set of motion constraints on M , which are eventually cast in the form

$$v^i = N^i_{\alpha} v^{\alpha} \quad (i = 1, \ldots, n \,;\; \alpha = 1, \ldots, m), \tag{10}$$

where $\underline{v}_A = v^{\alpha} \underline{e}_{\alpha}$ is a vector of $T_{p_A} M_A$ and $\underline{v} = v^i \underline{e}_i$ is an element of $T_p M$. Then, it was shown in a previous study that if the original manifold M is Newtonian, the new manifold M_A remains Newtonian, provided that the metric and connection on M_A satisfy the compatibility conditions

$$g_{\alpha\beta} = N^i_{\alpha} g_{ij} N^j_{\beta} \tag{11}$$

and

$$(\Lambda^{\lambda}_{\beta\alpha} g_{\lambda\gamma} - N^i_{\alpha,\gamma} N^j_{\beta} g_{ij} - N^i_{\alpha} N^j_{\beta} N^k_{\gamma} \Lambda^{\ell}_{ji} g_{\ell k}) v^{\beta} v^{\gamma} = 0 \,, \tag{12}$$

with $N^i_{\alpha,\gamma} = \partial N^i_{\alpha} / \partial q^{\gamma}$ [26]. Using Eq. (8), the last condition yields

$$\Lambda^{\lambda}_{\beta\alpha} = g^{\lambda\gamma} [N^j_{\beta} (N^i_{\alpha,\gamma} g_{ij} + N^i_{\alpha} N^k_{\gamma} \Lambda^{\ell}_{ji} g_{\ell k}) + \sigma_{\alpha\beta\gamma}] \,,$$

where $\sigma_{\alpha\beta\gamma} = -\sigma_{\alpha\gamma\beta}$ and the remaining part corresponds to what is known in the literature as "the metric compatibility condition" [4, 24].

3 GEOMETRIC PROPERTIES OF EVENT MANIFOLD - APPLICATION OF NEWTON'S LAW

For a mechanical system, the geometric properties of the configuration manifold M can be determined through enforcement of a set of constraints on the motion of a system of N unconstrained particles, taking place within an archetypal Euclidean manifold E^{3N}, with dimension $3N$ [9, 17]. When inertial Cartesian coordinates are used, the metric of this space involves only constant diagonal elements, while all the affinities vanish [19]. Furthermore, even when general curvilinear coordinates are used, the geometric properties of this manifold may depend on the position on the manifold but they do not depend on time explicitly. In this way, E^{3N} presents a raw model for a scleronomic manifold. Then, for a general scleronomic manifold M, it is true that

$$g_{ij} = g_{ij}(q) \quad \text{and} \quad \Lambda_{ij}^{k} = \Lambda_{ij}^{k}(q)\,, \tag{13}$$

where the coordinates q are related to position on the manifold through Eq. (1). However, in several cases, the motion constraints imposed on the original system of particles or the transformations performed are such that the geometric properties of a configuration manifold M appear in the form

$$g_{ij} = g_{ij}(q(t),t) \quad \text{and} \quad \Lambda_{ij}^{k} = \Lambda_{ij}^{k}(q(t),t) \tag{14}$$

and the manifold is rheonomic. In fact, this can occur artificially, even in the archetypal scleronomic manifold E^{3N}, by performing a velocity transformation like that of Eq. (2), with elements $A_i^j(q,t)$, depending on time [9, 16]. Another way to introduce time dependence is through enforcement of a set of motion constraints. These ideas will become more concrete in Sections 4 and 5, respectively.

When the geometric properties of a manifold M are time dependent, the need to keep the form invariance of Newton's law, as expressed by Eq. (9) through the covariant derivative of momentum, makes it convenient to perform the analysis of the motion on the so called event or extended configuration manifold, denoted by $\bar{M}$, with dimension $n+1$ [12, 23]. A natural way to introduce this manifold is through coordinate maps. Specifically, if $\bar{\varphi}$ is a coordinate map of $\bar{M}$, corresponding to a coordinate map φ on M, then the coordinates of point p of $\bar{M}$ can be selected by

$$\bar{q} = \bar{\varphi}(p) = (q,\tau)\,,$$

where τ is a new coordinate, introduced for accommodating time. This means that

$$\bar{q}^{i} = q^{i} \quad (i=1,\ldots,n) \quad \text{and} \quad \bar{q}^{n+1} \equiv \bar{q}^{0} = \tau\,. \tag{16}$$

Consequently, the tangent vector $\underline{\bar{v}}$ to the image curve $\bar{\gamma}(s)$ on $\bar{M}$ of a curve $\gamma(s)$ on M at point p belongs to an $(n+1)$-dimensional vector space $T_p\bar{M}$, with components

$$\bar{v}^{i} = \tfrac{d}{ds}(\bar{\varphi}\circ\bar{\gamma})^{i} \quad (i=1,\ldots,n) \quad \text{and} \quad \bar{v}^{n+1} \equiv \bar{v}^{0} = d\tau/ds \tag{17}$$

in the natural basis $\mathfrak{B}_{\bar{g}} = \{\underline{\bar{g}}_1 \quad \cdots \quad \underline{\bar{g}}_n \quad \underline{\bar{g}}_0\}$ of $T_p\bar{M}$, created by the tangent vectors to the coordinate lines corresponding to the coordinate map defined by Eq. (15). The last result can be put in the form

$$\underline{\bar{v}} = \bar{v}^I \underline{\bar{g}}_I = \bar{v}^i \underline{\bar{g}}_i + \bar{v}^0 \underline{\bar{g}}_0 \quad (I = 1,\ldots,n+1;\ i = 1,\ldots,n). \tag{18}$$

Similar expressions can also be obtained for bases $\mathfrak{B}_{\bar{e}}$ of $T_p\bar{M}$ other than the natural basis $\mathfrak{B}_{\bar{g}}$ but respecting the separation of the temporal from the spatial coordinates induced by Eq. (19). Such bases will be referred to as separable bases of $T_p\bar{M}$ (or $\bar{M}$, for simplicity) in the sequel.

In essence, incorporation of time into the set of coordinates helps in converting the original manifold M into an extended configuration manifold $\bar{M}$, which is scleronomic [17]. Then, a linear velocity transformation similar to that of Eq. (10) can always be established between the two scleronomic manifolds $\bar{E}^{3N} \equiv E^{3N} \times \mathbb{R}$ and $\bar{M}$. Before employing this transformation, it is first necessary to determine the geometric properties of $\bar{E}^{3N}$ and $\bar{M}$. Based on the definition of the former manifold as a Cartesian product of E^{3N} and $\mathbb{R}$, its metric matrix appears in the form

$$\bar{G} = [\bar{G}_{IJ}] = \begin{bmatrix} G(q) & \underline{0} \\ \underline{0}^T & G_{00}(\tau) \end{bmatrix}, \tag{19}$$

where the $n \times n$ submatrix $G = [G_{ij}]$ includes the components of the metric tensor on E^{3N}, while $G_{00}(\tau)$ is a non-negative scalar, which may be a function of the temporal coordinate. In addition, the set of affinities on $\bar{E}^{3N}$, say $\bar{\Gamma}^K_{IJ}$ (with $I,J,K = 1,\ldots,n+1$), includes the following elements

$$\bar{\Gamma}^k_{ij} = \Gamma^k_{ij}(q) \quad (i,j,k = 1,\ldots,n) \quad \text{and} \quad \bar{\Gamma}^0_{00} = \Gamma^0_{00}(\tau), \tag{20}$$

where Γ^k_{ij} are the affinities on E^{3N}, while all the remaining mixed type affinities (involving any combination of the spatial coordinates and the temporal coordinate) are zero.

Next, knowledge of the set of motion constraints imposed on $\bar{E}^{3N}$ in order to get the motion on $\bar{M}$ permits evaluation of the velocity transformation matrix between the tangent spaces of these manifolds, expressed by Eq. (10) (see Section 5). Then, the geometric properties of $\bar{M}$ can be determined by application of Eqs. (11) and (12). First, the metric matrix on $\bar{M}$ is obtained in the form

$$\bar{g}(\bar{q}) = [\bar{g}_{IJ}] = \begin{bmatrix} \hat{g}(q,\tau) & \underline{\bar{g}}_0(q,\tau) \\ \underline{\bar{g}}_0^T(q,\tau) & \bar{g}_{00}(q,\tau) \end{bmatrix}, \tag{21}$$

where $\hat{g} = [\hat{g}_{ij}]$ is an $n \times n$ matrix, while $\underline{\bar{g}}_0$ is an n-vector and $\bar{g}_{00}$ is a scalar quantity. In addition, the set of affinities becomes complete, in the sense

$$\bar{\Lambda}^K_{IJ}(\bar{q}) = [\bar{\Lambda}^k_{ij}, \bar{\Lambda}^k_{i0}, \bar{\Lambda}^k_{0j}, \bar{\Lambda}^k_{00}, \bar{\Lambda}^0_{ij}, \bar{\Lambda}^0_{i0}, \bar{\Lambda}^0_{0j}, \bar{\Lambda}^0_{00}]. \tag{22}$$

Taking into account the qualitative difference in the role of the temporal and the spatial coordinates and Eq. (19), it is frequently advantageous to select a special basis in $T_p\bar{M}$, in which

$$\bar{g}_0(q,\tau) = \underline{0}\,.$$

Such a basis will be called a standard basis of $\bar{M}$ in the sequel. Based on Eq. (5), this means that standard is a special separable basis, with base vector corresponding to the temporal coordinate being normal to the base vectors associated with the subspace of $T_p\bar{M}$ spanned by the spatial coordinates. Then, it is easy to show that in a standard basis of $T_p\bar{M}$ it is true that

$$\bar{v}^i = v^i \quad (i = 1,\ldots,n), \tag{23}$$

where v^i represents velocity components in the corresponding basis of T_pM. Due to the symmetry of the metric matrix, this choice is always possible through a transformation.

For the problem at hand, the communication between the configuration manifold M and the event manifold $\bar{M}$, after selecting $s = \tau$, is achieved by imposing the single holonomic constraint

$$\bar{q}^0 - \tau = 0 \quad \Rightarrow \quad \bar{v}^0 - 1 = 0\,. \tag{24}$$

Moreover, Eqs. (17) and (23) define an $(n+1)\times n$ transformation between the spaces T_pM and $T_p\bar{M}$. By employing a standard basis in $T_p\bar{M}$, it can be put in the following compact form

$$\bar{v}^I = \delta_i^I v^i + \delta_0^I \bar{v}^0 \quad (I = 1,\ldots,n+1;\ i = 1,\ldots,n). \tag{25}$$

Based on this transformation, the components g_{ij} and Λ_{ij}^k of the metric and the affinities on manifold M can be related to the components $\bar{g}_{IJ}$ and $\bar{\Lambda}_{IJ}^K$ of the metric and the affinities on manifold $\bar{M}$ through the compatibility conditions (11) and (12). More specifically, employing a separable basis on $\bar{M}$, the linear part of the velocity transformation expressed by Eq. (10) is given in the present case by

$$N_i^I = \delta_i^I\,. \tag{26}$$

Therefore, it is straightforward to verify that Eq. (11) is satisfied when

$$g_{ij} = \bar{g}_{ij} \quad (i, j = 1,\ldots,n), \tag{27}$$

while application of Eq. (14) yields the following condition on the affinities

$$(\Lambda_{ji}^{\ell} g_{\ell k} - \bar{\Lambda}_{ji}^{\ell} \bar{g}_{\ell k} - \bar{\Lambda}_{ji}^{0} \bar{g}_{0k}) v^j v^k = 0 \quad (i, j, k, \ell = 1,\ldots,n). \tag{28}$$

In a standard basis, the last condition is satisfied by the simpler choice $\bar{\Lambda}_{ij}^k = \Lambda_{ij}^k$.

The above help in establishing the interrelation between manifolds M and E^{3N}, through the interrelation between the event manifolds $\bar{M}$ and $\bar{E}^{3N}$, as shown schematically in Fig. 1.

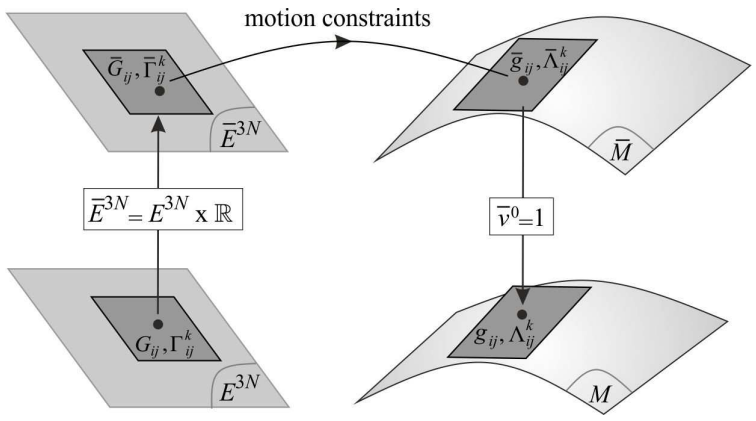

Fig. 1 Relation between manifolds M and E^{3N}, through their relation to $\bar{M}$ and $\bar{E}^{3N}$

Using the metric matrix in the form of Eq. (21), the kinetic energy of the system on the extended configuration manifold $\bar{M}$ can be put in the form

$$\bar{T} = \tfrac{1}{2}\bar{v}^I \bar{g}_{IJ} \bar{v}^J \equiv \bar{T}_2 + \bar{T}_1 + \bar{T}_0 \quad (I, J = 1, \ldots, n+1),$$

where, using Eqs. (18) and (27), the three individual terms are found in a separable basis as follows

$$\bar{T}_2 = \tfrac{1}{2}\bar{v}^i g_{ij} \bar{v}^j, \quad \bar{T}_1 = \bar{v}^i \bar{g}_{i0} \bar{v}^0 \quad \text{and} \quad \bar{T}_0 = \tfrac{1}{2}\bar{v}^0 \bar{g}_{00} \bar{v}^0 .$$

Therefore, all these terms are in fact quadratic in velocity. Moreover, the generalized momenta in the event manifold $\bar{M}$ can be determined in the form

$$\bar{p}_I = \bar{g}_{IJ} \bar{v}^J \quad (I, J = 1, \ldots, n+1),$$

with

$$\bar{p}_i = \bar{g}_{iJ} \bar{v}^J = g_{ij} \bar{v}^j + \bar{g}_{i0} \bar{v}^0 \quad (i = 1, \ldots, n) \quad \text{and} \quad \bar{p}_{n+1} \equiv \bar{p}_0 = \bar{g}_{0J} \bar{v}^J = \bar{g}_{0j} \bar{v}^j + \bar{g}_{00} \bar{v}^0 .$$

Finally, since the extended configuration manifold $\bar{M}$ is scleronomic, the true path of motion on it can be determined by application of Newton's second law in the generalized form

$$\nabla_{\underset{\sim}{\bar{v}}} \underset{\sim}{p}^*_{\bar{M}} = \underset{\sim}{f}^*_{\bar{M}}, \tag{29}$$

where $\underset{\sim}{f}^*_{\bar{M}}$ represents the applied forces on $\bar{M}$, while

$$\nabla_{\underset{\sim}{\bar{v}}} \underset{\sim}{p}^*_{\bar{M}} = (\bar{p}_{I,K} \bar{v}^K - \bar{\Lambda}^L_{JI} \bar{p}_L \bar{v}^J) \underset{\sim}{\bar{e}}^I, \tag{30}$$

where $\bar{p}_{I,J} \equiv \partial \bar{p}_I / \partial \bar{q}^J$ [10, 19].

Then, a special class of covectors, known as Newton covectors[21], can be defined on manifold $\bar{M}$ by

$$\underset{\sim}{h}^*_{\bar{M}} \equiv \nabla_{\underline{\bar{v}}} \underset{\sim}{p}^*_{\bar{M}} - \underset{\sim}{f}^*_{\bar{M}}, \tag{31}$$

with components in a general basis of $T_p^*\bar{M}$ given by

$$\bar{h}_I = (\bar{g}_{IJ}\bar{v}^J)_{,K}\bar{v}^K - \bar{\Lambda}^L_{JI}\bar{g}_{LK}\bar{v}^J\bar{v}^K - \bar{f}_I. \tag{32}$$

By definition of these covectors, the law of motion on manifold $\bar{M}$ is expressed in the form

$$\underset{\sim}{h}^*_{\bar{M}} = \underset{\sim}{0} \quad \Rightarrow \quad \bar{h}_I = 0, \tag{33}$$

in the absence of any motion constraints.

Next, based on Eq. (26), the components of the Newton covectors on the original manifold M are found by employing the following mapping from a separable basis of $T_p^*\bar{M}$ to T_p^*M

$$h_i = \delta_i^I \bar{h}_I. \tag{34}$$

Using Eqs. (32), (27) and performing simple mathematical operations, it eventually turns out that

$$h_i = (g_{ij}\bar{v}^j + \bar{g}_{i0})_{,k}\bar{v}^k + (g_{ij}\bar{v}^j + \bar{g}_{i0})_{,0} - \bar{\Lambda}^L_{Ji}\bar{g}_{LK}\bar{v}^J\bar{v}^K - f_i, \tag{35}$$

with

$$\begin{aligned}\bar{\Lambda}^L_{Ji}\bar{g}_{LK}\bar{v}^J\bar{v}^K = {} & (\bar{\Lambda}^\ell_{ji}g_{\ell k} + \bar{\Lambda}^0_{ji}\bar{g}_{0k})\bar{v}^j\bar{v}^k \\ & + (\bar{\Lambda}^\ell_{ji}\bar{g}_{\ell 0} + \bar{\Lambda}^0_{ji}\bar{g}_{00} + \bar{\Lambda}^\ell_{0i}g_{\ell j} + \bar{\Lambda}^0_{0i}\bar{g}_{0j})\bar{v}^j + (\bar{\Lambda}^\ell_{0i}\bar{g}_{\ell 0} + \bar{\Lambda}^0_{0i}\bar{g}_{00}).\end{aligned} \tag{36}$$

Again, in the special case of a standard basis of $\bar{M}$, the last expression is simplified considerably to

$$\bar{\Lambda}^L_{Ji}\bar{g}_{LK}\bar{v}^J\bar{v}^K = \Lambda^\ell_{ji}g_{\ell k}v^jv^k + (\bar{\Lambda}^\ell_{0i}g_{\ell j} + \bar{\Lambda}^0_{ji}\bar{g}_{00})v^j + \bar{\Lambda}^0_{0i}\bar{g}_{00}. \tag{37}$$

Furthermore, more terms disappear for scleronomic systems, since then all the mixed affinities vanish. Then, Newton's law on manifold M is written in the simpler form

$$h_i = (g_{ij}v^j)_{,k}v^k - \Lambda^\ell_{ji}g_{\ell k}v^jv^k - f_i = 0, \tag{38}$$

resembling fully that of Eq. (32) on $\bar{M}$. The extra terms in Eq. (35) are inertial and come either from terms involving the off-diagonal components $\bar{g}_{i0}$ of the metric of a non-standard basis or by mixed affinities, defined on the event manifold only and related to differentiation with respect to time.

4 APPLICATION OF A SPECIAL COORDINATE TRANSFORMATION ON THE EVENT MANIFOLD

Next, let ψ be an alternate coordinate map in the vicinity of point p on M, similar to that

defined by Eq. (1). Then, the corresponding set of coordinates of p on $\bar{M}$ can be selected by

$$\bar{x} = \bar{\psi}(p) = (x, \omega),$$

through a new coordinate map $\bar{\psi}$. The last equation can be combined with Eq. (15) to yield

$$\bar{x} = \bar{\chi}(\bar{q}) = (x(q,\tau), \omega(q,\tau)), \tag{39}$$

with composite map $\bar{\chi} = \bar{\psi} \circ \bar{\varphi}^{-1}$, so that

$$\bar{x}^i = x^i(q,\tau) \quad (i = 1,\ldots,n) \quad \text{and} \quad \bar{x}^{n+1} \equiv \bar{x}^0 = \omega(q,\tau). \tag{40}$$

In fact, for the purposes of the present study, the last coordinate can be selected by

$$\omega(q,\tau) = \tau. \tag{41}$$

Then, the Jacobian matrix $\bar{J} = [\bar{J}^I_{\hat{I}}]$ (with $I, \hat{I} = 1,\ldots,n+1$) corresponding to this particular type of coordinate transformation is given by

$$\bar{J}(\bar{q}) = \frac{\partial \bar{x}}{\partial \bar{q}} = \begin{bmatrix} J(q,\tau) & \underline{c}(q,\tau) \\ \underline{0}^T & 1 \end{bmatrix}, \tag{42}$$

where the $n \times n$ matrix $J = [J^i_{\hat{i}}]$ and the n-vector $\underline{c}$ are determined by

$$J(q,\tau) = \partial x / \partial q \quad \text{and} \quad \underline{c}(q,\tau) = \partial x / \partial \tau. \tag{43}$$

Based on the above, the class of transformations considered are similar to Eq. (2), but have the special structure exhibited by Eq. (42). Then, the new and old base vectors in the corresponding bases of $T_p\bar{M}$ and $T^*_p\bar{M}$ are related by

$$\underline{\bar{e}}_{\hat{I}} = \bar{J}^I_{\hat{I}}(\bar{q})\underline{\bar{e}}_I \quad \text{and} \quad \underline{\bar{e}}^I = \bar{J}^I_{\hat{I}}(\bar{q})\underline{\bar{e}}^{\hat{I}}, \tag{44}$$

while the components of the vectors and covectors in these bases are related by

$$\bar{v}^I = \bar{J}^I_{\hat{I}}(\bar{q})\bar{v}^{\hat{I}} \quad \text{and} \quad \bar{v}_{\hat{I}} = \bar{J}^I_{\hat{I}}(\bar{q})\bar{v}_I, \tag{45}$$

respectively [17]. Finally, the components of the metric tensor and the affinities in the new basis of $T_p\bar{M}$ are found by

$$\bar{g}_{\hat{I}\hat{J}} = \bar{J}^I_{\hat{I}}\bar{g}_{IJ}\bar{J}^J_{\hat{J}} \quad \text{and} \quad \bar{\Lambda}^{\hat{K}}_{\hat{I}\hat{J}} = \bar{J}^I_{\hat{I}}\bar{J}^J_{\hat{J}}\bar{B}^{\hat{K}}_K\bar{\Lambda}^K_{IJ} + \bar{J}^K_{\hat{J},\hat{I}}\bar{B}^{\hat{K}}_K,$$

respectively. These relations demonstrate that the new metric components and affinities are time dependent, when at least one element of matrix J or vector $\underline{c}$ is time dependent, even if the original components do not depend on time. Specifically, the new metric matrix appears in the form

$$\hat{\bar{g}} = [\bar{g}_{\hat{I}\hat{J}}] = \bar{J}^T\bar{g}\bar{J} = \begin{bmatrix} \hat{g} & \underline{g}_{\hat{0}} \\ \underline{g}^T_{\hat{0}} & g_{\hat{0}\hat{0}} \end{bmatrix} \tag{47}$$

on the extended configuration manifold $\bar{M}$. Taking Eq. (21) into account, it turns out that

$$\hat{g} = [g_{\hat{i}\hat{j}}] = J^T\hat{g}J, \quad \underline{g}_{\hat{0}} = J^T\hat{g}\underline{c} + J^T\underline{\bar{g}}_0 \quad \text{and} \quad g_{\hat{0}\hat{0}} = \underline{c}^T\hat{g}\underline{c} + 2\underline{c}^T\underline{\bar{g}}_0 + \bar{g}_{00}. \tag{48}$$

The above results hold even in cases where the elements of matrix J and vector $\underline{c}$ in Eq. (42) do not satisfy Eq. (43). Then, the new basis, defined by Eq. (44), will be anholonomic in general. However, it is easy to verify that it will remain separable. In this respect, it is noteworthy that the set of matrices expressed by Eq. (42) presents similarities with the Galilean group of transformations applied to a particle in order to preserve the form of Newton's law in Cartesian coordinate systems [1, 23]. Also, even when a standard basis is employed in $T_p\bar{M}$ originally (i.e., when $\underline{\bar{g}}_0 = \underline{0}$), the new basis will turn into a separable basis eventually, if $\underline{c} \neq \underline{0}$. Finally, when the transformation is such that $\underline{c} = \underline{0}$, a standard basis yields a new standard basis, since then Eqs. (47) and (48) lead to

$$\hat{\bar{g}} = \begin{bmatrix} J^T \bar{g} J & \underline{0} \\ \underline{0}^T & \bar{g}_{00} \end{bmatrix}. \tag{49}$$

Now, based on Eq. (45b), the components of the Newton covectors in the new basis of $T_p^*\bar{M}$ are

$$\bar{h}_{\hat{I}} = \bar{J}^I_{\hat{I}}\, \bar{h}_I \,. \tag{50}$$

Substituting Eq. (32) in the right hand side of the last equation and performing simple operations leads to

$$\bar{h}_{\hat{I}} = (\bar{J}^I_{\hat{I}}\, \bar{g}_{IJ} \bar{J}^J_{\hat{J}} \bar{v}^{\hat{J}})_{,\hat{K}}\, \bar{v}^{\hat{K}} - (\bar{J}^I_{\hat{I},\hat{K}} \bar{J}^J_{\hat{J}}\, \bar{g}_{IJ} + \bar{J}^I_{\hat{I}} \bar{J}^J_{\hat{J}} \bar{J}^K_{\hat{K}} \bar{\Lambda}^L_{JI} \bar{g}_{LK}) \bar{v}^{\hat{J}} \bar{v}^{\hat{K}} - \bar{J}^I_{\hat{I}}\, \bar{f}_I \,. \tag{51}$$

Next, following an application of the compatibility conditions expressed by Eqs. (11) and (12) in the more appropriate form

$$\bar{g}_{\hat{I}\hat{J}} = \bar{J}^I_{\hat{I}} \bar{g}_{IJ} \bar{J}^J_{\hat{J}} \quad \text{and} \quad (\bar{\Lambda}^{\hat{L}}_{\hat{J}\hat{I}} \bar{g}_{\hat{L}\hat{K}} - \bar{J}^I_{\hat{I},\hat{K}} \bar{J}^J_{\hat{J}}\, \bar{g}_{IJ} - \bar{J}^I_{\hat{I}} \bar{J}^J_{\hat{J}} \bar{J}^K_{\hat{K}} \bar{\Lambda}^L_{JI} \bar{g}_{LK}) \bar{v}^{\hat{J}} \bar{v}^{\hat{K}} = 0 \,, \tag{52}$$

it eventually turns out that

$$\bar{h}_{\hat{I}} = (\bar{g}_{\hat{I}\hat{J}} \bar{v}^{\hat{J}})_{,\hat{K}}\, \bar{v}^{\hat{K}} - \bar{\Lambda}^{\hat{L}}_{\hat{J}\hat{I}} \bar{g}_{\hat{L}\hat{K}} \bar{v}^{\hat{J}} \bar{v}^{\hat{K}} - \bar{f}_{\hat{I}} \,. \tag{53}$$

Note that the form of the last equation is identical to the fundamental form of Eq. (32). Finally, by employing the mapping from a separable basis of $T_p^*\bar{M}$ to T_p^*M defined by

$$h_i = \delta^{\hat{I}}_i \bar{h}_{\hat{I}} \tag{54}$$

and performing simple mathematical operations it eventually turns out that

$$h_i = (g_{i\hat{j}} \bar{v}^{\hat{j}} + \bar{g}_{i\hat{0}})_{,\hat{k}}\, \bar{v}^{\hat{k}} + (g_{i\hat{j}} \bar{v}^{\hat{j}} + \bar{g}_{i\hat{0}})_{,\hat{0}} - \bar{\Lambda}^{\hat{L}}_{\hat{J}\hat{I}} \bar{g}_{\hat{L}\hat{K}} \bar{v}^{\hat{J}} \bar{v}^{\hat{K}} - f_i \,, \tag{55}$$

with

$$\begin{aligned} \bar{\Lambda}^{\hat{L}}_{\hat{j}\hat{i}} \bar{g}_{\hat{L}\hat{K}} \bar{v}^{\hat{j}} \bar{v}^{\hat{K}} = {} & (\bar{\Lambda}^{\hat{\ell}}_{\hat{j}\hat{i}} \bar{g}_{\hat{\ell}\hat{k}} + \bar{\Lambda}^{\hat{0}}_{\hat{j}\hat{i}} \bar{g}_{\hat{0}\hat{k}}) \bar{v}^{\hat{j}} \bar{v}^{\hat{k}} \\ & + (\bar{\Lambda}^{\hat{\ell}}_{\hat{j}\hat{i}} \bar{g}_{\hat{\ell}\hat{0}} + \bar{\Lambda}^{\hat{0}}_{\hat{j}\hat{i}} \bar{g}_{\hat{0}\hat{0}} + \bar{\Lambda}^{\hat{\ell}}_{\hat{0}\hat{i}} \bar{g}_{\hat{\ell}\hat{j}} + \bar{\Lambda}^{\hat{0}}_{\hat{0}\hat{i}} \bar{g}_{\hat{0}\hat{j}}) \bar{v}^{\hat{j}} + (\bar{\Lambda}^{\hat{\ell}}_{\hat{0}\hat{i}} \bar{g}_{\hat{\ell}\hat{0}} + \bar{\Lambda}^{\hat{0}}_{\hat{0}\hat{i}} \bar{g}_{\hat{0}\hat{0}}). \end{aligned} \tag{56}$$

Eq. (55) is similar to Eq. (35), while Eq. (56) is similar to Eq. (36). Moreover, in a standard basis, the last equation can be put in a form similar to Eq. (37). Obviously, the last observations reveal that the form of the components of the Newton covectors remains invariant under the special transformation performed. This confirms the form invariance of Newton's law when expressed in different bases.

To complete the picture, consider a companion change of basis in the configuration manifold M, relating the new and old base vectors in T_pM and T_p^*M by

$$\underline{e}_{\hat{i}} = J_{\hat{i}}^{i}(q,t)\underline{e}_i \quad \text{and} \quad \underline{\bar{e}}^{i} = J_{\hat{i}}^{i}(q,\tau)\underline{\bar{e}}^{\hat{i}},$$

respectively, where matrix $J=[J_{\hat{i}}^{i}]$ is selected to coincide with the $n\times n$ matrix covering the upper left part of matrix $\bar{J}$ defined by Eq. (42). Then, the components of the vectors and covectors in T_pM and T_p^*M are related by

$$v^i = J_{\hat{i}}^{i}(q,t)v^{\hat{i}} \quad \text{and} \quad v_{\hat{i}} = J_{\hat{i}}^{i}(q,t)v_i, \tag{57}$$

respectively, while the components of the metric and the affinities in the new basis of M are given by

$$g_{\hat{i}\hat{j}} = J_{\hat{i}}^{i}g_{ij}J_{\hat{j}}^{j} \quad \text{and} \quad \Lambda_{\hat{i}\hat{j}}^{\hat{k}} = J_{\hat{i}}^{i}J_{\hat{j}}^{j}B_{k}^{\hat{k}}\Lambda_{ij}^{k} + J_{\hat{j},\hat{i}}^{k}B_{k}^{\hat{k}}, \tag{58}$$

respectively, with

$$J_{\hat{i}}^{i}B_{j}^{\hat{i}} = \delta_j^i \quad \text{and} \quad B_i^{\hat{j}}J_{\hat{i}}^{i} = \delta_{\hat{i}}^{\hat{j}}. \tag{59}$$

Consequently, the components of the Newton covectors in the transformed basis of the original manifold M are found in the form

$$h_{\hat{i}} = J_{\hat{i}}^{i}h_i. \tag{60}$$

Employing Eq. (35) and performing lengthy but simple mathematical operations in the right hand side of the last equation, which are similar to those involved in Eqs. (51) and (52), it eventually turns out that $h_{\hat{i}}$ regains the form of Eq. (55). This verifies the existence of commutativity between the special type of coordinate transformation examined and the transformation between the original manifold M and the extended manifold $\bar{M}$.

Finally, using Eq. (23) in conjunction with Eq. (57a) yields

$$\bar{v}^i = v^i = J_{\hat{i}}^{i}(q,t)v^{\hat{i}} \quad (i,\hat{i}=1,\ldots,n),$$

where $\bar{v}^i$ is the velocity component in the corresponding standard basis of $\bar{M}$. Taking into account Eq. (59), the last equation leads to

$$v^{\hat{i}} = \bar{v}^{\hat{i}} + \hat{v}^{\hat{i}}, \tag{61}$$

with

$$\hat{v}^{\hat{i}} = B_i^{\hat{i}}J_{\hat{0}}^{i}\bar{v}^{\hat{0}} = B_i^{\hat{i}}c^i. \tag{62}$$

Eq. (61) shows that $v^{\hat{i}} \neq \bar{v}^{\hat{i}}$, in general, even when $v^i = \bar{v}^i$. Substitution of the term $\bar{v}^{\hat{i}}$ from Eq. (61) into Eq. (55) yields the equations of motion on manifold M in terms of the velocity components $v^{\hat{i}}$ in T_pM and $\hat{v}^{\hat{i}}$. By their definition, Eq. (62), the terms $\hat{v}^{\hat{i}}$ are known and due to the presence of the n-vector $\underline{c}$ in the Jacobian $\bar{J}(\bar{q})$, defined by Eq. (42). Based on Eq. (43), it is clear that this vector becomes zero when a time independent chart (i.e., coordinate system) is selected on $\bar{M}$, defined by

$$x = x(q). \tag{63}$$

This means that the terms $\hat{v}^{\hat{i}}$ can be eliminated by a proper selection of the chart on manifold $\bar{M}$. Therefore, only such charts may have meaningful counterparts on M, which clarifies some of the terminology employed in the literature on "time dependent" charts.

5 APPLICATION OF A SPECIAL COORDINATE TRANSFORMATION ON THE EVENT MANIFOLD

In the present section, it is assumed that the motion of the system examined on configuration manifold M is subject to an additional set of k constraints with form

$$A(q,t)\underline{v} + \underline{a}(q,t) = \underline{0}\,, \tag{64}$$

where $A=[a_i^R]$ is a known $k\times n$ matrix. Then, the motion of the system takes place on a curve $\gamma_A(t)$ of another manifold M_A, with dimension $m=n-k$ [19]. Next, let $\{\theta^\alpha\}$ ($\alpha=1,\ldots,m$) be a set of generalized coordinates in a neighborhood of a point p_A of M_A, related to point p of M through Eq. (64). Furthermore, let $\{\underline{e}_\alpha\}$ and and $\{\underline{e}^\alpha\}$ be a basis of $T_{p_A}M_A$ and $T^*_{p_A}M_A$, respectively.

The new fundamental item in Eq. (64) is not so much the explicit appearance of time but rather the acatastatic term $\underline{a}$ [21]. This term destroys the linearity and provides an affine nature to the constraint equations. In principle, Eq. (64) can be used in order to establish a mapping between the tangent spaces $T_{p_A}M_A$ and T_pM. Namely, Eq. (64) can easily be recast in the form

$$\underline{v} = N(q,t)\dot{\underline{\theta}} + \underline{\upsilon}(q,t)\,, \tag{65}$$

where the $n\times m$ matrix N and the n-vector $\underline{\upsilon}$ are determined in terms of the elements of the $k\times n$ matrix A and the k-vector $\underline{a}$ [12, 19]. To overcome the loss of linearity, due to the presence of the term $\underline{\upsilon}$, the last equation is put in the form of a linear transformation between the tangent spaces $T_{p_A}\bar{M}_A$ and $T_p\bar{M}$ of the corresponding event manifolds. This permits conversion of Eq. (65) into the following linear relation between the components of tangent vectors

$$\bar{v}^I = \bar{N}^I_\Phi(\bar{q})\bar{v}^\Phi\,, \tag{66}$$

with $\Phi=1,\ldots,m+1$ and $I=1,\ldots,n+1$, where the extended matrix $\bar{N}$ appears in the form

$$\bar{N}=[\bar{N}^I_\Phi(\bar{q})]=\begin{bmatrix} N(q,\tau) & \underline{\upsilon}(q,\tau) \\ \underline{0}^T & 1 \end{bmatrix}. \tag{67}$$

This $(n+1)\times(m+1)$ matrix has a similar structure with the Jacobian matrix defined by Eq. (42).

Next, the metric matrix on manifold $\bar{M}$ is assumed to have the general form expressed by Eq. (21), while the set of affinities is complete, in the sense of Eq. (22). Then, based on the velocity transformation represented by Eq. (66), the components of the metric matrix and the affinities on the new manifold are determined by employing Eqs. (11) and (12) in the form

$$\bar{g}_{\Phi\Psi} = \bar{N}^I_\Phi \bar{g}_{IJ}\bar{N}^J_\Psi \quad \text{and} \quad (\bar{\Lambda}^{\mathrm{X}}_{\Psi\Phi}\bar{g}_{\mathrm{X}\Omega} - \bar{N}^I_{\Phi,\Omega}\bar{N}^J_\Psi\bar{g}_{IJ} - \bar{N}^I_\Phi\bar{N}^J_\Psi\bar{N}^K_\Omega\bar{\Lambda}^L_{JI}\bar{g}_{LK})\bar{v}^\Psi\bar{v}^\Omega = 0\,. \tag{68}$$

Obviously, any time dependence of matrix N and vector $\underline{\upsilon}$ is transferred into the geometric properties of manifold $\bar{M}_A$. In particular, the metric matrix on the new Newtonian manifold $\bar{M}_A$ is

$$\bar{g}_A = [\bar{g}_{\Phi X}] = \bar{N}^T \bar{g} \bar{N} = \begin{bmatrix} N^T \hat{g} N & N^T (\hat{g}\underline{\upsilon} + \underline{\bar{g}}_0) \\ (\underline{\upsilon}^T \hat{g} + \underline{\bar{g}}_0^T) N & \underline{\upsilon}^T \hat{g} \underline{\upsilon} + 2\underline{\upsilon}^T \underline{\bar{g}}_0 + \bar{g}_{00} \end{bmatrix}.$$

In general, this $(m+1)\times(m+1)$ matrix is full. Therefore, unless

$$N^T (\hat{g}\underline{\upsilon} + \underline{\bar{g}}_0) = \underline{0}, \tag{70}$$

the new basis obtained in $T_{p_A}\bar{M}_A$ is not standard, even when the basis of $T_p\bar{M}$ is standard.

As usual, application of Eq. (66) means that the base vectors in $T_{p_A}\bar{M}_A$ and $T_p\bar{M}$ are related by

$$\underline{e}_\Phi = \bar{N}^I_\Phi(\bar{q})\underline{e}_I \quad (\Phi = 1,\ldots,m+1;\ I = 1,\ldots,n+1),$$

while the components of the covectors are related by

$$\bar{v}_\Phi = \bar{N}^I_\Phi(\bar{q})\bar{v}_I . \tag{71}$$

Therefore, the components of the Newton covectors in the basis of $T^*_{p_A}\bar{M}_A$ are found through

$$\bar{h}_\Phi = \bar{N}^I_\Phi \bar{h}_I . \tag{72}$$

Substituting Eq. (32) in the right hand side of the last equation and performing simple operations yields first the following relation

$$\bar{h}_\Phi = (\bar{N}^I_\Phi \bar{g}_{IJ} \bar{N}^J_\Psi \bar{v}^\Psi)_{,\Omega}\bar{v}^\Omega - (\bar{N}^I_{\Phi,\Omega}\bar{N}^J_\Psi \bar{g}_{IJ} + \bar{N}^I_\Phi \bar{N}^J_\Psi \bar{N}^K_\Omega \bar{\Lambda}^L_{JI}\bar{g}_{LK})\bar{v}^\Psi \bar{v}^\Omega - \bar{N}^I_\Phi \bar{f}_I . \tag{73}$$

Next, application of the compatibility conditions expressed by Eqs. (68), leads to the final form

$$\bar{h}_\Phi = (\bar{g}_{\Phi\Psi}\bar{v}^\Psi)_{,\Omega}\bar{v}^\Omega - \bar{\Lambda}^X_{\Psi\Phi}\bar{g}_{X\Omega}\bar{v}^\Psi\bar{v}^\Omega - \bar{f}_\Phi . \tag{74}$$

Once again, the form of the last equation is similar to Eq. (32). Also, in accordance with Eq. (34), the transformation between separable bases from $T^*_{p_A}M_A$ to $T^*_p\bar{M}$ appears in the form

$$h_\alpha = \delta^\Phi_\alpha \bar{h}_\Phi . \tag{75}$$

Consequently, by performing simple mathematical operations one can originally obtain the components of the Newton covectors on the manifold M_A in the form

$$\begin{aligned} h_\alpha = {} & (\bar{g}_{\alpha\beta}\bar{v}^\beta + \bar{g}_{\alpha 0})_{,\gamma}\bar{v}^\gamma + (\bar{g}_{\alpha\beta}\bar{v}^\beta + \bar{g}_{\alpha 0})_{,0} - (\bar{\Lambda}^\gamma_{\beta\alpha}\bar{g}_{\gamma\delta} + \bar{\Lambda}^0_{\beta\alpha}\bar{g}_{0\delta})\bar{v}^\beta\bar{v}^\delta \\ & - (\bar{\Lambda}^\gamma_{\beta\alpha}\bar{g}_{\gamma 0} + \bar{\Lambda}^0_{\beta\alpha}\bar{g}_{00} + \bar{\Lambda}^\gamma_{0\alpha}\bar{g}_{\gamma\beta} + \bar{\Lambda}^0_{0\alpha}\bar{g}_{0\beta})\bar{v}^\beta - (\bar{\Lambda}^\gamma_{0\alpha}\bar{g}_{\gamma 0} + \bar{\Lambda}^0_{0\alpha}\bar{g}_{00}) - f_\alpha = 0. \end{aligned} \tag{76}$$

Some simplifications apply to the last equation when the transition from manifold $\bar{M}_A$ to M_A is performed by using a standard basis in $T_{p_A}\bar{M}_A$, so that

$$\bar{v}^\alpha = v^\alpha, \quad \bar{g}_{\alpha\beta} = g_{\alpha\beta}, \quad \bar{\Lambda}^\gamma_{\alpha\beta} = \Lambda^\gamma_{\alpha\beta} \quad (\alpha,\beta,\gamma = 1,\ldots,m)$$

and the new metric matrix is block diagonal. In addition, some more terms drop out when the system is scleronomic. Then, Eq. (76) can eventually be put in the form

$$h_\alpha = (g_{\alpha\beta} v^\beta)_{,\gamma} v^\gamma - \Lambda^\gamma_{\beta\alpha} g_{\gamma\delta} v^\beta v^\delta - f_\alpha ,$$

which is identical to that of Eq. (38), obtained for the original manifold M in Section 3.

6 APPLICATION OF FOLIATION THEORY AND DEFINITION OF A SCLERONOMIC MANIFOLD

The material presented in this section completes the geometrical picture created in Section 3 for the event manifold $\bar{M}$. First, the attention is focused on creating the extended configuration manifold $\bar{M}$ based on the configuration manifold M at a fixed time $\tau = t$. This is done by considering the flow

$$p = \psi(p_0, t; \tau) \equiv \psi_{\tau,t} p_0 , \tag{77}$$

taking points $p_0 \in M \subset \bar{M}$ at time t to points $p \in \bar{M}$ at a later time τ, as shown in Fig. 2, so that a local coordinate chart on M and a time independent chart on $\bar{M}$ share the same spatial coordinates at each point. Using terminology of foliation theory, the local coordinates (q, τ) on $\bar{M}$, where q are also coordinates on manifold M for each τ, are called distinguished coordinates, while the temporal coordinate τ is known as a transverse coordinate [14]. In this setting, the chart corresponding to Eqs. (39) and (41) is a foliated or distinguished chart, while manifold M is considered to be a leaf of $\bar{M}$ through point p under this foliation. The specific foliation examined here has codimension 1 and partitions the event manifold $\bar{M}$ into manifolds M of dimension n, one at each time τ. Moreover, T denotes a transverse submanifold of $\bar{M}$, which is single dimensional and is described by the temporal coordinate. In fact, it is a total transversal since it meets all the leaves of the foliation, by construction [22]. In addition, the collection of the subspaces of $T_p\bar{M}$ possessing vectors with projection on T_pM only, at all points of $\bar{M}$, forms the special distribution D_M on $\bar{M}$. This is known as the structural distribution of $\bar{M}$, while its complement D_T is called the transversal distribution on $\bar{M}$ [3]. Finally, the tangent space of the event manifold $\bar{M}$ at point p can be split in the form

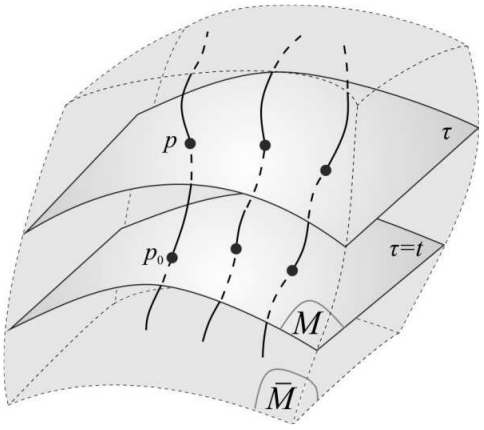

Fig. 2 Construction of manifold $\bar{M}$ by M and the time flow

$$T_p\bar{M} = H_p \oplus V_p , \tag{78}$$

where H_p and V_p are subspaces of $T_p\bar{M}$, forming the distribution D_M and D_T, respectively. Among other things, Eq. (78) implies that any vector of $T_p\bar{M}$ can be split uniquely in the form

$$\underline{u} = \underline{h} + \underline{v}, \tag{79}$$

with $\underline{h} \in H_p$ and $\underline{v} \in V_p$, where $\underline{v}$ is a tangent vector along the time flow defined by Eq. (77).

Next, it is assumed that manifold M is a fixed set of points but its metric components and affinities may depend on time. The objective is to provide conditions for M to be scleronomic. To achieve this goal, it is first necessary to define two special sets of curves on $\bar{M}$. The first set includes "leaf curves" $\gamma_M(\tau; s)$, lying entirely on M for each fixed τ, with tangent vector $\underline{h} = d\gamma_M / ds$ belonging to D_M, as depicted in Fig. 3. Likewise, the second set includes "transverse curves" $\gamma_T(q; \sigma)$, with tangent vector $\underline{v} = d\gamma_T / d\sigma$ belonging entirely to the transversal distribution D_T.

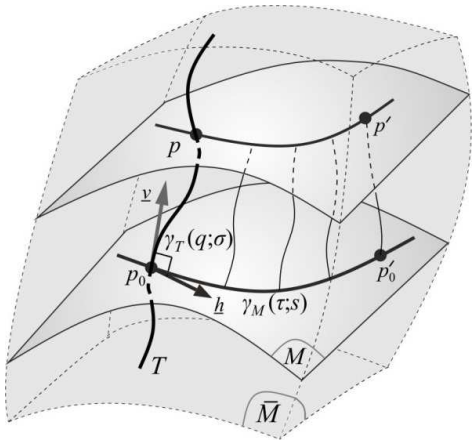

Fig. 3 Definition of two special families of curves on $\bar{M}$

By definition, a scleronomic manifold M can be viewed as a fixed surface within a Euclidean space of a bigger dimension [7, 23]. This means that its geometric properties may depend on its position in M but not on time. Then, the corresponding event manifold $\bar{M}$ can be seen as a product

$$\bar{M} = M \times T. \tag{80}$$

When a manifold possesses properties depending on time in an explicit manner, it can be viewed as a surface varying with time within a Euclidean space possessing a sufficiently bigger dimension [4, 17]. However, time dependence may also be introduced in the geometric properties by performing a transformation in $\bar{M}$ even in inherently scleronomic manifolds, as was shown in Section 4. The key to resolving this problem comes from the product form expressed by Eq. (80), which is true for a scleronomic manifold only. This is crucial in revealing and stating its geometric properties, since it implies that the event manifold $\bar{M}$ carries two complementary foliations [3]. Specifically, in such a case, a second foliation exists, which has codimension n and partitions the event manifold $\bar{M}$ into manifolds T of dimension 1, one for each combination of the spatial coordinates q. Based on this, for a configuration manifold M to be scleronomic, it is required that an autoparallel curve starting at a point of M and

ending on another point of M, for a fixed τ, should always remain on M. Likewise, an autoparallel curve starting on T and ending on T, for a fixed set of spatial coordinates q, should always remain on T. Taking into account the definition of the special families of curves γ_M and γ_T, these statements are expressed by the following mathematical conditions

$$\nabla_{\underline{h}}\underline{h} \in D_M \quad \text{and} \quad \nabla_{\underline{v}}\underline{v} \in D_T \,. \tag{81}$$

Furthermore, the Lie derivative of the vector fields created by extending the vector $\nabla_{\underline{h}}\underline{h}$ on all of $\bar{M}$, along a vector field on $\bar{M}$ with tangent vector $\underline{v}$ (i.e., the time flow represented by Eq. (77)), should be zero. Likewise, the Lie derivative of the vector fields created by extending the vector $\nabla_{\underline{v}}\underline{v}$ on all of $\bar{M}$, along a vector field on $\bar{M}$ with tangent vector $\underline{h}$, should also be zero. Mathematically, these statements are equivalent to

$$L_{\underline{v}}(\nabla_{\underline{h}}\underline{h}) = \underline{0} \quad \text{and} \quad L_{\underline{h}}(\nabla_{\underline{v}}\underline{v}) = \underline{0} \,, \tag{82}$$

where the above Lie derivatives can be determined through the corresponding Lie brackets by

$$L_{\underline{v}}(\nabla_{\underline{h}}\underline{h}) = [\underline{v}, \nabla_{\underline{h}}\underline{h}] \quad \text{and} \quad L_{\underline{h}}(\nabla_{\underline{v}}\underline{v}) = [\underline{h}, \nabla_{\underline{v}}\underline{v}] \,,$$

respectively. Moreover, the parallel transfer of the tangent vector $\underline{h}$ of a leaf curve $\gamma_M(\tau; s)$ along a transverse curve $\gamma_T(q; \sigma)$ and vice versa is preserved on a scleronomic manifold. This means that

$$\nabla_{\underline{v}}\underline{h} = \underline{0} \quad \text{and} \quad \nabla_{\underline{h}}\underline{v} = \underline{0} \,.$$

On a scleronomic manifold M, conditions should also be imposed on the metric tensor of $\bar{M}$. First, based on the product form of $\bar{M}$, expressed by Eq. (80), its metric matrix in the holonomic basis defined by the foliated coordinates can be decomposed in the special form

$$\bar{g} = \begin{bmatrix} g_M(q) & \underline{0} \\ \underline{0}^T & g_T(\tau) \end{bmatrix} .$$

Then, the following conditions must also be true for preserving the form of the metric tensor along the vector fields created by the special vectors $\underline{v}$ and $\underline{h}$ on a scleronomic manifold

$$L_{\underline{v}}\bar{g}_M = 0 \quad \text{and} \quad L_{\underline{h}}\bar{g}_T = 0 \,, \tag{84}$$

where $\bar{g}_M$ and $\bar{g}_T$ represent the restriction of metric $\bar{g}$ on the structural and transverse distribution of $\bar{M}$, respectively. Among other things, the last conditions guarantee that the metric $\bar{g}$ is bundle-like and any autoparallel of $\bar{M}$, which is orthogonal to a leaf of the foliation, is also orthogonal to every other leaf it meets [22].

In summary, the manifold scleronomicity conditions are expressed by Eqs. (81)-(84). These conditions do not depend on the basis selected on $T_p\bar{M}$. However, they take a very explicit and useful form when they are expressed in the special coordinate basis corresponding to the foliated coordinates of $\bar{M}$. In fact, taking into account that the metric is Riemannian, the two complementary foliations of $\bar{M}$ are now orthogonal, that is $D_T = D_M^{\perp}$ [3]. Therefore, the base vector $\underline{\bar{g}}_0$, corresponding to the temporal coordinate, is orthogonal to all the base vectors $\underline{\bar{g}}_i$ ($i = 1, \ldots, n$), corresponding to the spatial coordinates. At this point, it is clear that a foliated basis is a holonomic separable basis, while a foliated basis with $\underline{\bar{g}}_0$ orthogonal to $\underline{\bar{g}}_i$

corresponds to a holonomic standard basis. Also, the special vectors which are tangent to the leaf and transverse family of curves can be expressed in the form

$$\underline{h} = h^i(q)\underline{\overline{g}}_i \quad \text{and} \quad \underline{v} = v^0(\tau)\underline{\overline{g}}_0 ,$$

respectively, in a holonomic standard basis. Next, employing the first of Eqs. (81) and performing the necessary mathematical operations it turns out originally that

$$\nabla_{\underline{h}}\underline{h} = (h^K_{,I} + \overline{\Lambda}^K_{IJ}h^J)h^I\,\underline{\overline{g}}_K = (h^k_{,i} + \overline{\Lambda}^k_{ij}h^j)h^i\,\underline{\overline{g}}_k + \overline{\Lambda}^0_{ij}h^ih^j\,\underline{\overline{g}}_0 .$$

Then, a simultaneous application of Eq. (82a) leads eventually to the conditions

$$\overline{\Lambda}^k_{ij} = \overline{\Lambda}^k_{ij}(q) \quad \text{and} \quad \overline{\Lambda}^0_{ij} = 0 . \tag{85}$$

Treating Eqs. (81b) and (82b) in a similar manner yields

$$\overline{\Lambda}^0_{00} = \overline{\Lambda}^0_{00}(\tau) \quad \text{and} \quad \overline{\Lambda}^i_{00} = 0 . \tag{86}$$

Likewise, application of the two conditions in Eq. (83) leads to

$$\overline{\Lambda}^K_{0j} = 0 \;\Rightarrow\; \overline{\Lambda}^k_{0j} = \overline{\Lambda}^0_{0j} = 0 \quad \text{and} \quad \overline{\Lambda}^K_{i0} = 0 \;\Rightarrow\; \overline{\Lambda}^k_{i0} = \overline{\Lambda}^0_{i0} = 0 , \tag{87}$$

respectively. Finally, substituting the appropriate vector and tensor quantities in Eqs. (84) and performing the necessary mathematical operations, taking into account that the Lie derivative of the metric tensor along the flow defined by Eq. (77) is given by

$$L_{\underline{v}}g = [v^I g_{JK,I} + (v^I_{,J} - c^I_{LJ}v^L)g_{IK} + (v^I_{,K} - c^I_{LK}v^L)g_{IJ}]\underline{e}^J \otimes \underline{e}^K ,$$

leads eventually to

$$\tfrac{\partial}{\partial t}(g_M)_{ij} = 0 \;\Rightarrow\; g_M = g_M(q) \quad \text{and} \quad \tfrac{\partial}{\partial q}g_T = 0 \;\Rightarrow\; g_T = g_T(\tau) . \tag{88}$$

Thus, Eqs. (85)-(88) provide a set of scleronomicity conditions in component form, with respect to a standard basis. Obviously, these conditions are identical to the conditions stated earlier in the form of Eq. (13) or, alternatively, Eqs. (19) and (20).

7 EQUATIONS OF MOTION ON THE CONFIGURATION MANIFOLD

In Section 5, a set of equations of motion was derived on the constrained manifold M_A, with respect to a minimal set of coordinates. Such an approach is inconvenient to apply, especially for complex systems, since it requires the selection of a specific set of independent coordinates and elimination of the dependent coordinates through the constraint equations at every time instant. In general, this is not an easy task to achieve. Moreover, it requires differentiation of the constraint equations, leading to their violation at the lower kinematic level [2, 11]. In addition, the geometric properties of the constrained manifold need to be redetermined at every step, through Eqs. (11) and (12). For these reasons, it is frequently advantageous to derive the equations of motion on the original manifold M, for which the geometric properties are known and not affected by the additional constraints.

Next, it is assumed that the original configuration manifold M of the class of systems examined possesses time dependent geometric properties. Moreover, the system is subject to an additional set of k time dependent acatastatic motion constraints, in the form of Eq. (64), or equivalently in the form

$$\dot{\psi}^R(q,\underline{v},t) \equiv a^R_i(q,t)v^i + a^R_0(q,t) = 0 \quad (R = 1,\ldots,k). \tag{89}$$

When a constraint is holonomic, Eq. (89) can be integrated and cast in the form

$$\phi^R(q,t)=0\,.$$

The derivation of the equations of motion is based on a consistent application of Newton's law of motion, similar to that performed in an earlier study [15]. One of the basic ideas in that study was to consider the configuration manifold M as the total space of a fiber bundle with base space M_A and fibers consisting of the Cartesian product manifold $M_C=M_1\times\cdots\times M_k$, where the single dimensional manifolds M_R, $R=1,\ldots,k$, are related to the action of the R-th motion constraint. Since that study is applicable to scleronomic systems, some modifications are necessary before applying it here. First, based on Eq. (89), the velocity components of a vector in $T_p\bar{M}$ and $T_{p_R}\bar{M}_R$ are related by

$$\bar{v}^i=c_R^i\bar{v}^R+c_{R0}^i\bar{v}_R^0\quad(i=1,\ldots,n)\quad\text{and}\quad\bar{v}^0=\bar{v}_R^0\,,$$

which can be combined and put in the form of Eq. (65). Moreover, the components c_R^i and c_{R0}^i correspond to special vectors of $T_p\bar{M}$, for each constraint R, satisfying the conditions

$$a_i^R c_R^i=1\quad\text{and}\quad a_i^R c_{R0}^i=-a_0^R\quad(R=1,\ldots,k;\ i=1,\ldots,n).\tag{90}$$

In addition, a transformation similar to that represented by Eqs. (66) and (67) can be established between $T\bar{M}$ and $T\bar{M}_R$, through the $(n+1)\times 2$ matrix

$$\bar{N}_R=\begin{bmatrix}\underset{\sim}{c}_R(q,\tau) & \underset{\sim}{c}_{R0}(q,\tau)\\ 0 & 1\end{bmatrix}.$$

Therefore, the components of the metric and the affinities on the event manifold $\bar{M}_R$ can be determined by an equation similar to Eq. (68), while the Newton covectors on the dual space $T^*_{p_R}M_R$ are obtained by application of an equation similar to Eq. (76), with form

$$\begin{aligned}h_R=&(g_{RR}\bar{v}^R+\bar{g}_{R0})_{,R}\bar{v}^R+(g_{RR}\bar{v}^R+\bar{g}_{R0})_{,0}-(\bar{\Lambda}^R_{RR}g_{RR}+\bar{\Lambda}^0_{RR}\bar{g}_{0R})\bar{v}^R\bar{v}^R\\&-(\bar{\Lambda}^R_{RR}\bar{g}_{R0}+\bar{\Lambda}^0_{RR}\bar{g}_{00}+\bar{\Lambda}^R_{0R}g_{RR}+\bar{\Lambda}^0_{0R}g_{0R})\bar{v}^R-\bar{\Lambda}^R_{0R}\bar{g}_{R0}-\bar{\Lambda}^0_{0R}\bar{g}_{00}-f_R.\end{aligned}$$

Employing the connection compatibility condition and performing simple mathematical operations, the last expression can eventually be put in the form

$$h_R=(\bar{m}_{RR}\dot{\bar{\lambda}}^R+\bar{m}_{R0})^{\cdot}+\bar{c}_{RR}\dot{\bar{\lambda}}^R+\bar{k}_{RR}\bar{\lambda}^R-\bar{f}_R\,.\tag{91}$$

The quantity $\bar{\lambda}^R$ represents the spatial coordinate of the two dimensional manifold $\bar{M}_R$. Also, in the last equation and in the sequel, the convention on repeated indices does not apply to index R, while

$$\bar{m}_{RR}\equiv g_{RR}=c_R^i g_{ij}c_R^j\,,\quad \bar{m}_{R0}\equiv\bar{g}_{R0}=c_R^i(g_{ij}c_{R0}^j+\bar{g}_{i0})\,,\quad \bar{c}_{RR}=-c_R^i\frac{\partial f_i}{\partial v^j}c_R^j-c_{R,0}^i g_{ij}c_R^j\,,\quad \bar{k}_{RR}=-c_R^i f_{i,j}c_R^j$$

and

$$\bar{f}_R=c_R^i f_i+c_{R,0}^i(g_{ij}c_{R0}^j+\bar{g}_{i0})\,.\tag{92}$$

Following the analysis presented in [15], by incorporating the above modifications into the constraint equations and omitting the details, the equations of motion can be put in the form

$$\underset{\sim}{h}^*_M=\underset{\sim}{h}^*_C\tag{93}$$

on manifold M, with

$$\underset{\sim}{h}_M^* = h_i \, \underset{\sim}{e}^i \,,$$

where h_i is given by Eqs. (35) and (36), while

$$\underset{\sim}{h}_C^* = \sum\nolimits_{R=1}^{k} h_R \, a_i^R \underset{\sim}{e}^i \,,$$

with h_R given by Eq. (91). Next, substitution of the last two equations in Eq. (93) leads eventually to the following set of equations of motion on the original configuration manifold M

$$\begin{aligned}(g_{ij}\overline{v}^j + \overline{g}_{i0})^{\cdot} - (\overline{\Lambda}^{\ell}_{ji}\overline{g}_{\ell k} + \overline{\Lambda}^{0}_{ji}\overline{g}_{0k})\overline{v}^j\overline{v}^k + (\overline{\Lambda}^{\ell}_{ji}\overline{g}_{\ell 0} + \overline{\Lambda}^{0}_{ji}\overline{g}_{00} + \overline{\Lambda}^{\ell}_{0i}\overline{g}_{\ell j} + \overline{\Lambda}^{0}_{0i}\overline{g}_{0j})\overline{v}^j \\ + \overline{\Lambda}^{\ell}_{0i}\overline{g}_{\ell 0} + \overline{\Lambda}^{0}_{0i}\overline{g}_{00} - f_i = \sum\nolimits_{R=1}^{k} a_i^R[(\overline{m}_{RR}\dot{\overline{\lambda}}^R + \overline{m}_{R0})^{\cdot} + \overline{c}_{RR}\dot{\overline{\lambda}}^R + \overline{k}_{RR}\overline{\lambda}^R - \overline{f}_R],\end{aligned} \tag{94}$$

where

$(g_{ij}\overline{v}^j)^{\cdot} = (g_{ij}\overline{v}^j)_{,\ell}\,\overline{v}^{\ell} + (g_{ij}\overline{v}^j)_{,0}$ and $(\overline{m}_{RR}\dot{\overline{\lambda}}^R)^{\cdot} = (\overline{m}_{RR}\dot{\overline{\lambda}}^R)_{,R}\,\dot{\overline{\lambda}}^R + (\overline{m}_{RR}\dot{\overline{\lambda}}^R)_{,0}$.

The additional information needed for a complete mathematical formulation is obtained by incorporating an appropriate form of the k equations of the constraints. In particular, proceeding in a manner similar to that followed in previous work [15], a second order ordinary differential equation (ODE) is obtained for each holonomic constraint, with form

$$(\overline{m}_{RR}\dot{\phi}^R)^{\cdot} + \overline{c}_{RR}\dot{\phi}^R + \overline{k}_{RR}\phi^R = 0 \,, \tag{95}$$

which forces both $\dot{\phi}^R$ and ϕ^R to become zero eventually. Likewise, each nonholonomic constraint gives rise to a scalar ODE with form

$$(\overline{m}_{RR}\dot{\psi}^R)^{\cdot} + \overline{c}_{RR}\dot{\psi}^R = 0 \,, \tag{96}$$

causing $\dot{\psi}^R$ to become zero.

Next, by introducing the matrix notation

$\underline{\overline{q}} = (\overline{q}^1 \;\; \cdots \;\; \overline{q}^n)^T$, $\underline{\dot{\overline{\lambda}}} = (\dot{\overline{\lambda}}^1 \;\; \cdots \;\; \dot{\overline{\lambda}}^k)^T$, $\underline{\overline{v}} = (\overline{v}^1 \;\; \cdots \;\; \overline{v}^n)^T$ and $M = [g_{ij}]$,

Eq. (94) can be put in the following general form

$$(M(\underline{\overline{q}},t)\underline{\overline{v}})^{\cdot} + \underline{h}(\underline{\overline{q}},\underline{\overline{v}},t) = A^T(\underline{\overline{q}},t)[(\overline{M}\,\underline{\dot{\overline{\lambda}}})^{\cdot} + \underline{\overline{h}}(\underline{\overline{\lambda}},\underline{\dot{\overline{\lambda}}},t)] \,. \tag{97}$$

The array $\underline{h}(\underline{\overline{q}},\underline{\overline{v}},t)$ includes all the terms in Eq. (94) multiplied by the affinities or originating from the components $\overline{g}_{i0}$ of the metric on the event manifold $\overline{M}$, together with the applied forces f_i. Likewise, the elements of the diagonal matrix $\overline{M} = diag(\overline{m}_{11} \;\; \cdots \;\; \overline{m}_{kk})$ and the array $\underline{\overline{h}} \equiv \overline{C}\,\underline{\dot{\overline{\lambda}}} + \overline{K}\,\underline{\overline{\lambda}} + \underline{\dot{\overline{m}}}_0 - \underline{\overline{f}}$,

including the diagonal matrices $\overline{C} = diag(\overline{c}_{11} \;\; \cdots \;\; \overline{c}_{kk})$ and $\overline{K} = diag(\overline{k}_{11} \;\; \cdots \;\; \overline{k}_{kk})$ and the arrays $\underline{\dot{\overline{m}}}_0 = (\dot{\overline{m}}_{10} \;\; \cdots \;\; \dot{\overline{m}}_{k0})^T$ and $\underline{\overline{f}} = (\overline{f}_1 \;\; \cdots \;\; \overline{f}_k)^T$, are determined through application of Eq. (92).

In summary, Eq. (94) furnishes a set of n second order ODEs. These equations together with Eqs. (95) and (96) form a set of $n+k$ second order ODEs in the $n+k$ unknown coordinates q^i and λ^R, describing the behavior of mechanical systems with an arbitrary (but finite) number of coordinates, possessing a time dependent original configuration manifold and being subject to time dependent and acatastatic motion constraints. In general, solution of these equations can only be achieved by numerical means, after applying a suitable numerical discretization [20, 25]. For the scleronomic case, it is easy to verify that these equations are simplified considerably and become identical with those presented in [15]. The ODE form of the

set of equations derived is associated with several advantages over formulations leading to sets of algebraic-differential equations (DAEs) [2, 11]. It also presents advantages over previous formulations leading to an ODE form after elimination of the redundant coordinates or the Lagrange multipliers from the equations of motion, since this is done at the expense of violating the motion constraints at the lower kinematical levels [2, 15]. Finally, another advantage of the present approach is that the affinities are independent and not derived from the metric components (i.e., the connection is not necessarily metric compatible). This allows for the most general and consistent derivation of the equations of motion [19].

8 EXAMPLES

Two examples are presented in this section, illustrating theoretical aspects investigated in the previous sections. The first refers to motion of a constrained particle, with attention on recognizing when a constraint is scleronomic or rheonomic. Then, the problem of the rolling motion of a sphere over a rotating table is re-examined, by employing the scleronomicity conditions developed in Section 6.

8.1 Spherical pendulum with a moving end

Consider the spatial motion of a particle with mass m. The unconstrained motion is described by three coordinates x^i with respect to an inertial Cartesian coordinate frame $\mathbb{X}$. Then, the components of the metric tensor and the affinities can be easily determined for both the configuration manifold $M = E^3$ and the corresponding event manifold $\bar{E}^3 = E^3 \times \mathbb{R}$. The particle motion is constrained by a rigid bar with negligible mass and length L, as shown in Fig. 5. The particle is located at one end of the bar, while the other end (point P) moves along the axis Ox^3 with a known displacement history

$$x_P(t) = \hat{x}_P \cos \omega t \, .$$

This is represented by a holonomic constraint with equation

$$\phi^1(x,t) = (x^1)^2 + (x^2)^2 + (x^3 - x_P(t))^2 - L^2 = 0 \, , \tag{98}$$

which by differentiation with respect to time can be put in the general form of Eq. (89), with

$$\underset{\sim}{a}^1(x,t) = (2x^1 \quad 2x^2 \quad 2(x^3 - x_P(t))) \quad \text{and} \quad a_0^1(x,t) = -2(x^3 - x_P(t))\dot{x}_P(t) \, .$$

Next, consider the motion of the particle with respect to a new set of coordinates, corresponding to a new frame $\mathbb{S}$. This frame has origin at point P and axes remaining parallel to the axes of frame $\mathbb{X}$. Due to the constraint by Eq. (98), the position of the particle can be fully determined by the angular spherical coordinates θ^1 and θ^2, as depicted in Fig. 5. Specifically, the following relations are established between the original Cartesian coordinates and these spherical coordinates

$$x^1 = L \sin\theta^1 \cos\theta^2 \, , \quad x^2 = L \sin\theta^1 \sin\theta^2 \quad \text{and} \quad x^3 = L \cos\theta^1 + \hat{x}_P \cos \omega t \, . \tag{99}$$

Then, the velocity transformation (66) is set up with extended matrix $\bar{N}$ in the form of Eq. (67), with

$$N = \begin{bmatrix} L\cos\theta^1 \cos\theta^2 & -L\sin\theta^1 \sin\theta^2 \\ L\cos\theta^1 \sin\theta^2 & L\sin\theta^1 \cos\theta^2 \\ -L\sin\theta^1 & 0 \end{bmatrix} \quad \text{and} \quad \underline{v} = \begin{pmatrix} 0 \\ 0 \\ -\omega \hat{x}_P \sin \omega t \end{pmatrix} .$$

Substituting the above into Eq. (69), the metric matrix is determined in the form

$$\bar{g}_A = \begin{bmatrix} mL^2 & 0 & m\omega L\hat{x}_P \sin\theta^1 \sin\omega t \\ 0 & mL^2 \sin^2\theta^1 & 0 \\ m\omega L\hat{x}_P \sin\theta^1 \sin\omega t & 0 & g_{00} + m(\omega\hat{x}_P \sin\omega t)^2 \end{bmatrix}.$$

This result shows that the basis obtained in $\bar{M}_A$ is not standard. In addition, it is found that there exist both pure and mixed affinities, which are expressions of coordinates θ^1, θ^2 and t.

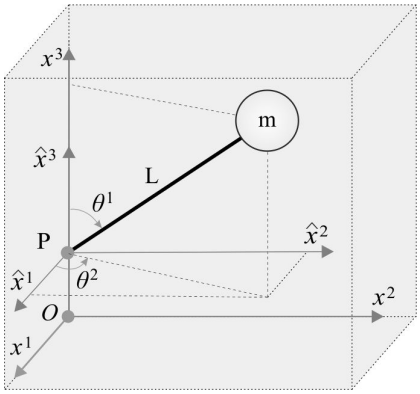

Fig. 5 A spherical pendulum with a translating end

Next, the emphasis was placed in investigating whether these effects are removable by a change of basis in $\bar{M}_A$. Using integrability conditions, the following change of coordinates

$$\theta^1 = 2\tan^{-1}(e^{\hat{\theta}^1 + \cos\omega\hat{\tau}}), \quad \theta^2 = \hat{\theta}^2 \quad \text{and} \quad \tau = \hat{\tau}, \tag{100}$$

was found to lead to a coordinate basis where the new metric matrix is block diagonal. In fact, the metric matrix in the new coordinate system is obtained in the 3×3 diagonal form

$$\hat{\bar{g}}_A = diag(mL^2 \sin\eta(\hat{\theta}^1,\hat{\tau}) \quad mL^2 \sin\eta(\hat{\theta}^1,\hat{\tau}) \quad g_{00} + m[\omega\hat{x}_P \cos\eta(\hat{\theta}^1,\hat{\tau})\sin\omega t]^2),$$

with

$$\eta(\hat{\theta}^1,\hat{\tau}) = 2\tan^{-1}(e^{\hat{\theta}^1 + \cos\omega\hat{\tau}}).$$

However, all its elements have a mixed dependence on both the spatial coordinate $\hat{\theta}^1$ and the temporal coordinate $\hat{\tau}$. Similar findings resulted in evaluating the corresponding affinities. These imply that conditions (13), or alternatively Eqs. (85)-(88), do not hold in the case examined. Therefore, the manifold M_A is rheonomic. Since the original manifold M is scleronomic, the motion constraint expressed by Eq. (98) is rheonomic, in accordance with the classical definitions [12].

Next, consider the motion of the particle with respect to a new Cartesian coordinate frame $\mathbb{Y}$, with coordinates y^i $(i=1,2,3)$, in the same configuration manifold M. In particular, the origin of this frame is point P, while its axes remain parallel to the corresponding axes of frame $\mathbb{X}$, as shown in Fig. 5. Then, the two sets of coordinates are related by

$$x^1 = y^1, \quad x^2 = y^2 \quad \text{and} \quad x^3 = y^3 + \hat{x}_P \cos\omega t. \tag{101}$$

In the new coordinate system, the motion constraint appears also in a holonomic form

$$\phi^1(y,t) = (y^1)^2 + (y^2)^2 + (y^3)^2 - L^2 = 0. \tag{102}$$

However, in contrast to Eq. (98), this now appears in a scleronomic catastatic form, according to common terminology [12, 23]. In order to explain the discrepancy with Eq. (98), it is useful to view Eq. (101), together with $t = \hat{t}$, as a coordinate transformation in the original event manifold $\bar{M} = \bar{E}^3$, similar to that expressed by Eq. (39). Then, the Jacobian is obtained in the form of Eq. (42), with

$$J = I_3 \quad \text{and} \quad \underline{c} = (0 \quad 0 \quad -\omega \hat{x}_P \sin \omega t)^T .$$

Consequently, evaluation of the metric in the new basis of $\bar{E}^3$ through Eq. (48) yields

$$\hat{g} = g = mI_3 , \quad \underline{g}_{\hat{0}} = (0 \quad 0 \quad -m\omega \hat{x}_P \sin \omega t)^T \quad \text{and} \quad g_{\hat{0}\hat{0}} = g_{00} + m(\omega \hat{x}_P \sin \omega t)^2 .$$

As expected, based on the fact that $\underline{c} \neq \underline{0}$, the new basis in $T_p \bar{M}$ is not standard, since $\underline{g}_{\hat{0}} \neq \underline{0}$ for $\omega \hat{x}_P \neq 0$. Moreover, all the affinities on $\bar{M}$ are found to be equal to zero, exception for

$$\bar{\Lambda}^{\hat{3}}_{\hat{0}\hat{0}} = \omega^2 \hat{x}_P \cos \omega t .$$

Therefore, despite the fact that it does not involve time in an explicit manner, the motion constraint expressed by Eq. (102) is in fact rheonomic, since the configuration manifold M is scleronomic, while the constrained manifold M_A is rheonomic, as shown above. This result resolves the difference observed in the time dependence appearing in the constraint equations (98) and (102). Furthermore, it demonstrates that the classical classification of constraints on a mechanical system with configuration manifold possessing time dependent geometric properties is accurate only when the components involved in the constraint equations are expressed with respect to standard bases in both $\bar{M}$ and $\bar{M}_A$.

8.2 Rolling of a sphere on a rotating table

Next, consider the motion of a rigid sphere, rolling without slipping on a horizontal table [9]. This table rotates with an angular speed $\Omega(t)$ with respect to a fixed vertical axis Ox^3, as shown in Fig. 6. The sphere has radius r, mass m and a known mass moment of inertia J with respect to any axis passing through its center of mass C. The coordinate system $\mathbb{F}$, shown in Fig. 6, is fixed (inertial) and the angular velocity of the table is

$$\underline{\omega}_T(t) = \Omega(t)\underline{e}_3 . \tag{103}$$

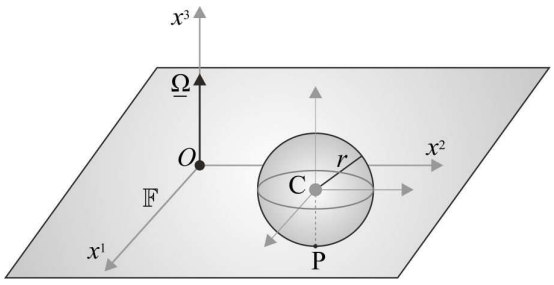

Fig. 6 Rigid sphere rolling over a rotating table

First, the position of the sphere is determined at any time t by the generalized coordinates

$$\underline{q}(t) = (\underline{x}_C^T \quad \underline{\theta}^T)^T , \tag{104}$$

where the arrays

$$\underline{x}_C = (x^1 \quad x^2 \quad x^3)^T \quad \text{and} \quad \underline{\theta} = (\theta^1 \quad \theta^2 \quad \theta^3)^T$$

represent the position of the center of mass and the orientation of the sphere, respectively, with respect to the inertial reference frame $\mathbb{F}$. Due to the symmetry of the sphere, the classical Cartesian rotation vector is selected for the description of its rotational motion [11]. The coordinates $\underline{q}(t)$ represent a point on a product configuration manifold $M = \mathbb{R}^3 \times M(3)$, with dimension n=6 [18]. Then, the motion of the system can be viewed as the motion of a point along a specific path $\gamma(t)$ on manifold M, with tangent vector given by

$$\underline{v}(t) = (\underline{v}_C^T \quad \underline{\omega}^T)^T,$$

where

$$\underline{v}_C = (v^1 \quad v^2 \quad v^3)^T \quad \text{and} \quad \underline{\omega} = (\omega^1 \quad \omega^2 \quad \omega^3)^T,$$

with $v^i = \dot{x}^i$ $(i = 1,2,3)$. Moreover, the quasi-velocities $\underline{\omega}$ are related to the true angular velocities $\dot{\underline{\theta}}$ through the corresponding tangent operator $T(\underline{\theta})$ at $\underline{\theta}$ [11], by

$$\underline{\omega} = T^T(\underline{\theta})\dot{\underline{\theta}}.$$

Then, based on the kinetic energy of the sphere, the metric of M is found in the block diagonal form

$$g = [g_{ij}] = \begin{bmatrix} mI_3 & 0 \\ 0 & JI_3 \end{bmatrix}. \tag{105}$$

Moreover, since the manifold M examined is a product manifold, its affinities appear in product form as well. In particular, all the affinities related to the translational part can be selected to be zero, while the non-zero affinities related to the rotational part of the motion can be chosen to take the following constant values in a body frame

$${}_R\Lambda^1_{23} = -{}_R\Lambda^1_{32} = {}_R\Lambda^2_{31} = -{}_R\Lambda^2_{13} = {}_R\Lambda^3_{12} = -{}_R\Lambda^3_{21} = 1. \tag{106}$$

Moreover, all the mixed affinities are zero [18]. Then, the affinities can be evaluated in the coordinate system used by employing the rotation matrix $R = \exp(\tilde{\theta})$ as a transformation matrix in Eq. (46).

Next, due to the constraints imposed on the motion of the sphere, there appear $k = 3$ constraint equations, so that the dimension of manifold M_A is just $m = 3$. Specifically, the first constraint is holonomic and guarantees that the center of the sphere stays on a constant height

$$\phi^1 = x^3 - r = 0 \quad \Rightarrow \quad \dot{\phi}^1 = v^3 = 0. \tag{107}$$

In addition, the rolling condition of the sphere leads to two more constraints, namely

$$\psi^2 = \dot{x}^1 - r\omega^2 + \Omega x^2 = 0 \quad \text{and} \quad \psi^3 = \dot{x}^2 + r\omega^1 - \Omega x^1 = 0, \tag{108}$$

which are nonholonomic and acatastatic. Therefore, the 3×6 matrix of constraints A and the vector $\underline{a}$ appearing in Eq. (64) take the form

$$A = \begin{bmatrix} 0 & 0 & 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & -r & 0 \\ 0 & 1 & 0 & r & 0 & 0 \end{bmatrix} \quad \text{and} \quad \underline{a}(\underline{q},t) = \begin{pmatrix} 0 \\ \Omega x^2 \\ -\Omega x^1 \end{pmatrix}. \tag{109}$$

Based on these results, one can determine the components of the special constraint vectors $\underline{c}_R$ and $\underline{c}_{R0}$ by Eq. (90). For instance, a possible choice for these vectors is the following

$$\underline{c}_1 = (0 \quad 0 \quad 1 \quad 0 \quad 0 \quad 0)^T, \quad \underline{c}_2 = (0 \quad 0 \quad 0 \quad 0 \quad -1/r \quad 0)^T, \quad \underline{c}_3 = (0 \quad 0 \quad 0 \quad 1/r \quad 0 \quad 0)^T,$$

$$\underline{c}_{10} = \underline{0}, \quad \underline{c}_{20} = (0 \quad 0 \quad 0 \quad 0 \quad \Omega x^2/r \quad 0)^T \quad \text{and} \quad \underline{c}_{30} = (0 \quad 0 \quad 0 \quad \Omega x^1/r \quad 0 \quad 0)^T.$$

Consequently, application of the first two relations in Eq. (92) leads to determination of the elements of the diagonal mass matrix $\bar{M}$ and the vector $\bar{\underline{m}}_0$ in the form

$$\bar{m}_{11} = m, \quad \bar{m}_{22} = \bar{m}_{33} = J/r^2, \quad \bar{m}_{10} = 0, \quad \bar{m}_{20} = -\Omega x^2 J/r^2 \quad \text{and} \quad \bar{m}_{30} = \Omega x^1 J/r^2.$$

Likewise, given a set of applied forces acting on the sphere, which can be represented by a resultant force $\underline{f}(\underline{q}, \underline{\dot{q}}, t)$ and moment $\underline{m}_C(\underline{q}, \underline{\dot{q}}, t)$ with respect to its center C [21], the elements $\bar{c}_{RR}$ and $\bar{k}_{RR}$ of the diagonal damping and stiffness matrices $\bar{C}$ and $\bar{K}$, as well as the corresponding forcing terms $\bar{f}_R$ ($R = 1, \ldots, 3$) are also evaluated by applying Eq. (92).

Collecting all the above and substituting in Eq. (94) leads to the equations of motion of the constrained system examined on the original configuration manifold in matrix form. The set of coordinates $\underline{q}$ is given by Eq. (104), while the Lagrange multipliers $\underline{\lambda} = (\lambda^1 \quad \lambda^2 \quad \lambda^3)^T$ correspond to the set of constraints (107) and (108). In the present formulation, the six ODEs represented by Eq. (97) are accompanied by a constraint equation in the form of Eq. (95) and two constraint equations in the form of Eq. (96), where the terms ϕ^1, $\dot{\phi}^1$, ψ^2 and $\dot{\psi}^3$ are taken from Eqs. (107) and (108). This leads to a system of 9 second order ODEs for the 9 unknowns, $\underline{q}$ and $\underline{\lambda}$, of the problem.

Finally, a simple inspection of Eqs. (105) and (106) reveals that the original configuration manifold M is scleronomic. Moreover, based on Eq. (109), an appropriate 7×4 transformation matrix $\bar{N}$ is first determined in the form of Eq. (67), so that the 4×4 metric matrix corresponding to the event constrained manifold $\bar{M}_A$ is determined by application of Eq. (69) in the diagonal form

$$\bar{g}_A = diag((m + J/r^2) \quad (m + J/r^2) \quad J \quad g_{00} + mJ\Omega^2[(\theta^1)^2 + (\theta^2)^2]/(mr^2 + J)),$$

where θ^α (with $\alpha = 1, \ldots, 4$) is a coordinate set on $\bar{M}_A$. This corresponds to a standard basis. Evaluation of the corresponding structure constants shows that they are all zero, except for

$$c^1_{02} = -c^1_{20} = J\Omega/(mr^2 + J) = c^2_{10} = -c^2_{01}.$$

This indicates that the basis selected in $\bar{M}_A$ is not holonomic. Therefore, it is more convenient here to apply the scleronomicity checks in the coordinate invariant form presented in Section 6 in order to judge safely whether the constrained manifold is rheonomic or not. Indeed, application of Eq. (84) to the example considered reveals that the first condition on the metric is satisfied identically. However, evaluation of the Lie derivative required by the second condition in the same equation shows that there appears the following non-zero term

$$(L_{\underline{h}} \bar{g}_T)_{00} = 2mJ\Omega^2/(mr^2 + J),$$

which becomes zero only when $\Omega = 0$, corresponding to a stationary table. This demonstrates that Eq. (84) is violated when $\Omega \neq 0$ and reveals that manifold M_A is rheonomic, indeed.

9 SYNOPSIS

This study was devoted to mechanical systems possessing configuration manifolds with time dependent geometric properties and being subject to additional acatastatic equality motion constraints involving time explicitly. This time dependence, in conjunction with the need to keep invariant the form of Newton's law in different manifolds, led to an introduction and consideration of the corresponding event manifold. These time dependent terms were shown to be introduced by either a basis transformation in the event manifold or by additional motion constraints. Moreover, the time terms introduced by a basis transformation are artificial and can be removed from the equations of motion. These results were reinforced and enhanced further by exploiting some concepts of foliation theory. Apart from providing useful clarifications on the geometry of the motion, this theory was also employed in establishing a set of coordinate invariant conditions for judging whether a configuration manifold is scleronomic. Finally, the equations of motion were obtained in the original configuration manifold, in the presence of constraints. Also, some of the analytical findings were illustrated by examining two systems exhibiting basic features of the class of systems examined.

The results presented in this work are applicable and cover a wide range of engineering systems. To obtain them, some useful tools from differential geometry were employed. In return, apart from providing a nice interpretation of the key concepts, these tools helped in performing a consistent application of Newton's law to manifolds with general time dependent geometric properties. Eventually, this led to a system of second order ODEs, which are much easier to handle than sets of DAEs [2, 11]. In addition, the final set of equations of motion was obtained on the original configuration manifold, whose geometric properties are not affected by the presence of the additional motion constraints. Also, these equations involve properties of the corresponding event manifold. These provide fertile ground for developing new advanced formulations, leading to more accurate, effective and robust numerical methods for solving these equations, by enhancing available techniques [6, 13, 20].

Abstract. *In this work, a computational framework is presented in order to estimate the optimal values of the linear and nonlinear components of large scale dynamical systems using vibration measurements. An extensible framework for Bayesian Uncertainty Quantification and Propagation of complex and computationally demanding physical models, was connected in an efficient way with a numerical code leading to an automated determination of dynamic response of linear and nonlinear mechanical systems. The effect of correlation in the prediction error models postulated in the Bayesian model selection and parameter estimation technique is investigated. The measurements are taken to be either response time histories or frequency response functions. The framework was applied in two complex mechanical systems. First examined a lightweight bicycle frame with the nonlinear front suspension component. In this system uncertainty models of the linear and nonlinear suspension components are identified using the experimentally obtained transmissibility functions. These uncertainties, integrated with uncertainties in the linear frame of the bicycle, are propagated in order to estimate the uncertainties for the combined system. The second system examined include a two stage gear transmission system. In this model the housing of the gearbox is modeled by using finite elements, while the essential effects of the gear-pair, the bearings and the shafts are taken into account via a lumped nonlinear mathematical model. This model possesses strongly nonlinear characteristics, accounting for gear backlash, meshing stiffness, transmission error properties and bearing stiffness nonlinearities. In order to identify the values of the parameters, accelerations time histories are used, obtained during various operating conditions of the gearbox. These measurements are recorded from a special experimental device (Drivetrain Prognostics Simulator). The computational challenges are outlined and the effectiveness of the framework on these two complex mechanical systems is demonstrated.*

1 INTRODUCTION

The main objective of the present work is to demonstrate the advantages of applying appropriate numerical and experimental methodologies in order to identify, update and optimize the model parameters and develop a high fidelity finite element model of both linear and non-linear components, comprising the whole assembly of the examined structure. In this process, many issues are taken into account, related to the development of FE model, the experimental modal analysis procedure and the development of effective computational model updating techniques.

The equations of motion of mechanical systems with complex geometry are first set up, applying classical finite element techniques. As the order of these models increases, the existing numerical and experimental methodologies for a systematic determination of their dynamic response become inefficient to apply. Therefore, there is a need for the development, improvement and application of new suitable methodologies for investigating dynamics of large-scale mechanical models in a systematic and efficient way. Moreover, in order to optimize the FE model of a structure, structural model updating methods [11], have been proposed in order to reconcile the numerical (FE) model, with experimental data. Structural model parameter estimation based on measured modal data (e.g. [4-10]) are often formulated as weighted least-squares estimation problems in which metrics, measuring the residuals between measured and model predicted modal characteristics, are build up into a single weighted residuals metric formed as a weighted average of the multiple individual metrics using weighting factors. Standard gradient-based optimization techniques are then used to find the optimal values of the structural parameters that minimize the single weighted residuals metric representing an overall measure of fit between measured and model predicted modal characteristics. Due to model error and measurement noise, the results of the optimization are affected by the values assumed for the weighting factors.

In this work, the applicability and effectiveness of the updating methods, coupled with robust, accurate and efficient finite element analysis software are applied on linear and non-linear components of a whole structure using experimentally identified modal data. The framework was applied in two complex mechanical systems. First examined a lightweight bicycle frame with the nonlinear front suspension component. The second system examined include a two stage gear transmission system. In this work was selected to be presented in detail only the results of the first system. More specifically, a lightweight and geometrically complex bicycle frame as well as the suspension-fork subassembly of a real bicycle are examined, comprising the linear and nonlinear subsystems of the whole bike assembly. Furthermore, the suspension-fork subassembly is consisted of two linear parts (upper and lower fork part) connected with two springs and two seals which impose strong nonlinearity in the system. Issues related to estimating unidentifiable solutions [12-15] arising in FE model updating formulations are also addressed. A systematic study is carried out to demonstrate the effect of model error, finite element model parameterization, number of measured modes and number of mode shape components on the optimal models and their variability. It is demonstrated that the updated finite element models obtained using measured modal data may vary considerably.

The organization of this paper is as follows. First in the first section, the theoretical formulation of finite element model updating based on modal characteristics and frequency response functions is briefly presented. In the second section, the experimental device is introduced. First, a quick presentation of the digitization of the bicycle components leading to the final parametric CAD model is shown with the corresponding detailed FE models. Next presented the experimental modal analysis procedure followed in order to identify the modal

characteristics and the FRF's. Finally, the parametric studies on updating the linear and nonlinear FE models of the bicycle components, with the predictions of frequency response functions and time histories, based on the optimal models, are presented in the fourth section. Conclusions are summarized in the fifth section.

2 FINITE ELEMENT MODEL UPDATING METHODS

2.1 Modal Residuals

Let $D=\{\hat{\omega}_r,\hat{\underline{\phi}}_r \in R^{N_o}, r=1,\cdots,m\}$ be the measured modal data from a structure, consisting of modal frequencies $\hat{\omega}_r$ and mode shape components $\hat{\underline{\phi}}_r$ at N_o measured DOFs, where m is the number of observed modes. Consider a parameterized class of linear structural models used to model the dynamic behavior of the structure and let $\underline{\theta}\in R^{N\theta}$ be the set of free structural model parameters to be identified using the measured modal data. The objective in a modal-based structural identification methodology is to estimate the values of the parameter set $\underline{\theta}$ so that the modal data $\{\omega_r(\underline{\theta}),\ \underline{\phi}_r(\underline{\theta})\in R^{N_0}, r=1,\cdots,m\}$ predicted by the linear class of models at the corresponding N_0 measured DOFs best matches the experimentally obtained modal data in D. For this, let

$$\varepsilon_{\omega_r}(\underline{\theta})=\frac{\omega_r^2(\underline{\theta})-\hat{\omega}_r^2}{\hat{\omega}_r^2} \quad \text{and} \quad \varepsilon_{\underline{\phi}}(\underline{\theta})=\frac{\left\|\beta_r(\underline{\theta})\underline{\phi}_r(\underline{\theta})-\hat{\underline{\phi}}_r\right\|}{\left\|\hat{\underline{\phi}}_r\right\|} \tag{1}$$

be the measures of fit or residuals [16] between the measured modal data and the model predicted modal data for the r-th modal frequency and mode shape components, respectively, where $\|\underline{z}\|^2=\underline{z}^{\mathrm{T}}\underline{z}$ is the usual Euclidean norm, and $\beta_r(\underline{\theta})=\hat{\underline{\phi}}_r^T\underline{\phi}_r(\underline{\theta})/\left\|\underline{\phi}_r(\underline{\theta})\right\|^2$ is a normalization constant that guaranties that the measured mode shape $\hat{\underline{\phi}}_r$ at the measured DOFs is closest to the model mode shape $\beta_r(\underline{\theta})\underline{\phi}_r(\underline{\theta})$ predicted by the particular value of $\underline{\theta}$. To proceed with the model updating formulation, the measured modal properties are grouped into two groups. The first group contains the modal frequencies while the second group includes the mode shape components for all modes. For each group, a norm is introduced to measure the residuals of the difference between the measured values of the modal properties involved in the group and the corresponding modal values predicted from the model class for a particular value of the parameter set $\underline{\theta}$. For the first group, the measure of fit $J_1(\underline{\theta})$ is selected to represent the difference between the measured and the model predicted frequencies for all modes. For the second group, the measure of fit $J_2(\underline{\theta})$ is selected to represent the difference between the measured and the model predicted mode shape components for all modes. Specifically, the two measures of fit are given by

$$J_1(\underline{\theta})=\sum_{r=1}^{m}\varepsilon_{\omega_r}^2(\underline{\theta}) \quad \text{and} \quad J_2(\underline{\theta})=\sum_{r=1}^{m}\varepsilon_{\underline{\phi}_r}^2(\underline{\theta})=\sum_{r=1}^{m}\left[1-MAC_r^2(\underline{\theta})\right] \tag{2}$$

where $MAC_r(\underline{\theta})=\underline{\phi}_r{}^T\hat{\underline{\phi}}_r(\underline{\theta})/\left\|\underline{\phi}_r\right\|\left\|\hat{\underline{\phi}}_r\right\|$ is the Modal Assurance Criterion [23] between experimentally identified and estimated mode shapes for the r-th mode. Alternative measures of fit can easily be used and found in literature [18-22].

2.2 Response Residuals

Derived from the MAC for any measured frequency point, ω_k a global correlation coefficient may be used [17, 24]:

$$x_s(\omega_k)=\frac{\left|\{H_X(\omega_k)\}^H\{H_A(\omega_k)\}\right|^2}{\left(\{H_X(\omega_k)\}^H\{H_X(\omega_k)\}\right)\left(\{H_A(\omega_k)\}^H\{H_A(\omega_k)\}\right)} \tag{3}$$

where $\{H_X(\omega_k)\}$ and $\{H_A(\omega_k)\}$ are the experimental (measured) and the analytical (predicted) response vectors at matching excitation - response locations. As the MAC value, $x_s(\omega_k)$ assumes a value between zero and unity and indicates perfect correlation with $x_s(\omega_k)=1$. For $x_s(\omega_k)=0$, no correlation exists. Similar to the MAC, $x_s(\omega_k)$ is unable to detect scaling errors and is only sensitive to discrepancies in the overall deflection shape of the structure. To emphasis this characteristic, $x_s(\omega_k)$ is accordingly called the shape correlation coefficient [24].

The lack of sensitivity to scaling of the shape correlation coefficient does not allow the identification of identical FRFs. This insufficiency becomes even more dramatic if just one measurement and its corresponding prediction are correlated. In this case, the column vectors reduce to scalars and $\{H_A(\omega_k)\}=k\{H_X(\omega_k)\}$ is always satisfied (constant k may be complex), therefore leading to $x_s=1$ across the full frequency spectrum for uncorrelated FRFs.

As a result, a supplementary correlation coefficient $x_a(\omega_k)$ is proposed by targeting the discrepancies in amplitude. The amplitude correlation coefficient is defined as:

$$x_a(\omega_k)=\frac{2\left|\{H_X(\omega_k)\}^H\{H_A(\omega_k)\}\right|}{\left(\{H_X(\omega_k)\}^H\{H_X(\omega_k)\}\right)+\left(\{H_A(\omega_k)\}^H\{H_A(\omega_k)\}\right)} \tag{4}$$

where the response vectors are identical to those used for $x_s(\omega_k)$. As for the shape correlation coefficient, $x_a(\omega_k)$ is defined to lie between zero and unity. This time, however, the correlation measure is more stringent and only becomes unity if $\{H_A(\omega_k)\}=\{H_X(\omega_k)\}$. That is to say, all elements of the response vectors must be identical in both phase and amplitude even if only one measurement is considered. Similarly to modal residuals, two measures of fit are proposed using $x_s(\hat{\omega}_r)$ and $x_a(\hat{\omega}_r)$ which correspond to the identified resonant frequencies of the system:

$$J_3(\underline{\theta})=\sum_{r=1}^{m}\left[1-x_s(\hat{\omega}_r,\underline{\theta})^2\right] \text{ and } J_4(\underline{\theta})=\sum_{r=1}^{m}\left[1-x_a(\hat{\omega}_r,\underline{\theta})^2\right] \tag{5}$$

2.3 Weighting Residuals Method

Minimizing at global minimum the following single objective, traditionally solves the parameter estimation problem:

$$J(\underline{\theta};\underline{w})=w_1J_1(\underline{\theta})+w_2J_2(\underline{\theta})+w_3J_3(\underline{\theta})+w_4J_4(\underline{\theta}) \tag{6}$$

formed by the four objectives $J_i(\underline{\theta})$, using the weighting factors $w_i\geq 0$, $i=1,2,3,4$, with $w_1+w_2+w_3+w_4=1$. The objective function $J(\underline{\theta};\underline{w})$ represents an overall measure of fit between the measured and the model predicted characteristics. The relative importance of the residual errors in the selection of the optimal model is reflected in the choice of the weights. The

results of the identification depend on the weight values used. The optimal solutions for the parameter set $\underline{\theta}$ for given $\underline{w}$ are denoted by $\underline{\hat{\theta}}(\underline{w})$ [12-15].

3 EXPERIMENTAL APPLICATION

The model updating methodologies are applied in order to update the FE model of a real bicycle. The bicycle consisted of the main frame, which presented in Figure 1 and is made of aluminum and from the front suspension which also consisted of two main parts which are presented respectively in Figures 3 and 4. The lower part of the fork, has the same material properties with the bicycle frame, while the upper fork part, consisted of steel tubes which are connected with a solid aluminum part. The thicknesses of the cross sections of the main frame as long as the lower part of the fork can vary along their length.

3.1 Digitization and FE Models

First, using a 3D Laser Scanner in order to collect, process and design the CAD model. Next, the geometry of the bicycle frame is discretized mainly by shell elements (triangular) and solid elements (tetrahedral). The total number of DOFs was 1,000,000. Similarly, the upper part of the fork was modeled with shell (triangular and quadrilateral) and solid (tetrahedral) elements resulting to 125,000 DOFs and the lower part of the fork was modeled only with solid (tetrahedral) elements resulting to 205,000 DOFs. The detailed FE models are presented in Figures 2, 3 and 4. For the development and solution of the finite element models appropriate software was used [25, 26].

Figure 4: Lower (part 2) of the suspension-fork

3.2 Experimental Modal Analysis

After developing the nominal finite element models, an experimental modal analysis of the frame and fork parts, was performed to quantify its dynamic characteristics. The frame and fork parts were hung up using a crane and straps, to approximate free-free boundary conditions for the test. First, all the necessary elements of the FRF matrix required for determining the response of the substructures were determined by imposing impulsive loading [5-9]. The measured frequency range was 0-2048 Hz, which includes the analytical frequency range of interest for the frame, 0-600 Hz, as well as for the fork parts, 0-500 Hz. An initial investigation indicated eleven natural frequencies for the frame and four for the fork parts, in this frequency range. A schematic illustration of the experimental arrangement is presented in Figure 5. In these figures, the locations and directions of acceleration measurements are presented, applying an impulsive load in all directions and at several locations. Based on the measured FR functions, the natural frequencies and the damping ratios of the substructures were estimated [10, 11, 15]. The identified mode shapes have also been recorded so that they can be used for updating the finite element models.

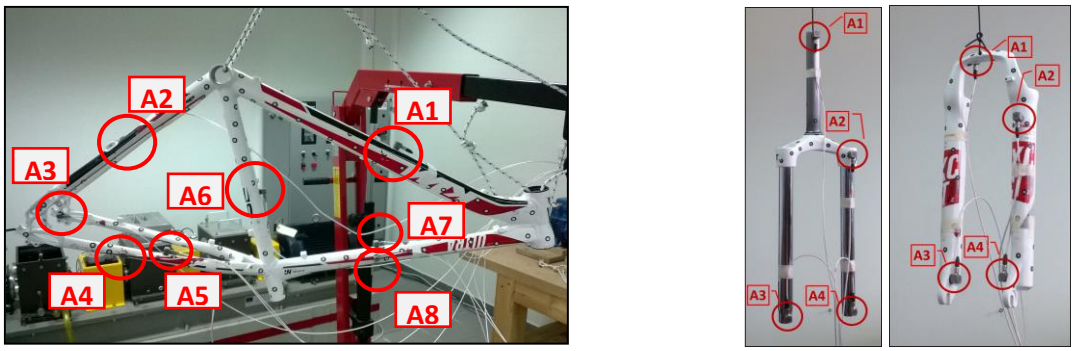

Figure 5: Accelerometer locations on main frame and fork parts 1 and 2

As an outcome of the above two procedures, in the Table 1 summarized the modal analysis results for the main frame, while similar results presented for the fork parts 1 and 2 in the Table 2.

Mode	Identified Modal Frequency	Nominal FE Predicted Modal Frequency	Difference between Identified and FE Predicted Modal Frequencies	Identified Modal Damping Ratio

4	497.25	553.03	10.09	0.11

Table 2: Modal frequencies and modal damping ratios of the two parts of the suspension-fork

More specifically, the first column of Table 1 presents the values of the lowest natural frequencies (ω_{rE}), while the corresponding damping ratios are included in the fourth column. In the same table, the second column presents the values of the natural frequencies obtained from the analysis of the nominal finite element model ($\omega_{rN_{FE}}$) and the third column compares these frequencies with the corresponding frequencies obtained by the experimental data. The errors determined between the nominal FE model and the experimental measurements are not insignificant, indicating that the FE model updating process is necessary.

4 FINITE ELEMENT MODEL UPDATING

4.1 Linear FE model parameterization

The parameterization of the finite element models is introduced in order to demonstrate the applicability of the proposed finite element model updating method. The parameterized models are consisted of thirteen, two and four parts, for the frame, fork part 1 and fork part 2, respectively, as shown in Figure 6. The first four parts (P1, P2, P3 and P4) of the frame are modeled with solid elements, while the remaining nine parts (P5-P13) are modeled with shell elements. Fork part 1 is modeled with shell and solid elements for P1 and P2 respectively and fork part 2 is modeled solely with solid elements. The thickness of the shell elements, the Young's modulus and the density are used as design variables. Thus, the final numbers of the design parameters are thirty-five (35), five (5) and eight (8) variables for the frame, fork part 1 and part 2 respectively.

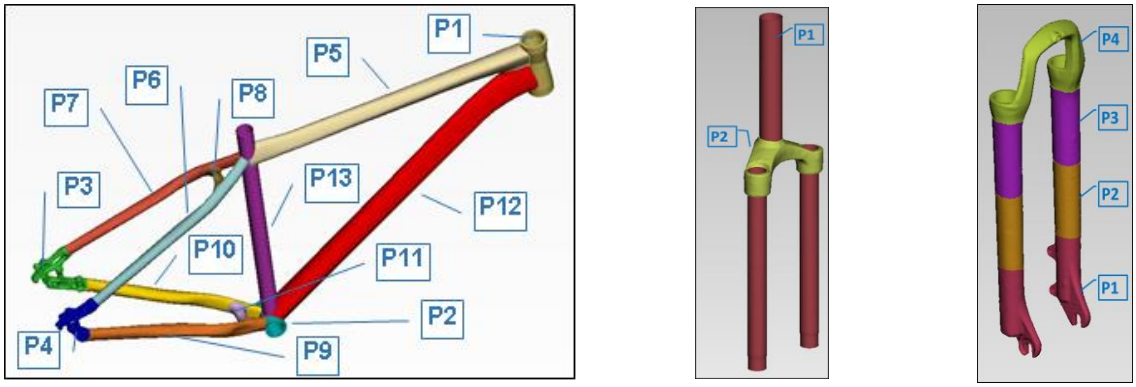

Figure 6: Parts of the parameterized FE Models of the frame and suspension- fork parts

The FE models of the main frame and the fork parts are updated using the identified modal frequencies and mode shapes shown in Tables 1 and 2. The identified mode shapes include components at all sensor locations. Additionally, we define as design response the total weight of the model, in order to be taken into consideration during the optimization process.

4.2 Linear FE Model Updating Results

The results from the FE model updating method are shown in Tables 3 and 4 for the frame and fork parts respectively. A comparison between identified (ω_{rE}) and optimal FE predicted modal frequencies ($\omega_{rO_{FE}}$) is also presented.

The FRF predicted by the optimal FE model (black dashed line) for the frame are compared in Figure 7 with the FRF computed directly from the measured data (red continuous line) at two indicative measurement locations in the frequency range [50Hz, 550Hz]. The FRF of the initial nominal model (blue dashed dot line) is also shown in these

figures to be inadequate to represent the measured FRF. Compared to the FRF of the initial nominal model, it is observed that the updated optimal model tend to considerably improve the fit between the model predicted and the experimentally obtained FRF close to the resonance peaks.

Mode	Identified Modal Frequency	Optimal FE Predicted Modal Frequency	Difference between Identified and FE Predicted Modal Frequencies
	$\omega_{rE}[Hz]$	$\omega_{rO_{FE}}[Hz]$	$\frac{\omega_{rO_{FE}}-\omega_{rE}}{\omega_{rO_{FE}}}100\%$

5 ANALYSIS OF NON-LINEAR SYSTEM

The FE model, of the nonlinear subassembly of the suspension-fork, was created connecting fork part 1 and 2 with two springs simulating the restoring force $f_r(x)$ and two non-linear bushing elements simulating the damping force $f_d(\dot{x})$. The final nonlinear suspension FE model with the corresponding lumped model presented in Figure 8.

In order to identify the parameters of the subsystem, which exhibit strongly nonlinear characteristics, a series of experimental trials was performed. In the experimental device

shown in Figure 9 two electromagnetic devices are used, at the top and at the bottom of the suspension, imposing harmonic excitation with $\pi/2$ rad phase difference using 0.2 Hz frequency step for three different forcing levels.

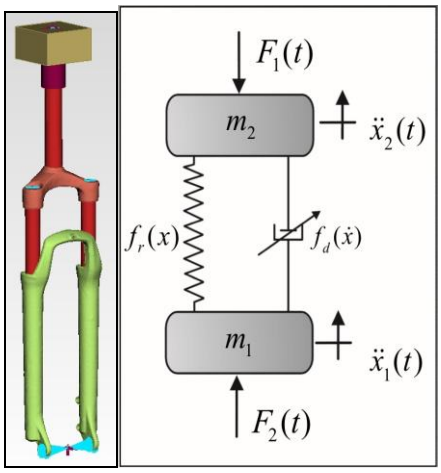

Figure 8: FE model of the suspension-fork and theoretical lumped model

Figure 9: Schematic illustration and experimental arrangement of suspension sub-assembly

In Figure 10 depicted the imposed forces $F_1(t)$ and $F_2(t)$ for the three different forcing levels at $\omega = 6Hz$ which is approximately the resonant frequency of the system, while in Figure 11 depicted the acceleration transmissibility functions of measurement location 2, for the three different forcing levels. A number of models of the restoring and damping forces, say f_r and f_d, respectively, were tried for modeling the action of the supports and compared with the experimental results. The classic linear dependence of the restoring force on the displacement and of the damping forces on the velocity of the support unit was first assumed. However, critical comparison with the experimental results using the Bayesian model selection framework demonstrated that the outcome was unacceptable in terms of accuracy. Eventually it was found that an acceptable form of the restoring forces is the one where they remain virtually in a linear relation with the extension of the spring, namely

$$f_r(x) = kx \tag{7}$$

while the damping force was best approximated by the following formula

$$f_d(\dot{x}) = c_1\dot{x} + \frac{c_2\dot{x}}{c_3 + |\dot{x}|} \tag{8}$$

As usual, the linear term in the last expression is related to internal friction at the support, while the nonlinear part is related to the existence and activation of dry friction. More specifically, in the limit $c_3 \to 0$, the second term in the right hand side of Equation (8) represents energy dissipation action corresponding to dry friction. On the other side, in the limit $c_3 \to \infty$ this term represents classical viscous action and can actually be absorbed in the first term.

The results for k, c_1, c_2 and c_3 are obtained based on the experimental response spectra values for the accelerations of the two suspension components, using the parameters of the updated linear parts (1 and 2) of the suspension fork subassembly and the transmissibility functions of the support system for three different forcing levels. Let $S = \{\hat{s}_r(\omega_r) \in R^{N_r}, r = 1,\cdots,n\}$

be the measured transmissibility functions at N_r measured frequencies where n is the number of involved frequencies. Let $\underline{\theta}=(k_1,c_1,c_2,c_3\in R^{N_\theta})$ be a parameter space, corresponding to the linear and nonlinear coefficients of the restoring and damping forces respectively.

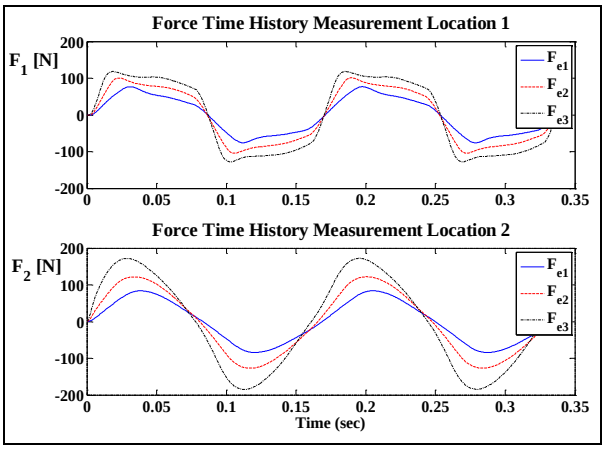

Figure 10: Time-history of the external forces applied at a fundamental harmonic frequency $\omega=6Hz$

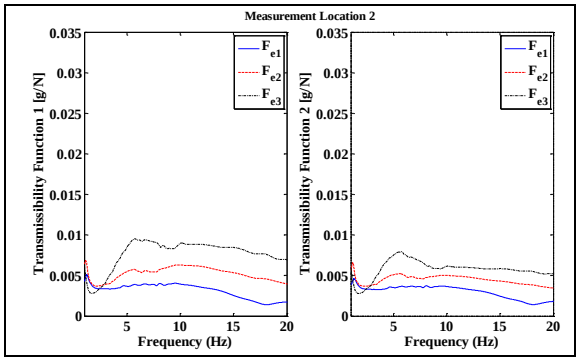

Figure 11: Transmissibility functions of the support system for three different forcing levels

The results for k, c_1, c_2 and c_3 are obtained based on the experimental response spectra values for the accelerations of the two suspension components, using the parameters of the updated linear parts (1 and 2) of the suspension fork subassembly and the transmissibility functions of the support system for three different forcing levels. Let $S=\{\hat{s}_r(\omega_r)\in R^{N_r}, r=1,\cdots,n\}$ be the measured transmissibility functions at N_r measured frequencies where n is the number of involved frequencies. Let $\underline{\theta}=(k_1,c_1,c_2,c_3\in R^{N_\theta})$ be a parameter space, corresponding to the linear and nonlinear coefficients of the restoring and damping forces respectively. Similarly to the linear model, the objective is to estimate the values of the parameter set $\underline{\theta}$ so that the analytical response spectra values, namely the transmissibility functions match the experimentally obtained functions estimated in S. In Figure 12, presented a comparison in two measured locations, between the numerical nonlinear FE model (red line), with the experimental measurements (black line), in harmonic excitation with forcing frequency of $\omega=6Hz$. More specifically, the nonlinear FE model with the estimated values of the stiffness and damping properties, was solved with nonlinear transient response analysis. The blue line was derived using the equivalent theoretical linear model and is presented also for comparison purposes.

From these results, it arises that the estimation of the values of the parameters is very close to the real values, since the theoretical nonlinear model is very close to those of the experimental results.

Finally, in order to test the reliability of the applied methodology, we examine the full bicycle model (Fork and frame). More specifically, with the use of two electrodynamic shakers imposing base excitation at the wheels locations and measuring the dynamic response in several locations in the frame and suspension substructures in the three directions.

An illustration of the fixed-free arrangement of the bike on the shakers with acceleration measurement locations is presented in Figure 14, while in Figure 13 the finite element model of the whole bike assembly is shown.

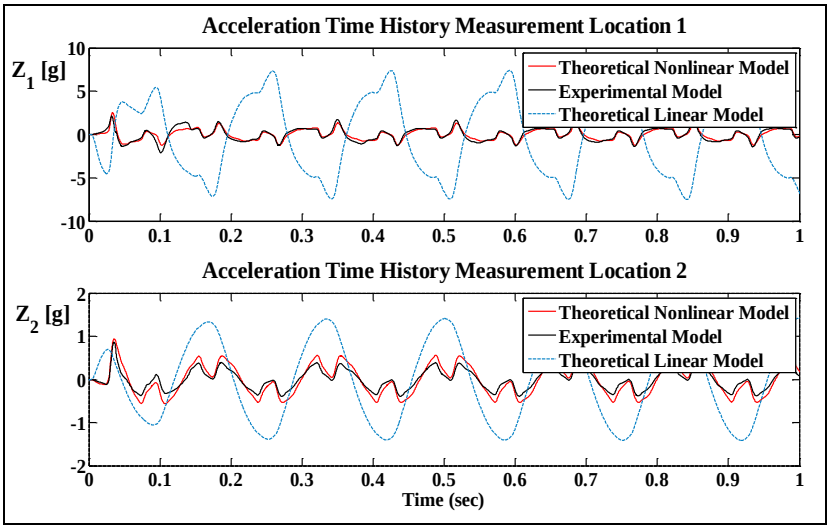

Figure 12: Acceleration time histories at two measured locations in harmonic excitation with frequency $\omega = 6Hz$

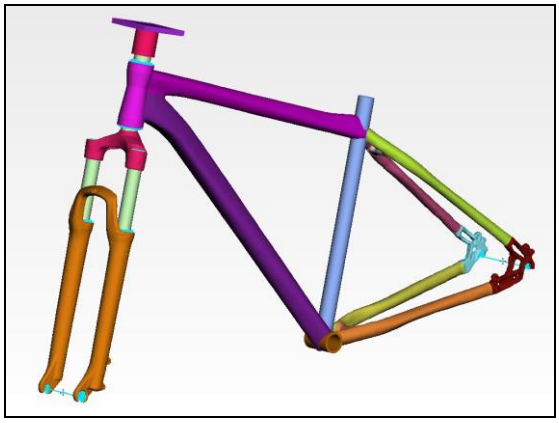

Figure 13: FE model of the bike assembly.

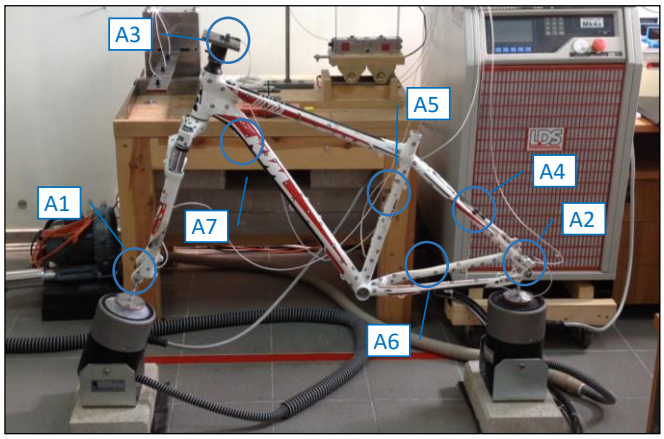

Figure 14: Fixed-free arrangement on electrodynamic shakers

The measured acceleration time histories in the three directions in the locations 1 and 2, were imported as base excitation in the finite element model of the system. In Figure 15, presented a comparison in three measured locations in the vertical direction, between the numerical nonlinear FE model (red line), with the experimental measurements (black line), in harmonic excitation with forcing frequency of $\omega = 6Hz$. The blue line was derived using the equivalent theoretical linear model and is presented again for comparison purposes.

From these results, it arises that the full bicycle theoretical nonlinear FE model is very close to those of the experimental results.

Also, in Figure 16, is shown an indicative point of time, of the dynamic response of the full nonlinear system.

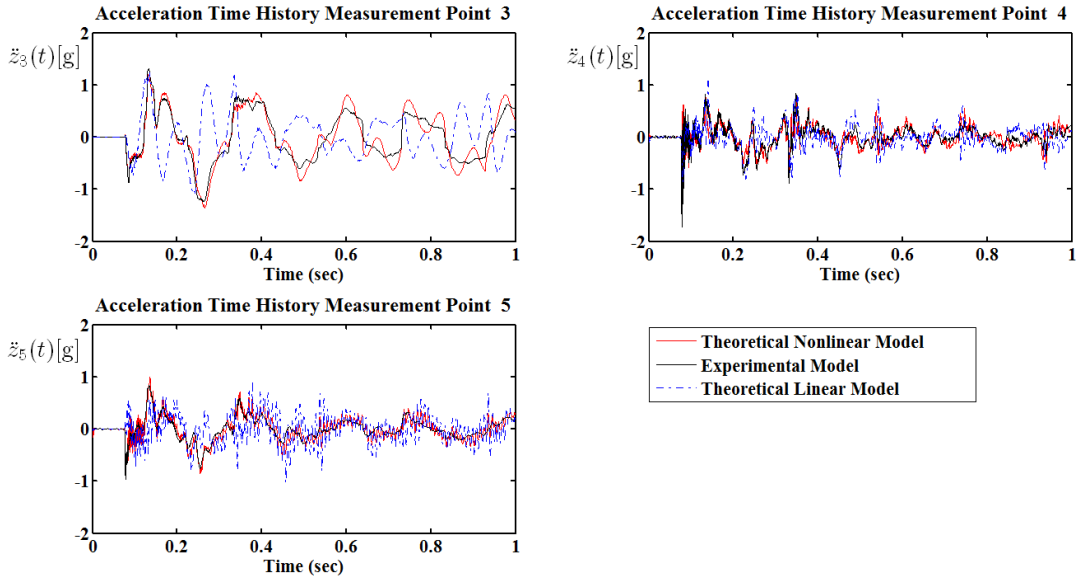

Figure 15: Acceleration time histories at three measured locations in harmonic excitation with frequency $\omega = 6Hz$

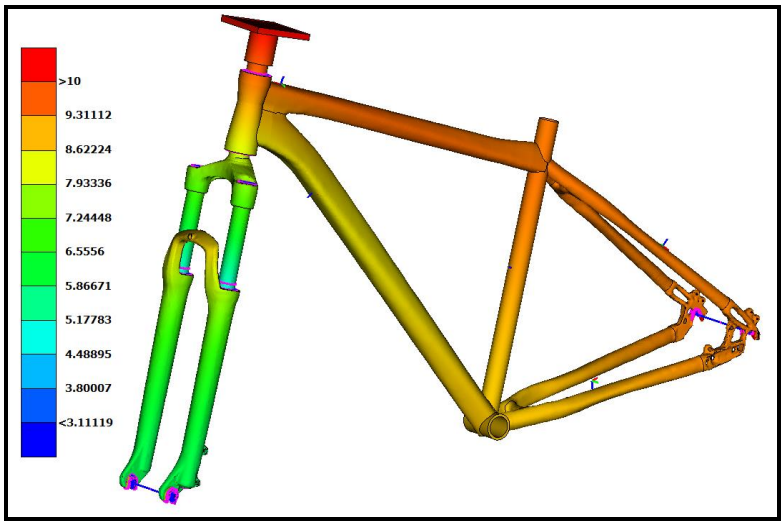

Figure 16: Dynamic response of the nonlinear full FE model in harmonic excitation with frequency $\omega = 6Hz$

6 SUMMARY

A computational framework is presented in order to estimate the optimal values of the linear and nonlinear components of large scale dynamical systems using vibration measurements. An extensible framework for Bayesian Uncertainty Quantification and Propagation of complex and computationally demanding physical models, was connected in an efficient way with a numerical code leading to an automated determination of dynamic response of linear and nonlinear mechanical systems. Numerical and experimental methodologies were applied in order to identify the model parameters and develop a high fidelity finite element model of the structure examined. The applicability and effectiveness of

the methods applied, is explored by updating finite element model of a lightweight and geometrically complex bicycle assembly, using experimentally identified modal data. Direct comparison of the numerical and experimental data verified the reliability and accuracy of the methodology applied.

Keywords: Aircraft Design, Set-Based Design, Surrogate Modelling, Variable-Fidelity Modelling, Krigging

Abstract. *The key to successful application of surrogate modelling is the ability to quickly generate high quality data over a large parameter space. This can be achieved through application of Variable Fidelity Modelling (VFM), which is a data fusion technique that allows data from different sources to be combined. VFM can be used to correct a dataset obtained by a simple and fast method with a small number of high quality samples in order to generate a high-fidelity surrogate at a marginal cost.*

This paper presents the results of a feasibility study of a VFM technique based on Hierarchical Kriging in the context of aerospace applications. A generic process for generation of a high quality surrogate using VFM and assessment of its accuracy is presented and validated for a number of realistic use case scenarios. Investigation of the impact of various parameters of the method is conducted, highlighting the importance of selection of the appropriate data correlation functions.

The potential of VFM to significantly reduce the computational cost required for generation of a high-fidelity surrogate is demonstrated for the case of a parametric study of wing cruise performance used at the early stages of the aircraft design process. In addition, an application where the VFM method is used to predict the effects of wing section optimization is shown. The VFM approach presented in this paper can be implemented in a number of different scenarios and can offer significant improvements for the surrogate generation process by quickly generating high-fidelity response surfaces.

1 INTRODUCTION

Due to the high costs involved, aircraft designers have to ensure that every new aircraft meets the required safety and performance standards long before it enters service. In practice, this is achieved during a long development process, which involves intensive calculations, tests and numerical simulations. Modern design offices make extensive use of computers, simulating almost every aspect of the aircraft system.

In practice, a significant number of important decisions, which have substantial impact on the design of a new aircraft, are taken at the preliminary design stage when the amount of available information is usually small and a large number of possible configuration variants are still considered. In a conventional approach, the so-called Point-Based Design (PBD), a baseline concept is developed at an early design stage and is subsequently modified to achieve a feasibility, and ideally, optimal design during the design process. Usually, this involves a number of iterations during which the aircraft can undergo significant modifications as more information becomes available. This means that a wrong decision taken at the beginning of the project can lead to problems downstream, once more information becomes available.

An alternative approach, using the Set-Based Design (SBD) paradigm, was proposed in the CONGA (Configuration Optimisation for Next Generation Aircraft) programme [1]. In this methodology, a number of designs are developed concurrently and, as more information becomes available, the unfeasible concepts are removed from the set. By keeping the design space open and reducing the number of additional iterations, SBD enables fast convergence on the designs which satisfy all constraints [2].

The main challenge of SBD is the fact that a large amount of data has to be developed at the early stage of the project. This can prove problematic, especially for a novel aircraft configuration, for which the amount of empirical, legacy data is limited. Even despite the continuous improvements in simulation algorithms and speed of computers, performing extensive simulations of large data sets is still not feasible in practice. A promising alternative is the use of surrogates generated from a reduced number of data points to explore the design space. This can considerably reduce the computational costs; however, a large number of simulations may still be necessary.

A further reduction of the effort required to generate an appropriate surrogate can be achieved if a low-fidelity method is used for its construction. This, however, may result in a loss of data quality. The Variable Fidelity Method (VFM) explored in this paper attempts to take advantage of speed offered by application of the low-fidelity methods, without compromising the accuracy of the final surrogate, by correcting it with a limited set of high-fidelity data points.

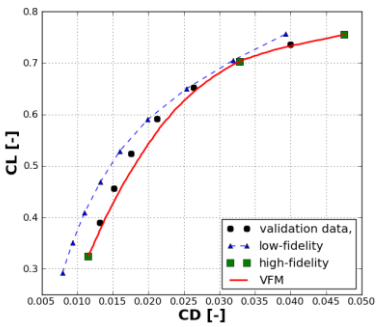

Figure 1: Illustration of the VFM concept.

The concept of VFM is illustrated in Figure 1. In principle, the VFM uses a simple fast method to construct a response surface that characterises the overall trends in the dataset. This is then corrected by a small set of high-fidelity data allowing a high-quality response surface to be obtained at a fraction of the cost required to generate it only from the high-fidelity data.

This paper evaluates the potential applications of VFM in the context of aerodynamic aircraft design. First, the VFM concept developed by DLR [3], which is used in this study, is briefly presented and discussed. This is followed by analysis of the results for four test cases aimed at the investigation of different features of the method. Next, a short discussion on possible application of the VFM approach is given. The paper finishes with short summary and main conclusions.

2 VARIABLE FIDELITY MODELLING

As described in the introduction, the VFM is a data fusion technique that allows the data with different levels of fidelity to be combined in order to generate a high-fidelity surrogate with a limited number of high-fidelity data points. The method discussed in this paper has been introduced in [3] and expanded further in [4]-[6]. This section provides an overview of the technique and outlines the main ideas used.

2.1 Method description

The VFM method discussed in this paper is based on the concept of Hierarchical Kriging (HK). Kriging is a statistical interpolation method introduced by Krige in [7], which models the interpolated variables by a Gaussian process and allows for their prediction based on covariance between the known samples. HK extends this concept to different levels of sample fidelities by adding the next step during which the low-fidelity surrogate is corrected by the high-fidelity data [4].

A low-fidelity surrogate is constructed during the first stage of the HK process. The values predicted by the surrogate can be calculated as:

$$\hat{y}_{lf}(\boldsymbol{x}) = \beta_{0,lf} + \boldsymbol{r}_{lf}^{T}(\boldsymbol{x})\boldsymbol{R}_{lf}^{-1}\left(\boldsymbol{y}_{S,lf} - \beta_{0,lf}\mathbf{1}\right) \tag{1}$$

where $\boldsymbol{y}_{,lf}$ are the low fidelity samples, $\boldsymbol{R}_{lf}$ is the correlation matrix representing the correlation between the available samples, $\boldsymbol{r}_{lf}$ is the correlation vector representing the correlation between the untried point, and the available samples and $\mathbf{1}$ is the identity matrix**.** $\beta_{0,lf}$ is an unknown constant calculated as $\beta_{0,lf} = \left(\mathbf{1}^{T}\boldsymbol{R}_{lf}^{-1}\mathbf{1}\right)^{-1}\mathbf{1}^{T}\boldsymbol{R}_{lf}^{-1}\boldsymbol{y}_{s,lf}$.

The VFM response surface, which corrects the low-fidelity surrogate with high-fidelity samples, is calculated in the second stage of the process. The resulting high-fidelity predictions are evaluated as:

$$\hat{y}(\boldsymbol{x}) = \beta_0\,\hat{y}_{lf}(\boldsymbol{x}) + \boldsymbol{r}^{T}(\boldsymbol{x})\boldsymbol{R}^{-1}(\boldsymbol{y}_S - \beta_0\boldsymbol{F}) \tag{2}$$

where $\boldsymbol{y}_S$ are the high fidelity samples, $F = \left[\hat{y}_{lf}\left(\boldsymbol{x}^{(1)}\right), \ldots, \hat{y}_{lf}\left(\boldsymbol{x}^{(n)}\right)\right]^{T}$, and $\beta_0 = (\boldsymbol{F}^{T}\boldsymbol{R}^{-1}\boldsymbol{F})^{-1}\,\boldsymbol{F}^{T}\boldsymbol{R}^{-1}\boldsymbol{y}_S$ is the scaling factor, indicating the correlation of the low- and high-fidelity functions.

It is quite clear that the generated response surface will strongly depend on the chosen correlation model, that has an impact on both high- and low-fidelity correlation matrices $\boldsymbol{R}$ and

$\boldsymbol{R}_{lf}$ as well as on the correlation vectors $\boldsymbol{r}$ and $\boldsymbol{r}_{lf}$. The most common correlation model is the Gaussian exponential function which can be written as:

$$\boldsymbol{R}(\boldsymbol{\theta}, \boldsymbol{x}, \boldsymbol{x}') = \prod_{k=1}^{m} \exp(-\theta_k |x_k - x_k'|^{p_k}), \qquad 1 < p_k \leq 2 \tag{3}$$

where θ are unknown hyper-parameters which need to be calculated. Different correlation models, such as Gauss correlation function, cubic splines or radial-basis-functions are also available.

Although the scaling factors β can be determined analytically, they depend on the θ hyper-parameters, which are obtained during surrogate construction process by maximum likelihood estimation. This essentially requires optimisation of the hyper-parameter values in a way that leads to minimising the variances in the surrogate. More information on the process can be found in [4].

2.2 Error estimation

One of the main advantages of the applied method is that it provides an estimate for the root mean-square error (RSME), which can be used to assess the quality of the generated surrogate. The RSME estimate can be used not only to evaluate the statistical accuracy of the generated response surface (e.g. max, mean), but also to highlight the surrogate regions with highest uncertainty in the results. This can be applied for adaptive surrogate refinement, as will be shown later.

It has to be noted, however, that the RSME estimate is based on the mathematical formulation and depends on the chosen correlation model, therefore it might not be accurate. In fact, it is generally found that, although it correctly highlights the surrogate regions with least confidence, the prediction is generally too optimistic when compared to true errors [4]. Hence, an additional test is required to validate the accuracy of the obtained response surface.

Different techniques for surrogate error analysis are available. If a sufficient number of high-fidelity data points is available, a cross-validation can be performed. In such a scenario, a subset of high-fidelity data is identified and removed from the set of points used for the generation of the VFM surrogate. The surrogate prediction can be then compared to the available high-fidelity data in order to determine the values of true errors.

Most often, however, the amount of high-fidelity data is so small that it is desirable to use all available data for generation of the surrogate. In those circumstances the so-called "leave-one-out test" [8] can be adopted. The principle of this technique is to generate several variants of the response surface. For each variant a single high-fidelity point is randomly removed and the true error is calculated by comparison of the surrogate prediction with the high-fidelity data. If the true error remains small for all tested variants, the surrogate can be considered as saturated, i.e. sufficiently accurate so that addition of new high-fidelity points will not lead to significant improvement in the quality of the generated response surface.

2.3 VFM process at ARA

This section describes how the VFM procedure, suggested in [6], was implemented at ARA. Figure 2 illustrates various steps of the process. First, Design of Experiment (DoE) techniques are used to define the samples for low- and high-fidelity data used to generate the VFM surrogate. The aim is to ensure that the entire design space is covered with as few data-points as possible. Usually the number of high-fidelity points is between 5-10% of the number of low-fidelity samples.

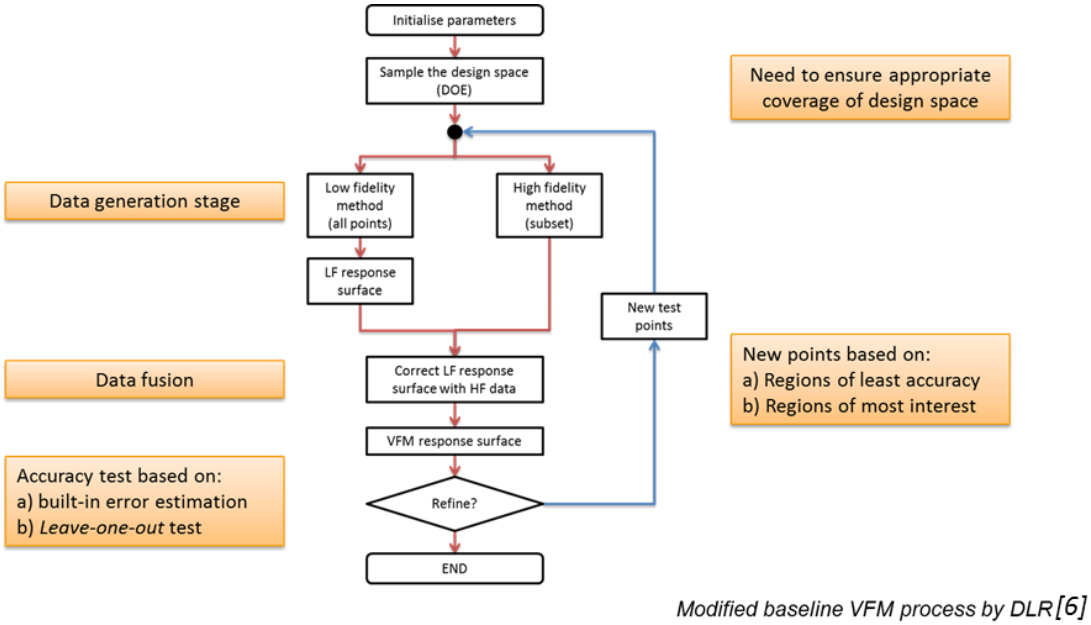

Figure 2: VFM process implemented at ARA.

Next, data for both sets of samples is generated either by simulation or through experiments. In fact, the source of data is irrelevant, as long as the fidelities of different data sets can be easily identified. Once the data are available, a low-fidelity response surface is generated and corrected with the high-fidelity data using the process described above.

The quality of the obtained surface is evaluated based on the VFM RSME prediction. If the estimated accuracy is sufficient, the surrogate is validated using either reference high-fidelity data or by means of the leave-one-out test. If this test is passed as well, the surrogate generation finishes, otherwise additional refinement is performed.

The choice of refinement points depends on the purpose of the generated surrogate, and weighting of errors in different regions of the surrogate. Either way, the new high-fidelity points are generated based on the RSME estimate, usually more than one at a time. Occasionally, if the RSME error prediction is small but the true errors are considerable, additional points can be added based on the true error values. The process concludes once a VFM model of sufficient accuracy is obtained.

3 FEASIBILITY STUDY

This section presents the results of the VFM feasibility study conducted at ARA in order to evaluate potential applications of this technique and offer a better understanding of its limitations. The tests described here focus on VFM applications in the field of aerodynamics and each of them aims at evaluation of a specific feature of the VFM approach.

3.1 Choice of the low-fidelity model

One of the obvious applications of the VFM is to combine the data obtained with methods characterized by different levels of fidelity. In general, the low-fidelity method allows for the results to be obtained quickly, but with a limited level of accuracy. The high-fidelity data, on the other hand, offers a greater accuracy, but requires more effort to be obtained. This test addresses the impact of the choice of the low-fidelity method on the resulting VFM surrogate and how the low-fidelity data affects the required number of high-fidelity correction data points.

The example presented here covers 2D simulations of the flow over a NACA 63_2-215 aerofoil resolved using the BVGK code [9] in two variants:

- low-fidelity – inviscid
- high-fidelity – inviscid with coupled boundary layer

Two scenarios are investigated. First, a lift polar at Mach number $M = 0.5$ is simulated over a linear incidence (α) range from 0 to 5 degrees. Figure 3 shows the lift coefficient as the function of the incidence angle for different levels of fidelity, along with the high-fidelity points used for generation of the VFM. It can be observed that although the low-fidelity data predicts higher values of the lift coefficient Cl, it predicts the same trend as the reference high-fidelity results. A VFM surrogate of a sufficient accuracy is be obtained for all investigated high-fidelity points configurations.

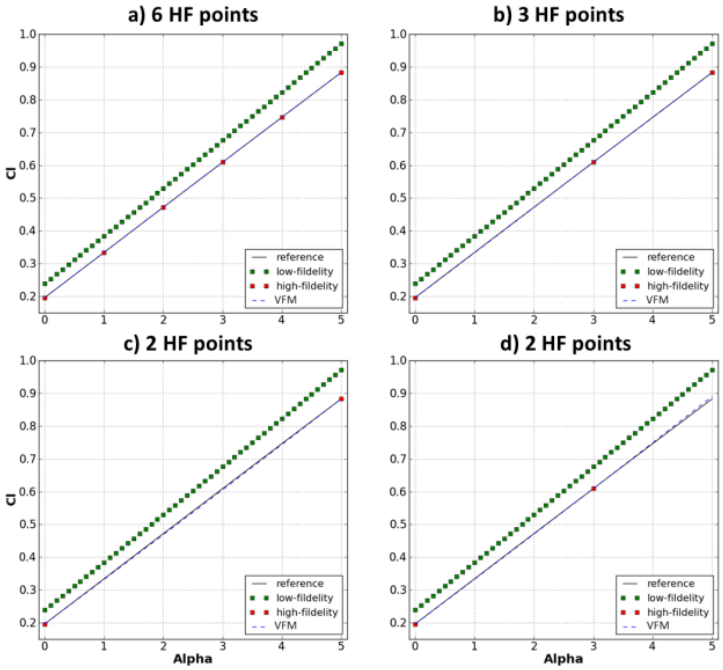

Figure 3: VFM of lift coefficient obtained with different high-fidelity points.

A comparison of error estimation obtained during the VFM generation with the 'true' error calculated as the difference between the lift coefficient predicted by the VFM and the reference high-fidelity data is shown in Figure 4. The figure demonstrates that reducing the number of high-fidelity points used to generate the VFM surrogate leads to higher errors. Also, apart from case (c), with 3 high-fidelity points, the error prediction has a similar behaviour to the 'true' error although they differ in magnitude.

The second scenario considered during this test was an investigation of a drag polar at $M = 0.6$ over a similar incidence range from 0 to 5 degrees. The resulting drag polars along with the used high-fidelity points are illustrated in Figure 5. Again, a sufficient number of high-fidelity points allows for a VFM surrogate of a reasonable quality to be obtained. On the other hand, using 3 high-fidelity points, which was sufficient in the previous scenario, now results in a VFM of a very poor accuracy. This can be explained by inspection of the low-fidelity data behaviour shown in Figure 6a. Since the low-fidelity model is inviscid, the resulting drag coefficient will be zero everywhere, apart from high incidences where wave drag effects are observed. The low-fidelity prediction of the drag coefficient has therefore

a completely different behaviour to the trends observed in the high-fidelity model, thus it actually impacts the VFM surrogate generation in a negative way. In fact, for this scenario, generation of a response surface from high-fidelity points only would result in a better prediction.

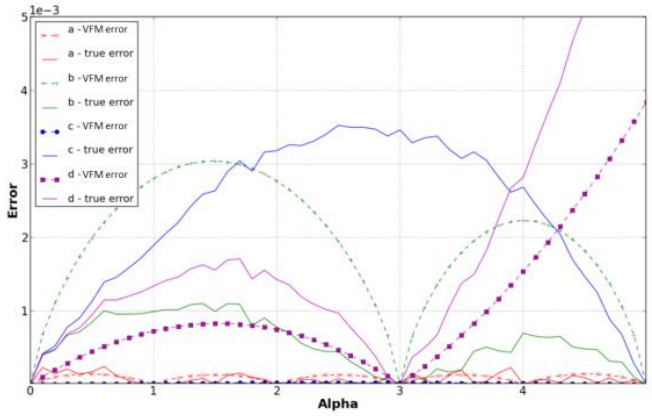

Figure 4: Comparison of errors for the lift coefficient prediction.

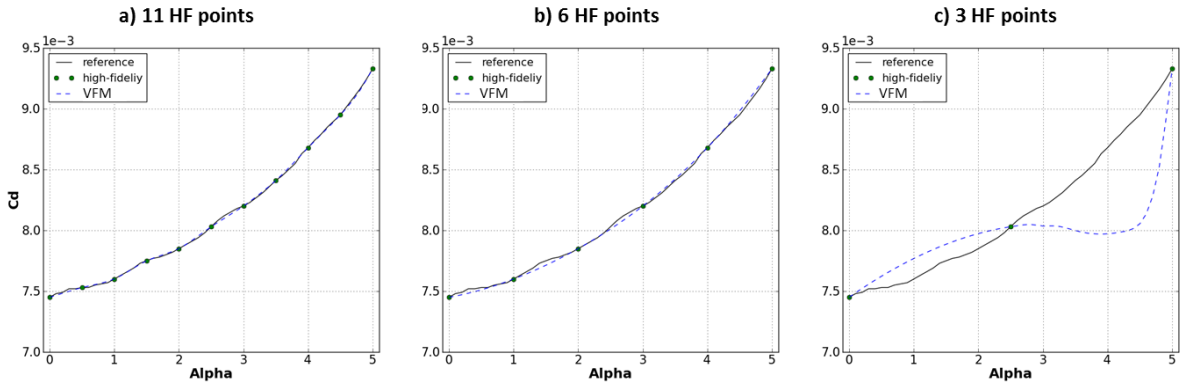

Figure 5: VFM of drag coefficient obtained with different high-fidelity points.

What is encouraging, however, is that the model errors, shown in Figure 6b, illustrate that the built-in VFM error prediction is capable of capturing the poor quality of the generated surrogate and highlighting the areas where improvement is required.

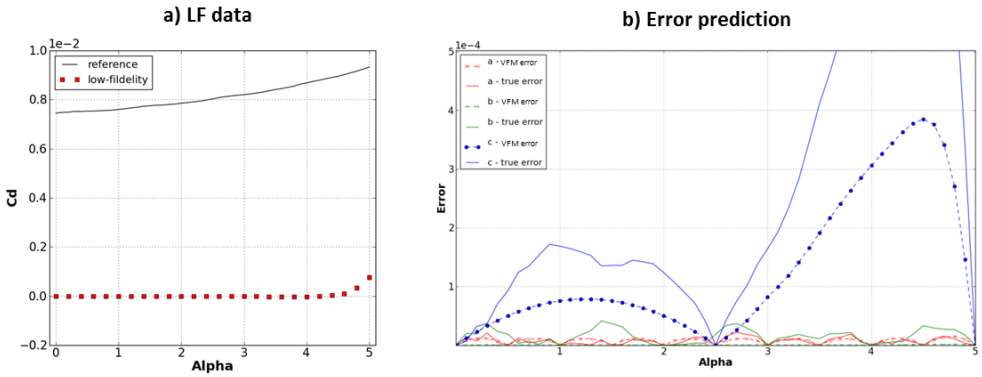

Figure 6: Comparison of errors of lift coefficient predictions.

The main conclusion from this test is that the choice of adequate low-fidelity data is critical to successful application of the VFM. The low-fidelity data should be characterised by a similar behaviour to the trends observed in the high-fidelity model. The second conclusion is that the error estimates obtained using the VFM, although not precisely correct, allow for the assessment of the quality of the surrogate and indicate the parameters for which more high-fidelity information should be provided.

3.2 VFM accuracy and surrogate refinement process

The second feasibility test focused on investigation of the accuracy improvement offered by adoption of the VFM when compared to a response surface generated only from the high-fidelity data points and on the impact of surrogate refinement process on the accuracy of the obtained data.

In this case, the drag coefficient dependency over a range of Mach numbers and incidences for a civil airliner wing was studied. The high-fidelity data was generated from the results of 3D simulations of the wing using the TAU RANS solver [10]. The low-fidelity data was obtained by spanwise integration of the results obtained for 2D simulations of the sections of the investigated wing. The concept of the process is illustrated in Figure 7.

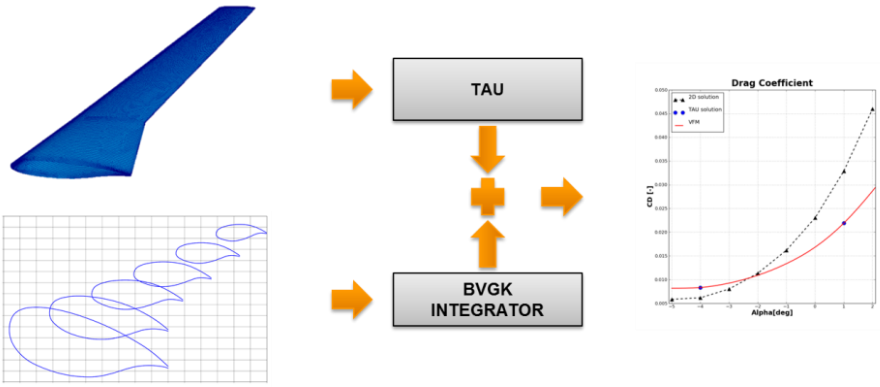

Figure 7: Illustration of the process used for surrogate refinement test.

Figure 8 shows the surrogates of the drag coefficient as a function of incidence angle at various Mach numbers obtained using VFM and by fitting a response surface (RSM) for high-fidelity points only. The initial surrogates were generated with 5 high-fidelity data points obtained by DoE (see highlighted circles in Figure 8a). The surrogates were subsequently refined by addition of new high-fidelity data points in the regions where VFM error prediction indicated the largest values of the relative error (ratio between error and drag coefficient value). The use of relative error was motivated by the fact that, in practice, the low drag coefficient values are of most interest. The surrogates were deemed as saturated, i.e. addition of new high-fidelity points resulted in a little difference in estimated errors, when 19 high-fidelity data points were used. The final surrogates are compared to each other and to the reference data (TAU) in Figure 8b.

The convergence of statistical characteristics (maximum, average, median) of the VFM error estimates is illustrated in Figure 9. A rapid, although non-monotonic, reduction in all statistical values describing the error estimates is observed at the beginning of the refinement process. Change in the relative error remains relatively small when 11 high-fidelity points are used and decreases monotonically when more than 15 points are available. Similar behaviour is observed for the absolute error values, although here, the maximum error remains relatively high.

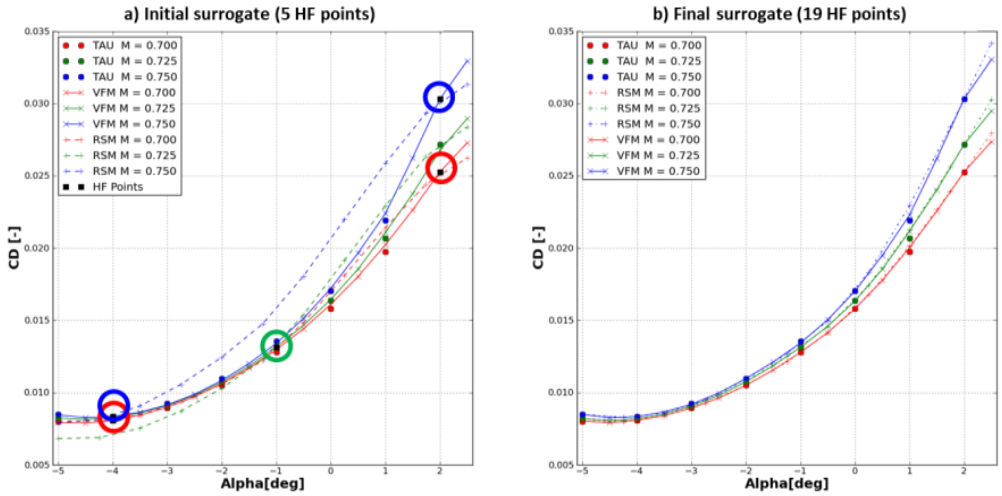

Figure 8: Surrogates of the drag coefficient polars at various Mach numbers obtained using VFM and fitting a response surface (RSM) from high-fidelity points only.

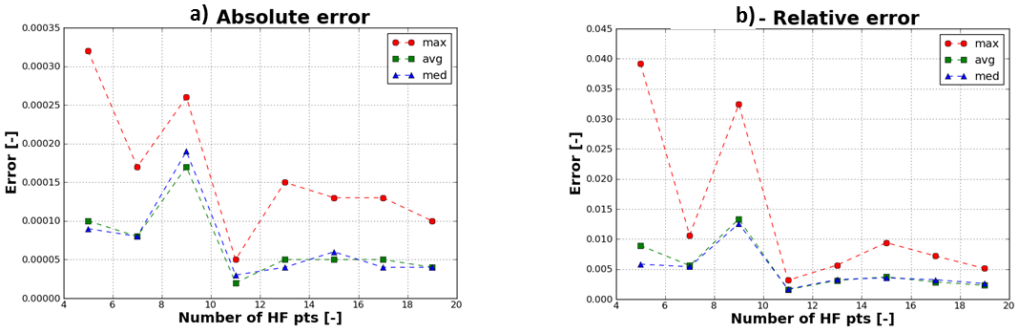

Figure 9: Convergence of the error estimates.

Figure 10: Comparison of absolute and relative error prediction for VFM and RSM.

A comparison of the statistics of the error predictions before and after the refinement process for the VFM and high-fidelity only surrogate (RSM) is shown in Figure 10. Although the error reduction for the RSM is considerably more pronounced, the RSM prediction remains

inferior to the VFM. Moreover, the VFM surrogate obtained with 5 high-fidelity data points offers similar accuracy as the refined RSM both in terms of absolute and relative errors. The refinement process, driven by the requirement to minimise the maximum relative error, allowed both the maximum absolute error and maximum relative error to be reduced by a factor of 3. In general the improvement in relative errors is stronger than for absolute errors.

High-fidelity solutions for a number of additional points, not used for surrogate refinement, were obtained for an additional validation stage. This allowed for the real errors, i.e. the difference between VFM prediction of the drag coefficient and the actual simulated value, to be calculated. The results of this validation for the initial and saturated surrogates are demonstrated in Figure 11.

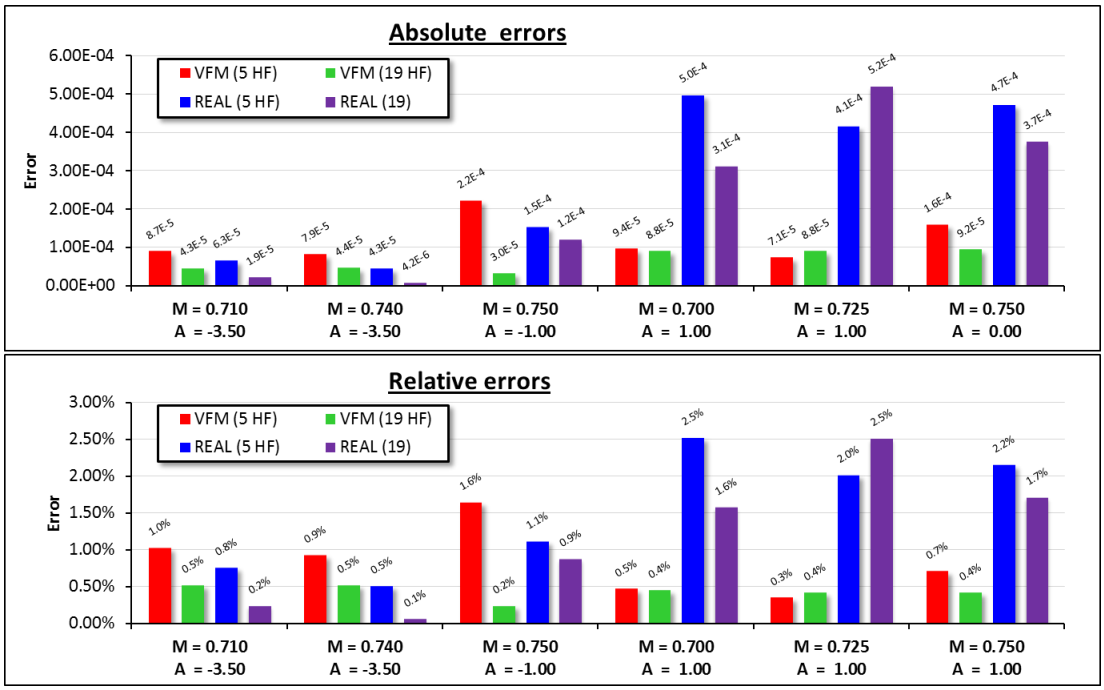

Figure 11: Comparison of the VFM error estimates and the actual prediction errors.

Both absolute and relative errors remain small for the low drag coefficient values, but the real errors are considerably larger in the high incidence range. Although in general, the surrogate refinement led to reduction of both estimated and actual errors, in some cases, i.e. $M = 0.725$ and $A = 1.0$, the errors have increased. No direct correlation between the errors predicted by the VFM and the actual errors can be identified. Nevertheless, the same trends can be observed, i.e. reduction in error estimate corresponds to the reduction of the actual inaccuracy of the prediction.

This test clearly demonstrates that given an appropriate low-fidelity model, VFM can be used to generate a surrogate of a superior quality to a response surface generated from high-fidelity data only. In practice, this means that by adopting the VFM technique the number of required high-fidelity data points can be significantly reduced or the quality of the surrogate can be improved.

The analysis of the error estimates shows how it can be used to drive the refinement process in the desired way (local vs. global, absolute vs. relative). Although the error estimates generally give a reasonable prediction of the surrogate accuracy, additional tests, using high-fidelity data, are required in order to ensure the quality of the obtained response surface.

3.3 Time benefits enabled by application of VFM

One of the main motivations for application of the VFM technique is to enable generation of a high-quality surrogate at a fraction of the cost required to generate the same surrogate based only on high-fidelity points. One of the main ARA requirements in the CONGA project was to construct a dataset with wing cruise performance (lift and drag coefficients) for a wing family with varying planform areas and spans at a range of incidences (see Figure 12 for illustration).

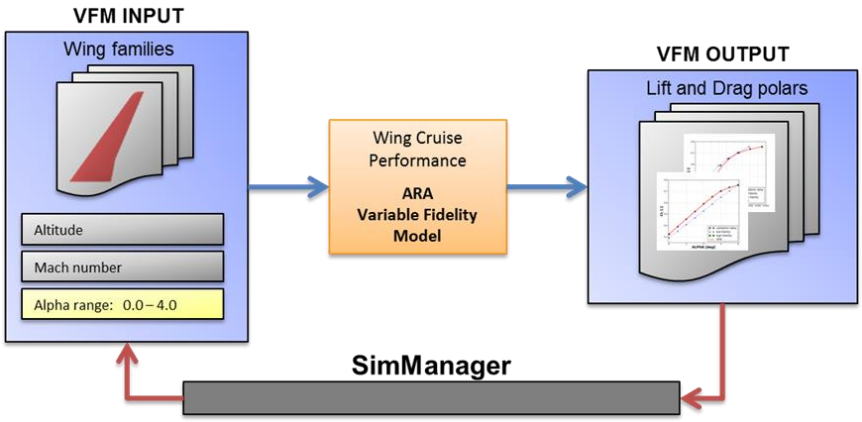

Figure 12: Illustration of the process adopted in CONGA project.

The required dataset was constructed from 108 points over a three-dimensional design space with 3 values of span, 4 values of wing surface area and 9 incidences. The low-fidelity data was computed with the Viscous Full-Potential method (VFP) [11], whereas the high-fidelity results were extracted from the results of TAU simulations. A surrogate refinement process, similar to the one described in previous section was adopted, with lift coefficient surrogate refinement driven by reduction of absolute error estimates, and drag coefficient surrogate driven by the relative error reduction. The leave-one-out test has been applied to ensure a sufficient quality of the obtained surrogates. The final VFM surrogate was constructed from 108 low-fidelity points and 20 high-fidelity results.

On average, 15 minutes were required to generate a single data point with VFP compared to 4 hours on a 20-core cluster needed for a single TAU solution. A comparison of the time needed to generate the VFM surrogate with the time required for 108 TAU simulations is shown in Figure 13. Application of VFM allowed the surrogate of appropriate quality to be obtained in 25% of the time necessary to simulate all 108 data points. In theory, it could be possible to construct a surrogate from a smaller number of high-fidelity data points, but, as already demonstrated in the previous example, it is unlikely that it would have similar quality and would still require significant computational effort.

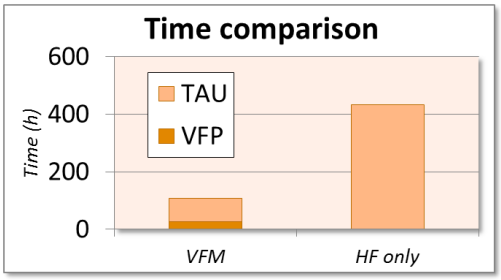

Figure 13: Comparison of the time required to generate the final data set.

This test case clearly demonstrates the time benefits of the application of the VFM technique. Generation of a surrogate has an additional advantage in that it can be used to examine the drag and lift coefficients at intermediate values of the design parameters, at virtually no cost, since the generated VFM response surface is continuous. Moreover, it is easily possible to extend the surrogate by increasing the range of parameters or by addition of new dimensions.

3.4 Impact of the correlation function

The final test presented in this paper investigates the impact of one of the most important parameters of the VFM technique, i.e. the choice of correlation function used to generate the response surface.

In order to assess the impact of the correlation function, surrogates with dependence of the aerofoil performance (L/D) on its thickness-to-chord ration (t/c) are analysed. Unlike in the previous examples, where two different methods were used to generate the solutions, here both low- and high-fidelity data are generated using the same 2D solver – BVGK. The difference in the level of data fidelity is attributed to the different means of obtaining the geometry. The high-fidelity data consists of 3 aerofoils of different thicknesses designed for optimum performance, while the low-fidelity geometries are generated by scaling the baseline section thickness while maintaining a fixed camber line (see Figure 14 for illustration).

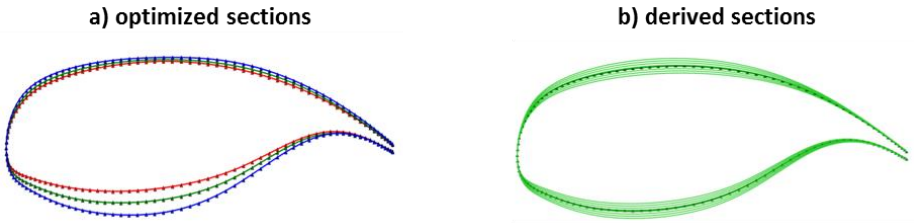

Figure 14: Sections used for generation of VFM surrogate.

This exercise is motivated by the fact that it is not normally possible, due to the time constraints, to optimise sections during the preliminary aircraft design stage. In fact, the wing sections probably do not exist at this point in time and even if some legacy data are available, this might not be suitable for the new aircraft model. Still, ability to predict the potential optimum aerodynamic performance would allow realistic performance targets to be set when sizing the aircraft, without actually performing the time and resource intensive optimisation.

The VFM surrogates generated with two different correlation functions, i.e. Gaussian Exponential function (GEXP) and Multi-Quadratic (MQ) Radial Basis Function (RBD), are shown in Figure 15. Both surrogates use the same low-fidelity data – performance (L/D) characteristics of the varying thickness sections are derived from the optimised baseline aerofoil. Two high-fidelity data points, corresponding to the baseline and thick sections, are used in both scenarios. The thin optimised aerofoil is used as a reference point for validation.

The data presented in Figure 15 highlight significant differences not only in the obtained VFM surrogates but also differences in the low-fidelity response surfaces constructed during the process. While the GEXP low-fidelity response surface closely follows the supplied data points, the MQ surface is smoother and follows the general trend rather than the actual data. Similar behaviour is observed for the generated VFM surrogates, i.e. in the extrapolation region the GEXP surrogate follows the low-fidelity data, whereas the MQ extends the original data trend. The magnitude of estimated errors is also smaller for the case of the MQ correlation function.

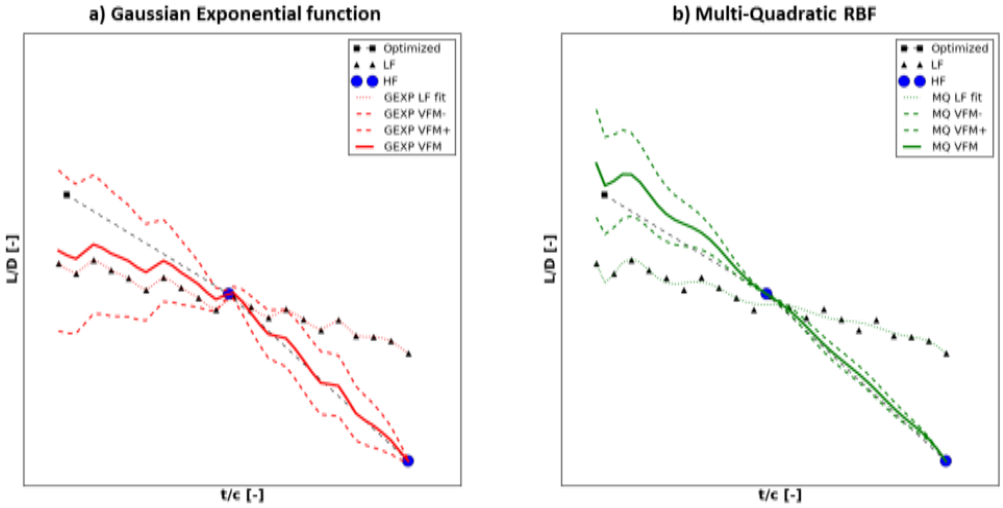

Figure 15: Comparison of the VFM surrogates obtained with different correlation functions.

The results presented for this test case show the importance of the choice of an appropriate correlation function. If the input data is characterised by a high level of noise it is beneficial to use RFB-based correlation functions, as they allow for a smooth surrogate to be generated. On the other hand, GEXP is more localised, so it is a more appropriate choice for data where the general behaviour is not necessarily smooth and local effects need to be considered. In all cases, however, care needs to be taken when extrapolating the data beyond the available high-fidelity data boundaries.

4 POSSIBLE APPLICATIONS OF VFM

The VFM technique has a range of possible applications in the context of modern aircraft design. This section attempts to summarise the various ways in which this method can be adopted. It is suggested to divide the range of possible VFM applications into two main groups, namely data fusion and local surrogate refinement.

The objective of data fusion is to combine two or more datasets with different level of fidelity into a single high-quality response surface. As demonstrated in previous sections, using the VFM not only offers significant reduction of the time needed to generate high quality surrogates from sparse datasets, but also allows for efficient assessment of the surrogate accuracy.

Below is a non-exhaustive list of possible scenarios for data fusion:

- Correcting low-fidelity code with high-fidelity code (e.g. EULER + RANS)
- Correcting partially converged CFD results with fully converged ones
- Combining results with different mesh refinement levels
- Combining wind tunnel data with CFD data
- Correcting CFD for aeroelasticity effects
- Combining results with different levels of geometry maturity

An alternative application of the VFM is to locally refine the surrogate during the optimisation process. Combined with an optimisation algorithm, VFM can be applied to find function minima efficiently (see Figure 16 for illustration). In such a case, the design space is

explored with the low-fidelity response surface, while high-fidelity results are used for local refinement of the surrogate. An example process is described below:

1. Find the function minimum with the low-fidelity response surface
2. Run the high-fidelity code on the optimum point
3. Generate the VFM surrogate with the addition of high-fidelity data
4. Use the VFM as response surface in step 1

It is believed that the approach presented above could significantly reduce the time required for optimisation, as only a few high-fidelity simulations would be necessary.

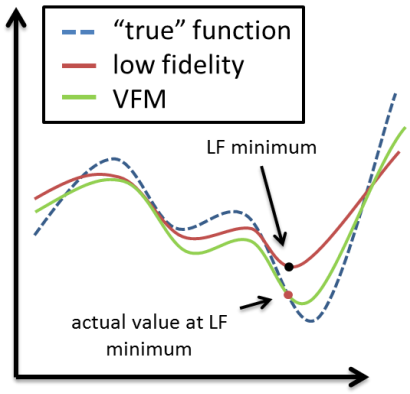

Figure 16: Illustration of VFM used for optimisation.

5 CONCLUSIONS

This paper explored the applicability of using the Variable Fidelity Modelling (VFM) in the context of aerodynamic analysis of modern aircraft designs. The VFM can be used for rapid generation of high-quality surrogate models by combining the results obtained from a low-fidelity method with a limited number of high-fidelity data points. By reducing the number of high-fidelity points required for generation of the surrogate, VFM enables the overall cost of creating the response surface to be significantly reduced.

A wide range of possible applications has been identified, which include, but are not limited to, combining results from simulations at different levels of fidelity, using different levels of input fidelities, as well as using the method to increase efficiency during an optimisation process. The studied examples have clearly demonstrated that applying VFM can offer significant time reduction without loss of surrogate quality, or can be applied to enhance the quality of an existing dataset.

Examination of the presented test cases allowed for the best practice for VFM application to be developed:

- The quality of VFM strongly depends on the trends observed in low-fidelity data
- VFM results are sensitive to the chosen correlation function. Gaussian Exponential Function is generally more robust, however Multi-Quadratic Radial Basis Function can be used to obtain smooth data and is more suitable for extrapolation

- The error estimates returned by the VFM can be used to indicate the error magnitudes and areas of poor surrogate quality, however, they do not offer accurate error values
- The best practice for surrogate construction is to drive the refinement process using the built-in error estimator and use additional techniques (e.g. leave-one-out test) for results verification

Keywords: Path integration method, nonlinear ship rolling, stochastic response.

Abstract. *In this paper, the Markov theory is introduced in order to model the roll motion excited by random wave excitation. Specifically, a four-dimensional (4D) Markov dynamic system is established by combing the single-degree-of-freedom (SDOF) model used to represent the ship rolling behavior in random beam seas with a second-order linear filter used to approximate the stationary wave excitation moment. Based on the Markov property of the 4D coupled dynamic system, a 4D path integration (PI) method is applied in order to solve the Fokker-Planck equation, which governs the probabilistic properties of the coupled dynamic system. The theoretical principle and numerical implementation of the current state of the art 4D PI method are presented. Furthermore, the numerical robustness and accuracy of the 4D PI method are evaluated by means of the versatile Monte Carlo simulation (MCS) technique.*

1 INTRODUCTION

The challenge to calculate the response statistics of nonlinear, marine structures subjected to a random seaway is still substantial. In this work, the rolling behavior of a vessel in random beam seas is to be studied since the associated high-level responses with low probability levels are important for reliability based ship design and operation in practice.

For the cases of beam seas, the roll motion is assumed to be decoupled from other motions and governed by a single-degree-of-freedom (SDOF) equation [1], which is also a second order differential equation. In the SDOF model, the nonlinearities associated with damping and restoring terms as well as the randomness of the wave excitation term are all incorporated.

Various probabilistic approaches have been proposed to analyze the stochastic response of the roll motion in random seas [2-4]. Among these strategies, the methodology based on the Markov diffusion theory is attractive because the probabilistic properties of the roll motion is governed by the Fokker-Planck (FP) equation. In order to build a Markov system for describing the random roll motion, a second order linear filter is applied in order to approximate the stationary wave excitation moment as a filtered white noise. Subsequently, a four-dimensional (4D) coupled system is generated but the corresponding high-dimensional FP equation leads to another challenge.

Analytical solutions of the FP equations are only available for some linear systems and a very limited class if nonlinear systems. Direct numerical methods aiming to solve the low-dimensional FP equations, such as the finite element method [5] and the finite difference method [6], are hardly feasible because for the high-dimensional FP equations. In this regard, the so-called "curse of dimension" problem comes into play, which means that difficulties arise due to the processing capacity as well as the storage needed for the computation increases dramatically with the dimension of the FP equation.

The path integration (PI) method is an efficient approximation for solving the FP equation and providing the stationary or non-stationary response probability density function (PDF) of the dynamic system [7-9]. The evolution of the response PDF is computed in short time steps via a step-by-step solution technique. Specifically, the based on the Chapman-Kolmogorov equation, the response PDF at a given time instant can be obtained when the response PDF at an earlier close time as well as the conditional PDF are already known. In this work, a 4D PI procedure is developed to address the challenge of determining the response statistics of the roll motion in random beam seas. The feasibility and reliability of the PI technique will be demonstrated by comparing with the Monte Carlo simulation.

2 MATHEMATICAL MODEL

When the ship is excited by beam wave loads, the roll motion is described by the following SDOF equation [10]:

$$\ddot{\theta}(t)+b_{44}\dot{\theta}(t)+b_{44q}\dot{\theta}(t)\,|\,\dot{\theta}(t)\,|+c_1\theta(t)-c_3\theta^3(t)=m(t) \tag{1}$$

where $\theta(t)$ and $\dot{\theta}(t)$ are the roll angle and the roll velocity, respectively. b_{44} and b_{44q} are the relative linear and quadratic damping coefficients, c_1 and c_3 are the relative linear and nonlinear roll restoring coefficients. m(t) is the relative roll excitation moment, it is a stationary Gaussian process and described by the spectrum $S_{mm}(\omega)$. The SDOF model (1) can be transformed into the following state-space equation which is written as:

$$\begin{cases} dx_1 = x_2 dt \\ dx_2 = (-b_{44}x_2 - b_{44q}x_2\,|\,x_2\,| - c_1x_1 + c_3x_1^3 + x_3)dt \end{cases} \tag{2}$$

where $x_1=\theta(t)$, $x_2=\dot{\theta}(t)$ and $x_3=m(t)$ is the driving process for the dynamic system (2).

The linear filter technique is widely used in the engineering community due to its simplicity and practicality. The driving process $m(t)$ is a stationary Gaussian process with appropriate spectral density, it can approximated quite satisfactorily by a suitable linear filter. In this work, a second-order linear is applied in order to approximate the desired spectrum, $S_{mm}(\omega)$.

The second-order linear filter is expressed by the following differential equation:

$$\begin{cases} dx_3 = (x_4 - \beta x_3)dt + \gamma dW \\ dx_4 = -\alpha x_3 dt \end{cases} \tag{3}$$

where x_3 and x_4 are the state variables in the filter equation with x_3 representing the output $m(t)$. $dW(t)=W(t+dt)-W(t)$ represents an infinitesimal increment of a standard Wiener process with $E\{dW(t)\}=0$ and $E\{dW(t)dW(s)\}=0$ for $t \neq s$ and $E\{dW(t)^2\}=0$. The spectrum generated by the second-order linear filter (3) is denoted as $S_{Filter}(\omega)$ and given as:

$$S_{Filter}(\omega)=\frac{1}{2\pi}\frac{\gamma^2\omega^2}{(\alpha-\omega^2)^2+(\beta\omega)^2} \tag{4}$$

where α, β, γ are the parameters of the linear filter and they are determined by minimizing the least square error between the spectral density of the filtered spectrum $S_{Filter}(\omega)$ and the spectral density of the target spectrum, $S_{mm}(\omega)$. It is worth emphasizing that the filtered spectrum (4) is double-sided, while the relative roll excitation spectrum $S_{mm}(\omega)$ is physically single-sided. This difference needs to be reflected when performing the simulation itself.

By combining the equation (2) with equation (3), the extended dynamic system is formed. Therefore, the roll motion in random beam seas can be described by the following 4D state space equation:

$$\begin{cases} dx_1 = x_2 dt \\ dx_2 = (-b_{44}x_2 - b_{44q}x_2 \mid x_2 \mid -c_1x_1 + c_3x_1^3 + x_3)dt \\ dx_3 = (x_4 - \beta x_3)dt + \gamma dW \\ dx_4 = -\alpha x_3 dt \end{cases} \tag{5}$$

3 4D PATH INTEGRATION METHOD

3.1 Main principle

The dynamic system represented by equation (5) is a Markov diffusion process and it can be expressed as the following stochastic differential equation:

$$d\mathbf{x} = \mathbf{a}(\mathbf{x},t)dt + \mathbf{b}(t)d\mathbf{W}(t) \tag{6}$$

where $\mathbf{x}(t)=(x_1(t),\ldots, x_4(t))^T$ is a 4D state space vector process, the vector $\mathbf{a}(\mathbf{x},t)$ is the drift term and $\mathbf{b}(t)d\mathrm{W}(t)$ represents the diffusive term. The vector $d\mathbf{W}(t)=\mathbf{W}(t+dt)-\mathbf{W}(t)$ denotes independent increments of a standard Wiener process.

For the Markov process $\mathbf{x}(t)$, its transition probability density, $p(\mathbf{x},t|\mathbf{x}',t')$, also known as the conditional PDF is governed by the FP equation, which is expressed as:

$$\frac{\partial}{\partial t}p(\mathbf{x},t\mid\mathbf{x}',t') = -\sum_{i=1}^{4}\frac{\partial}{\partial x_i}a_i(\mathbf{x},t)\,p(\mathbf{x},t\mid\mathbf{x}',t') + \frac{1}{2}\sum_{i=1}^{4}\sum_{j=1}^{4}\frac{\partial^2}{\partial x_i\partial x_j}(b(t)\cdot b^T(t))_{ij}\,p(\mathbf{x},t\mid\mathbf{x}',t') \tag{7}$$

where $\mathbf{x}'$ denotes the state space vector at time t' and $t'< t$.

For numerical solution of the time continuous stochastic differential equation (SDE) (6), discretization of the equation with respect to time t is essential. In this regard, Naess and Moe propose a fourth-order Runge-Kutta-Maruyama approximation:

$$\mathbf{x}(t) = \mathbf{x}(t') + \mathbf{r}(\mathbf{x}(t'), t')\Delta t + b(t')\Delta \mathbf{W}(t') \tag{8}$$

where $\Delta t = t - t'$ is the time increment and the vector $\mathbf{r}(\mathbf{x}(t'), t')$ denotes the explicit fourth-order Runge-Kutta (RK4) increment or RK4 approximation. Since $\mathbf{W}(t)$ is a Wiener process, for short time increment Δt, the independent increment $\Delta\mathbf{W}(t') = \mathbf{W}(t) - \mathbf{W}(t')$ is a Gaussian variable for every t' (a constant is considered to be a Gaussian variable with zero standard deviation).

With the introduction of the time discrete approximation, the time sequence $\{\mathbf{x}(i \cdot \Delta t)\}_{i=0}^{\infty}$ is a Markov chain and it can approximate the time-continuous Markov solution of the SDE (6) with satisfactory accuracy when the time increment Δt is sufficiently small [8].

For a time increment $\Delta t = t - t'$, the transition probability density of equation (8), $p(\mathbf{x}, t | \mathbf{x}', t')$, is given as a (degenerate) Gaussian distribution, which is written as:

$$\begin{aligned} p(\mathbf{x}, t \mid \mathbf{x}', t') = {} & \delta(x_1 - x_1' - r_1(\mathbf{x}', t', \Delta t)) \cdot \delta(x_2 - x_2' - r_2(\mathbf{x}', t', \Delta t)) \\ & \cdot \tilde{p}(x_3, t \mid x_3', t') \cdot \delta(x_4 - x_4' - r_4(\mathbf{x}', t', \Delta t)) \end{aligned} \tag{9}$$

where $\tilde{p}(x_3, t \mid x_3', t')$ is given by the relation:

$$\tilde{p}(x_3, t \mid x_3', t') = \frac{1}{\sqrt{2\pi\gamma^2 \Delta t}} \cdot \exp\left\{ -\frac{(x_3 - x_3' - r_3(\mathbf{x}', t', \Delta t))^2}{2\gamma^2 \Delta t} \right\} \tag{10}$$

in which $r_i(\mathbf{x}', t', \Delta t) = r_i(\mathbf{x}(t'), t', \Delta t)$, $i = 1,2,3,4$ are the Runge-Kutta increments for the state space variables.

For the PI method, the evolution of the response statistics, such as the PDF of the random process $\mathbf{x}$ at time t can be obtained by the following basic equation:

$$p(\mathbf{x}, t) = \int_{R^4} p(\mathbf{x}, t \mid \mathbf{x}', t') p(\mathbf{x}', t') d\mathbf{x}' \tag{11}$$

where $d\mathbf{x}' = \prod_{i=1}^{4} dx_i'$.

Since the expression for the transition probability density is obtained (i.e., the equations (9) and (10)), the PDF of $\mathbf{x}(t)$ can be obtained by the following iterative algorithm if an initial PDF (i.e. at time t_0) is given:

$$p(\mathbf{x}, t) = \int_{R^4} \cdots \int_{R^4} \prod_{s=1}^{n} p(\mathbf{x}^{(s)}, t_s \mid \mathbf{x}^{(s-1)}, t_{s-1}) \cdot p(\mathbf{x}^{(0)}, t_0) d\mathbf{x}^{(0)} \ldots d\mathbf{x}^{(n-1)} \tag{12}$$

where $\mathbf{x} = \mathbf{x}^{(n)} = \mathbf{x}(t_n)$, $t = t_n = t_0 + n \cdot \Delta t$, $\mathbf{x}^{(s)} = \mathbf{x}(t_s)$ and $t_s = t_0 + s \cdot \Delta t$.

3.2 Numerical implementation

Equation (12) describes the mathematical principle of the PI approach. For numerical implementation of the 4D PI method, a reasonable computational domain and the corresponding computational grid have to be determined at first. In this work, the initial PDF $p(\mathbf{x}^{(0)}, t_0)$ is chosen as a 4D Gaussian PDF in four dimensions with zero mean and variances evaluated by a simple Monte Carlo simulation [8]. The straightforward Monte Carlo simulation (MCS) ensures that the initial 4D Gaussian PDF includes all the information corresponding to the selected parameters of the dynamic system, and it also provides a rational computational domain and computational grid for the subsequent simulation.

As for the numerical implementation of the iterative algorithm (12) for each grid point, it represents the PDF at the previous time t' as an interpolating spline surface via Parabolic B-spline. Then, the RK4 approximation scheme is applied to calculate the deterministic trajectories backwards for each grid point. Therefore, each grid point at time t is mapped backwards with the corresponding starting point at the previous time t' and the PDF values at the backward-mapped points, i.e. the starting points, can be given by using the spline surface. Finally, the PDF at time t, i.e. the new PDF, is calculated by substituting the transition probability density given in terms of equations (9) and (10) into the integral equation (11). The flowchart of the numerical implementation of the 4D PI method with the iterative algorithm described above is shown in Figure 1.

4 NUMERICAL RESULTS

In this Section, an ocean surveillance ship is selected in order to study the stochastic roll response. The parameters for this parameters are given in Ref. [11]. The relative roll excitation moment spectrum $S_{mm}(\omega)$ for a given sea state [10] is presented in Figure 2.

As mentioned above, the parameters α, β, γ in the second-order filter (4) are determined by minimizing the square errors between the filtered spectrum and the target spectrum, S_{mm}. It can be readily seen that the filtered spectrum is reasonable in terms of bandwidth, peak frequency and peak value. However, there is a slight discrepancy between the two spectra in the critical region near the natural roll frequency ω_0. This discrepancy should not be neglected since the distribution of high level response is sensitive to the variation of the external excitation in this frequency region [12]. Therefore, a constant, c, should be introduced as a correc-

tion factor for the filtered spectrum in order to decrease the discrepancy in the critical frequency region. The filtered spectrum (4) can then be changed into:

$$S_{Filter}(\omega)=\frac{1}{2\pi}\frac{(c\cdot\gamma)^2\omega^2}{(\alpha-\omega^2)^2+(\beta\omega)^2} \tag{13}$$

and the corrected (or modified) spectrum in the critical region is also presented in Figure 2.

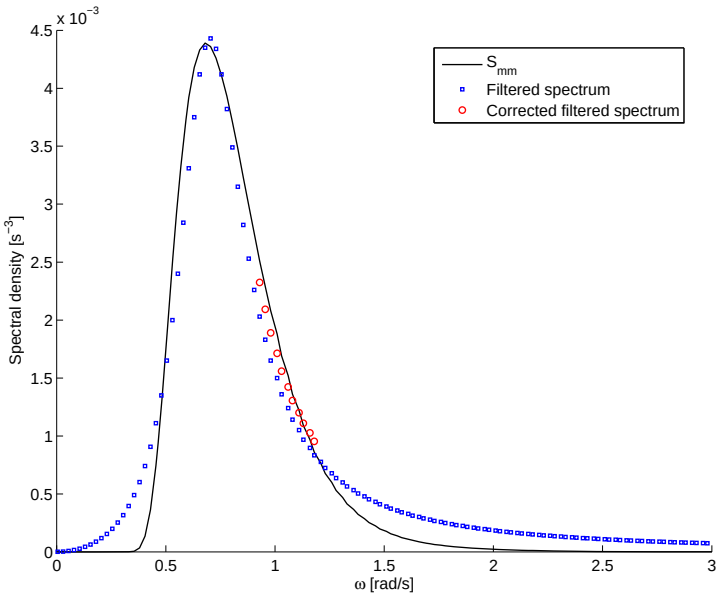

Figure 2: Relative roll excitation moment spectrum and the filtered spectrum, the corrected filtered spectrum (part) for a given sea state.

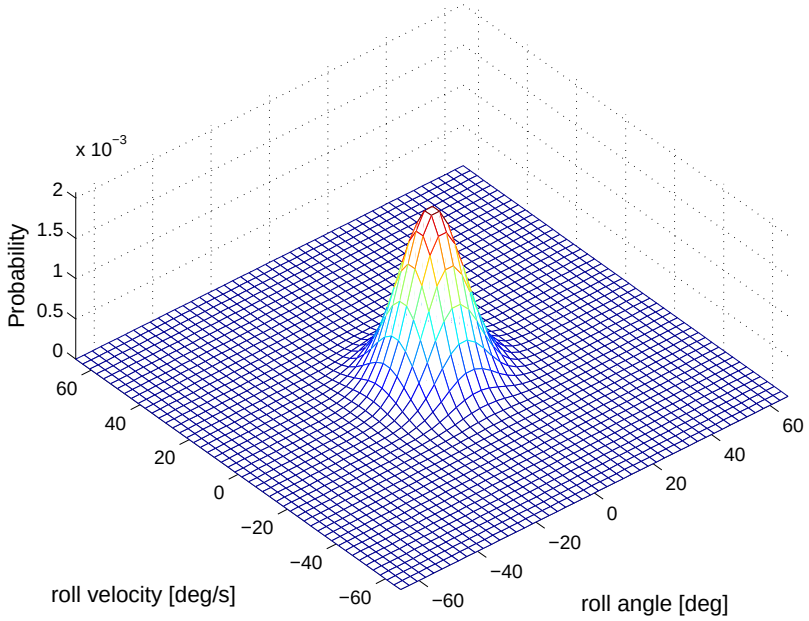

Figure 3: Joint PDF of the roll response obtained by the 4D PI method.

As mentioned in Section 3, the joint PDF of the roll angle process and the roll velocity process can be obtained directly by the 4D PI method. The joint PDF of the roll response yielded by the 4D PI method for the selected sea state is presented in Figure 3 and the mar-

ginal PDFs of the roll angle process and the roll velocity process are shown in Figure 4 and Figure 5, respectively.

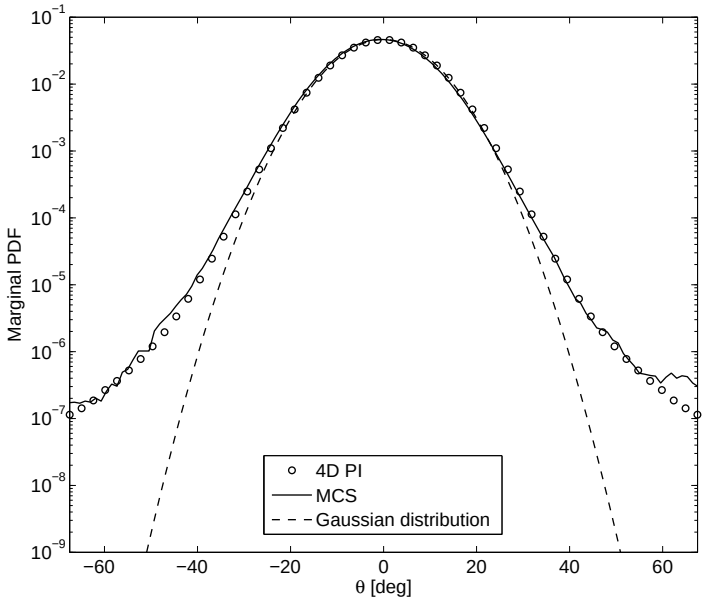

Figure 4: Marginal PDF of the roll angle process.

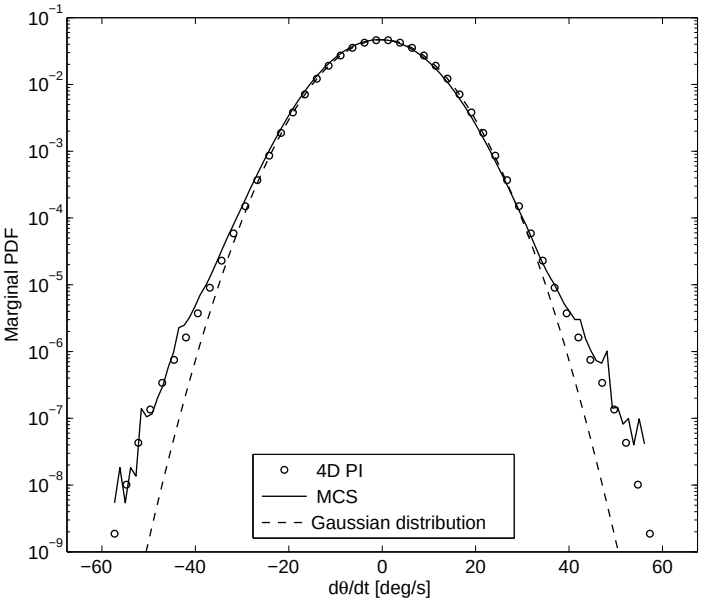

Figure 5: Marginal PDF of the roll velocity process.

In Figures 4 and 5, it is observed that the comparisons of the marginal PDFs obtained by the 4D PI method and the corresponding empirical estimations obtained by MCS demonstrate the high-level accuracy of the 4D PI method. Furthermore, the 4D PI method provides nice results for the low probabilities, but the distribution obtained by MCS are suffering from uncertainties. The Gaussian distributions of the marginal PDFs in Figures 4 and 5 are obtained by using the variances evaluated by the straightforward MCS technique mentioned in Section 3. Actually, they are the marginal PDFs of the 4D Gaussian PDF, $p(\mathbf{x}^{(0)}, t_0)$, which serves as the initial PDF in the 4D PI procedure. It is shown that the Gaussian distributions in Figures 4 and 5 provide reasonable approximations of the statistics of small amplitude roll motions.

However, for the high-level responses, the distributions of the roll angle process and the roll velocity process are very different from the normal distribution, which underestimates the corresponding low levels in this region.

The mean upcrossing rate is a key parameter for estimation of the large and extreme response statistics as well as for evaluation of the associated reliability of marine structures subjected to random external excitations. The calculation of the mean upcrossing rate of the roll angle process $\theta(t)$ is usually based on the Rice formula (14) and the joint PDF of the roll response, which can be obtained directly by the 4D PI technique. The mean upcrossing rate $v^+(\zeta)$ is given as follows:

$$\begin{aligned} v^+(\zeta) &= \lim_{t\to\infty} v^+(\zeta;t) \\ v^+(\zeta;t) &= \int_0^\infty \dot{\theta} f_{\theta\dot{\theta}}(\zeta,\dot{\theta};t)d\dot{\theta} \end{aligned} \tag{14}$$

where $v^+(\zeta;t)$ denotes the expected number of upcrossings for the ζ-level per unit time at time t by the roll angle process $\theta(t)$, $f_{\theta\dot{\theta}}(\theta,\dot{\theta};t)$ is the joint PDF of the roll angle process and the roll velocity process at the time instant t.

The upcrossing rate for the selected sea state calculated by application of the 4D PI approach and the corresponding empirical estimation of the upcrossing rate as well as the 95% confidence interval (CI) obtained by MCS are shown in Figure 6. It can be readily seen that the 4D PI technique yields quite accurate and reliable result, even in the high roll response region. Hence, the 4D PI method is suitable for evaluation of the response statistics with low probability levels.

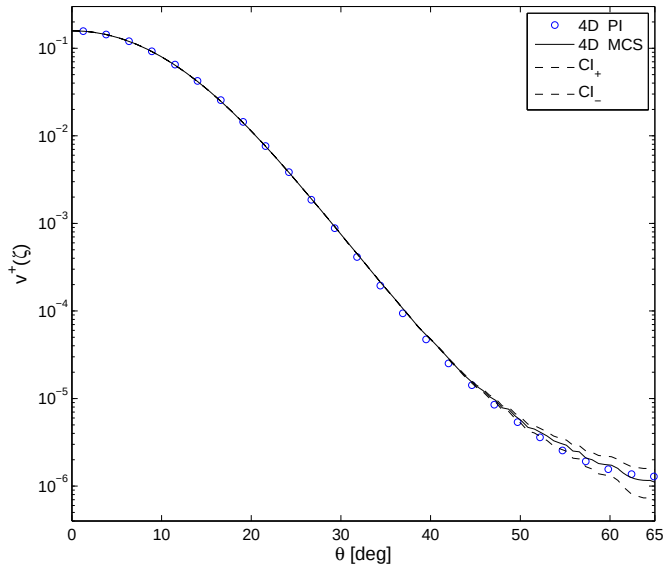

Figure 6: Upcrossing rates obtained by the 4D PI method and MCS.

5 CONCLUSIONS

In this work, a 4D Markov dynamic system is generated in order to describe the rolling behavior of a vessel subjected to random wave excitation. Based on the Markov property of the dynamic system, a 4D PI scheme is introduced to solve the high-dimensional FP equation. Comparisons of the response statistics obtained by the 4D PI method and MCS demonstrate the numerical robustness and accuracy of the 4D PI in calculating the statistics of the high roll response levels when subjected to random wave excitation.

Abstract. *We study the nonlinear static and dynamic analysis of problems with uncertain, spatially variable material properties using specifically tailored flexibility-based fiber elements. For deterministic problems, flexibility, or force-based, fiber elements have been proven able to provide accurate response estimates using a single beam element per structural member. We extent this formulation for the probabilistic assessment of structures whose properties are described by homogeneous non-Gaussian translation stochastic fields. The proposed modeling allows the use of different integration schemes, depending on the correlation length parameter of the stochastic field. This element formulation, contrary to ordinary displacement-based elements, allows to overcome the need for a very dense mesh of beam elements, which depends on the stochastic field and the regions where plastic rotations will occur. The performance of the proposed modeling approach is demonstrated on a steel portal frame. Considerable reduction of the computing effort is achieved in all cases. The paper underlines the importance of realistic uncertainty quantification and is expected to provide valuable guidance for the structural analysis and the design of systems with uncertain properties.*

1 INTRODUCTION

The stochastic approach continuously gains acceptance as a reliable and valuable tool for the calculation of the response variability of structures. The inherent randomness of certain systems in terms of material, geometry and loads prohibits deterministic treatment of the problem. Over the past 20 years the seismic reliability assessment of structures including uncertainties, has received considerable attention. The spatial variability of material and geometrical properties [1] along with the uncertainty of seismic excitation [2] and the coupling of stochasticity and nonlinearity [3], have been thoroughly investigated with various approaches.

Fiber elements have been used on many occasions for the reliability assessment of frame structures. Contrary to the deterministic problem where inelastic deformations are lumped at the beam ends, in stochastic analysis we need distributed plasticity elements so that our calculations consider the variation of system properties along the member [4]. The use of force-based fiber beam-column elements allows to consistently integrate the spatial variability of inelastic systems with uncertain system properties. For deterministic problems these elements are able to provide accurate response estimates using a single beam element per member. The use of force-based elements for the stochastic assessment of steel frames was first presented in [5] where the seismic capacity of a steel frame subjected to natural ground motion records was examined. In [6] the force-based formulation for the reliability assessment of bridges was used under moving loads, while [7] used force-based fiber elements for the nonlinear static assessment of a simple two-bay frame. Their numerical results are based on a series of measurements of the system properties [8].

2 INELASTIC FIBER BEAM-COLUMN ELEMENTS

2.1 Distributed plasticity elements

Distributed plasticity beam-column elements allow yielding to occur at any location along the element as opposed to plastic-hinge elements, where inelastic demand is lumped at the beam ends. The two most common formulations of distributed plasticity elements are the displacement-based (DB) and the force-based (FB) approach.

Displacement-based elements, also known as stiffness-based elements, follow the classical finite element theory and use cubic Hermitian shape functions to interpolate the displacement field. These elements require a fine mesh at the regions where inelastic deformations are expected to be high, e.g. the beam ends. On the other hand, force-based elements [9,10,11] use force interpolation functions to overcome the problem of the unknown curvature distribution once yielding occurs. This approach always maintains equilibrium of both forces and deformations and converges to a state that satisfies the constitutive laws within a specified tolerance. As a result, for deterministic problems a single force-based element per member is sufficient for accurately predicting the nonlinear behavior, provided that no element loads are present.

Nonlinear beam-column elements are usually based on the "natural" coordinate system (also known as "basic" or "corotational" system) which is a system that translates and rotates following the motion of the element. The beam elements have three degrees-of-freedom (Figure 1), the axial displacement u_1 and two rotations θ_1 and θ_2 which fully describe the inelastic demand and are grouped in $\mathbf{v} = [u_1, \theta_1, \theta_2]^T$. Following the Euler-Bernoulli beam theory, the strain $\varepsilon_x(x,y)$ is obtained as:

$$\varepsilon_x(x,y) = \begin{bmatrix} 1 & -y \end{bmatrix} \begin{bmatrix} \varepsilon_0(x) \\ k(x) \end{bmatrix} = \mathbf{a}_S(y)\,\mathbf{d}_{\text{sec}}(x) \tag{1}$$

where $\mathbf{a}_s(y)$ is the section kinematic matrix and $\mathbf{d}_{sec}$ (x) is the section deformation vector. The section stiffness matrix is calculated as the derivative of the section forces $\mathbf{D}_{sec}$ with respect to the section deformations $\mathbf{d}_{sec}$:

$$\mathbf{k}_{sec} = \frac{\partial \mathbf{D}_{sec}}{\partial \mathbf{d}_{sec}} = \frac{\partial \mathbf{D}_{sec}}{\partial \sigma}\frac{\partial \sigma}{\partial \varepsilon}\frac{\partial \varepsilon}{\partial \mathbf{d}_{sec}} = \int_A \mathbf{a}_S \frac{\partial \sigma}{\partial \varepsilon}\mathbf{a}_S^{\mathrm{T}} dA = \int_A \frac{\partial \sigma}{\partial \varepsilon}\begin{bmatrix} 1 & -y \\ -y & y^2 \end{bmatrix} dA \tag{2}$$

where $\partial\sigma/\partial\varepsilon$ is the tangent of the nonlinear uniaxial constitutive law and y is the distance from the neutral axis. Distributed plasticity elements are also known as "fiber" elements, since each section is discretized to a finite number of fibers which are used to numerically calculate the section stiffness $\mathbf{k}_{sec}$ of Eq. (2). If N is the axial force and M is the bending moment of a cross-section, the section forces are calculated by integrating the stress over the height of the cross-section as follows:

$$\mathbf{D}_{sec} = \begin{bmatrix} N \\ M \end{bmatrix} = \int_A \begin{bmatrix} 1 \\ -y \end{bmatrix} \sigma_x dA = \int_A \mathbf{a}_S^{\mathrm{T}} \sigma_x dA \tag{3}$$

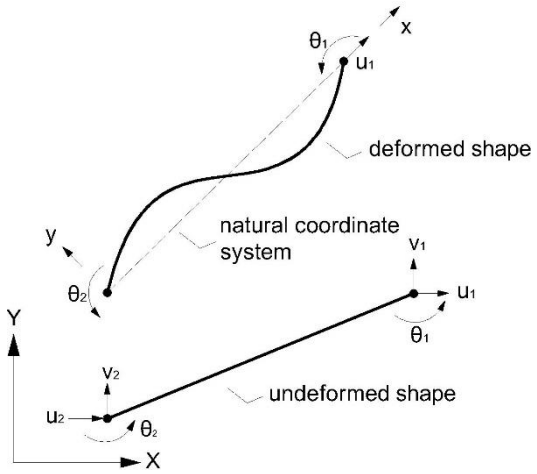

Figure 1: Cartesian and natural coordinates of a plane beam-column element.

2.2 Displacement-based elements

The displacement-based (DB) method uses the element interpolation functions and its derivatives in order to calculate section deformations and strains from the nodal displacements. The relationship of section and element deformations is given by:

$$\mathbf{d}_{sec} = \mathbf{B}_N(x)\mathbf{v} = \frac{1}{L}\begin{bmatrix} 1 & 0 & 0 \\ 0 & 2(3x/L-2) & 2(3x/L-1) \end{bmatrix}\mathbf{v} \tag{4}$$

$\mathbf{B}_N(x)$ is the strain-displacement transformation matrix of the element. The element stiffness matrix is calculated in the natural system as:

$$\mathbf{K}_N = \int_L \mathbf{B}_N^{\mathrm{T}} \mathbf{k}_{sec} \mathbf{B}_N dL \tag{5}$$

The Cartesian element stiffness is obtained from $\mathbf{K}_N$ with the aid of simple algebraic transformations [12].

2.3 Force-based elements

The force-based (FB) method uses force interpolation functions, which are always exact since the distribution of bending moments remains linear after element yielding. The force interpolation matrix $\mathbf{b}_s$ relates section forces with the natural forces **S**, thus:

$$\mathbf{D}_{\text{sec}} = \mathbf{b}_S \mathbf{S} \Leftrightarrow \mathbf{D}_{\text{sec}} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & x/L-1 & x/L \end{bmatrix} \mathbf{S} \tag{6}$$

The natural stiffness matrix is calculated as the inverse of the element flexibility matrix as:

$$\mathbf{K}_N^{-1} = \mathbf{F}_N = \int_L \mathbf{b}_S^T \left(\mathbf{k}_{\text{sec}}\right)^{-1} \mathbf{b}_S \, dL \tag{7}$$

For both displacement and force-based elements, the element stiffness matrix is calculated numerically using Gauss integration. For the case of force-based elements, Gauss-Lobatto integration is preferred which is a variation of Gauss integration that considers the beam ends as integration sections. This rule is preferred since the bending moment receives its maximum values at the beam ends.

3 THE STOCHASTIC FINITE ELEMENT METHOD

3.1 Stochastic field discretization

For nonlinear inelastic problems the discretization of the stochastic field requires special attention. A stochastic (or random) field $H(\mathbf{x},\omega)$ is a mapping from a random outcome ω to a function of space (or time) of a random variable x. It is usually called "field" when it varies in space and "process" when it varies in time. The statistical properties of stochastic fields (e.g. probability distribution and correlation structure) are either assumed or obtained from experimental measurements. In the stochastic finite element method the choice of the FE mesh size is critical, since this decision affects also the discretization of the stochastic field. In principle, the FE mesh size is controlled by the geometry and the expected gradient of the stress field, which in nonlinear problems is not constant during analysis, while the variation of the stochastic field is a property of the structure. The variation of the stochastic field is usually measured using the correlation length parameter b, which is the distance over which significant loss of correlation occurs. Therefore, the FE mesh should be short enough in order to capture the essential features of the random field and avoid loss of information.

3.2 Simulation of non-Gaussian stochastic fields

Non-Gaussian stochastic fields are suitable for the description of many practical engineering parameters, such as material properties, geometric characteristics, soil properties, waves, wind loads, etc. In order to simulate a non-Gaussian stochastic field, a transformation of a Gaussian field with known second-order statistics needs to be performed. The spectral representation method [13] is a direct method for the simulation of Gaussian stochastic fields. The method calculates the stochastic field as the sum of cosine functions with random phase angles and amplitudes. It is based on the power spectrum concept, which is a real, non-negative function that describes how the variance of the stochastic field data is distributed over the frequency domain. Spectral density functions include the variance and the correlation scale characteristics of the stochastic field and usually are functions of exponential or square exponential type.

A power spectrum of square exponential type is shown in Figure 2a for different values of the correlation length b, while the influence of the correlation length parameter to the sample

functions of a Gaussian stochastic field, generated by the spectral representation method, is shown in Figure 2b.

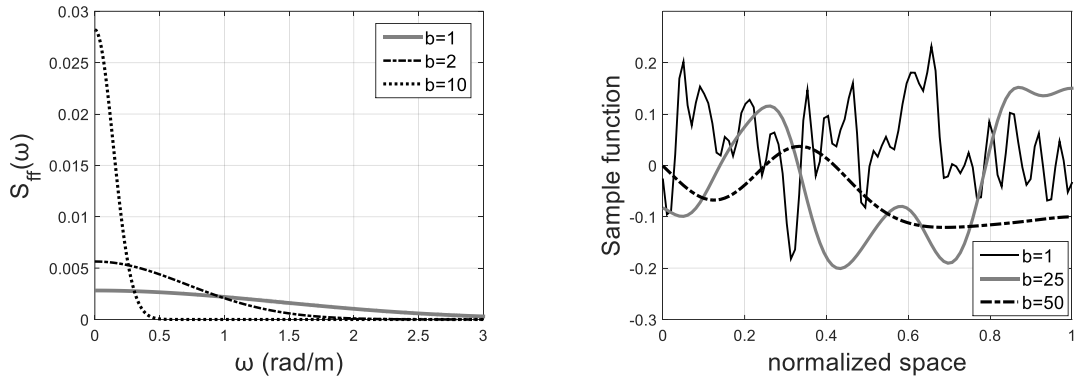

Figure 2: (a) Sample spectral density function $S_{ff}(\omega)$ of square exponential type with standard deviation σ_{ff}=0.1 and different correlation length values, (b) sample functions of a Gaussian stochastic field for different values of the correlation length parameter b.

A non-Gaussian stochastic field can be obtained as a translation field by properly transforming a Gaussian field. Specifically, a zero-mean homogeneous non-Gaussian stochastic field $f(\mathbf{x})$ with spectral density function $S_{ff}(\omega)$, can be obtained with the aid of a nonlinear monotonic transformation of a zero-mean Gaussian field $H(\mathbf{x})$ as:

$$f(\mathbf{x}) = F^{-1}\Phi\left[H(\mathbf{x})\right] \tag{8}$$

where F is the non-Gaussian marginal cumulative distribution function (CDF) of $f(\mathbf{x})$ and Φ is the standard Gaussian CDF. The above transformation is a memory-less translation of every space coordinate x_i. However, the choice of the marginal distribution for the translation field $f(x)$ imposes constraints to its correlation structure [14]. For non-Gaussian translation fields whose autocorrelation function has some inadmissible values, or is not positive-definite, the approximation error should be also taken into consideration [15].

4 PROPOSED METHODOLOGY

We propose the use of flexibility-based elements for the seismic probabilistic assessment of nonlinear frame structures with stochastic properties. For the deterministic analysis of inelastic frame structures, flexibility-based elements are able to capture the response using a single element per member. When stochastic problems are considered, the frame properties vary along the length of every member. Most FE types require appropriately modifying the FE mesh depending on the properties of the stochastic field and also on the regions where concentration of inelastic demand is expected, i.e. beam ends, region of concentrated forces etc. However, for stochastic problems the critical locations are not known a priori since the structural properties vary. We show that force-based elements, if combined with a pertinent numerical integration scheme, offer accurate estimates of the response variability, maintaining the advantage of a single element per member. The resulting FE scheme is suitable for full-scale frame structures with affordable computing cost and accuracy.

We use stochastic non-Gaussian fields to simulate the material properties. Constitutive laws typically depend on several parameters. A simple bilinear model depends on two parameters: the elastic modulus E and the yield stress f_y, while more parameters may be required for other materials, e.g. reinforced concrete. The material parameters may be denoted as D_i and

are here assumed uncorrelated. If $H(\mathbf{x})$ is the zero-mean stochastic field, each material property is distributed along each member. If $D_{0,i}$ is the expected value of each parameter the material property is described as $D_i(\mathbf{x}) = D_{0,i}(1 + H_i(\mathbf{x}))$. The section stiffness $\mathbf{k}_{sec}$ is calculated with the aid of Eq. (2), where the material properties are a function of $\mathbf{D} = [D_1, D_2, \ldots, D_N]^T$. For example for a bilinear steel material $\mathbf{D} = [E, f_y,]^T$ and the section stiffness is obtained with the aid of Eq. (2):

$$\mathbf{k}_{\text{sec}} = \int_A \mathbf{a}_S^T \frac{\partial \sigma(\mathbf{D})}{\partial \varepsilon} \mathbf{a}_S^T dA \tag{9}$$

The element stiffness matrix is calculated at the Gauss-Lobatto integration sections as:

$$\begin{aligned} &\mathbf{K}_N = \int_L \mathbf{b}^T \mathbf{k}_{\text{sec}}^{-1} \mathbf{b}^T dL \Leftrightarrow \\ &\mathbf{K}_N = w_1 \mathbf{b}^T(x_1)\mathbf{k}_{\text{sec}}^{-1}(x_1)\mathbf{b}(x_1) + w_{NIP}\mathbf{b}^T(x_{NIP})\mathbf{k}_{\text{sec}}^{-1}(x_{NIP})\mathbf{b}(x_{NIP}) + \\ &+ \sum_{i=2}^{NIP-1} w_i \mathbf{b}^T(x_i)\mathbf{k}_{\text{sec}}^{-1}(x_i)\mathbf{b}(x_i) \end{aligned} \tag{10}$$

where NIP is the number of integration points, w_i and x_i are the weights and the location of Gauss-Lobatto integration sections. Note that x_1 and x_{NIP} refer always to the two ends of the beam element. A similar integration is also adopted for the element internal forces. The above methodology is implemented with the aid of OpenSees [16]. OpenSees is an open-source structural analysis software that allows the user to define any numerical integration scheme. The pre and post processing of our results are performed with the aid of customized in-house software.

We first generate zero-mean Gaussian stochastic fields using the spectral representation method. These fields have a spectral density function of square exponential type:

$$S_{HH}(\omega) = \frac{\sigma^2 b}{2\sqrt{\pi}} \exp\left(-\frac{b^2\omega^2}{4}\right) \tag{11}$$

where σ is the standard deviation of the stochastic field and b is the correlation length parameter. The lognormal fields are subsequently obtained using Eq. (8). The spectral density function is expected to be slightly different from $S_{HH}(\omega)$, since the translation to the lognormal CDF adds a small approximation error.

5 STEEL PORTAL FRAME EXAMPLE

We consider the steel portal frame of Figure 3 as a case study. All the members of the frame have HEB 200 wide flange cross-sections and are modeled with a single force-based beam-column element. A distributed load q=40kN/m is applied at the bay and remains constant throughout the loading history. The uncertain material properties are the Young's modulus E and the yield stress f_y, both assumed to vary stochastically along each member. The material properties are described by the following expressions:

$$\begin{aligned} E(x) &= E_0\left[1 + H_1(x)\right] \\ f_y(x) &= f_{y0}\left[1 + H_2(x)\right] \end{aligned} \tag{12}$$

where $H_1(x)$, $H_2(x)$ are two zero-mean 1D-1V homogeneous lognormal stochastic fields with COV equal to 10% as indicated by the Joint Committee for Structural Safety [17]. Different values of the correlation length parameter b are considered in order to investigate the sensitiv-

ity of the response to the correlation scale of the stochastic fields. In order to validate the proposed method, we consider as reference solution FE models that use a very dense mesh of 50 displacement-based fiber elements per member. Such a dense mesh is expected to accurately describe randomness for any correlation length.

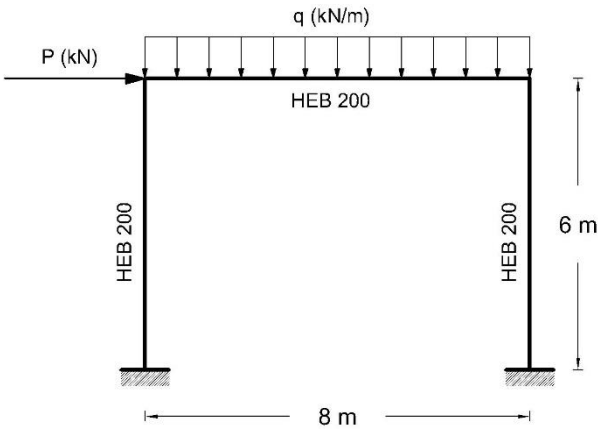

Figure 3: One-storey steel frame.

5.1 Nonlinear static analysis

The response variability of the steel frame is calculated through nonlinear static analysis for a sample size of 500 crude Monte Carlo simulations. For every simulation we obtain the capacity curve in terms of roof drift versus applied load. The mean capacity curve of the frame is shown in Figure 4a, together with the mean plus and minus one standard deviation curves. The vertical dashed line is used in order to separate the pre-yielding from the post-yielding phase of loading. Figure 4a clearly shows that the effect of E is rather small (pre-yielding phase), while considerable variability is observed after yielding where f_y comes into play.

According to Figure 4b the calculation of the mean capacity is not sensitive to the number of integration sections even for a small correlation length (b=0.1). On the other hand, Figure 5 examines the necessary number of integration points in order to capture the response variability defined as the COV (standard deviation divided by the mean value) conditional on the roof drift. As a reference solution we use the red solid curve obtained with the aid of a very dense mesh of 50 displacement-based elements per member. For four correlation length values, we compare the COV estimates using force-based elements of 5, 10, 15 and 20 integration sections. All four plots of Figure 5 show that increasing the number of integration points offers a better description of the random fields, since the COV values converge to the exact solution. The convergence is faster as the correlation length b becomes larger (e.g. compare Figure 5a and Figure 5d). The vertical dashed line (defined in Figure 4) provides the threshold between linear elastic and inelastic response. In the elastic regions the COV is practically constant and very low (2-6%). When the frame starts to yield, the COV increases almost monotonically as the roof drift also increases.

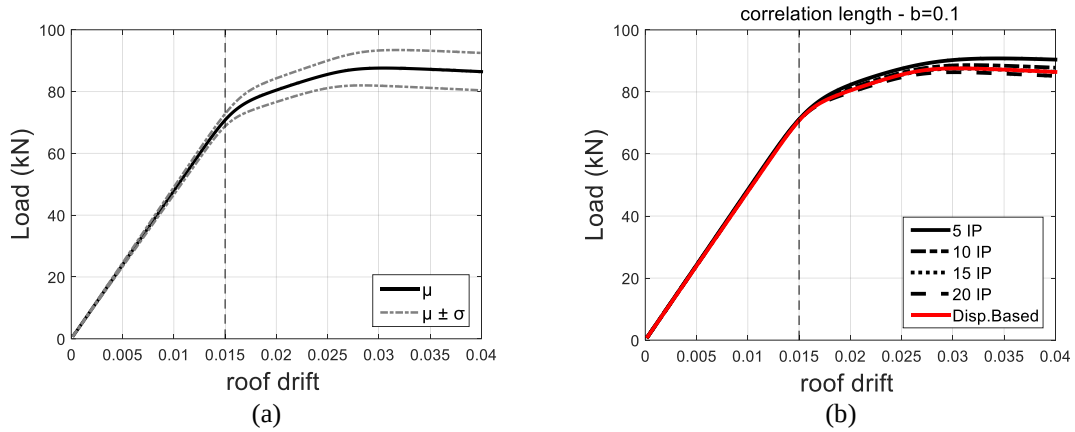

Figure 4: (a) Mean and mean ± one sigma capacity curves of the portal frame, (b) mean capacity curves for ranging number of integration points.

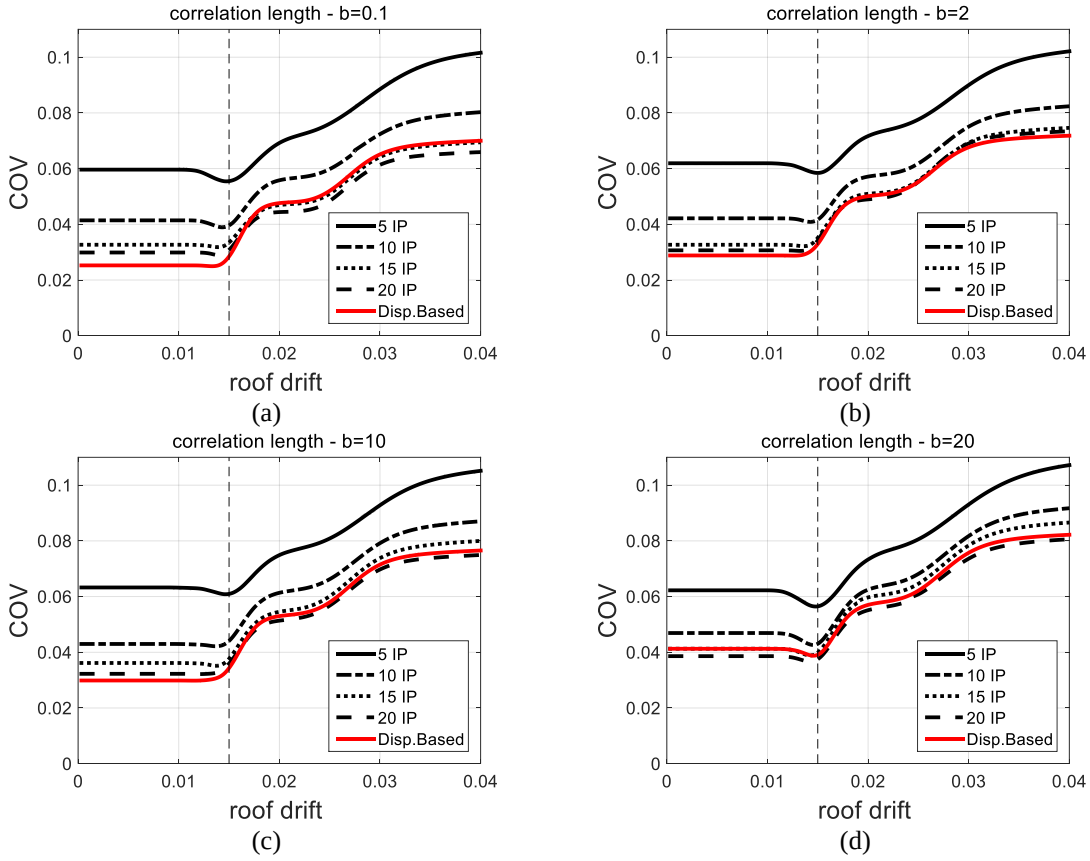

Figure 5: Sensitivity of response variability (COV) to the number of integration points for different correlation lengths.

5.2 Nonlinear response history analysis

The seismic performance of the steel portal frame is also studied using nonlinear response history analysis. Seismic demand is measured with the aid of the maximum roof drift ratio (θ_{max}). A lumped mass matrix is formed in agreement to the distributed load q (Figure 3). The fundamental mode of the frame was found equal to T_1=1.24sec when the mean value of the Young's modulus E is used, while the damping matrix was obtained assuming 5%-Rayleigh

damping on the first and the second mode. All response history analyses were performed using a single force-based beam-column element per member with 20 Gauss-Lobatto integration sections. Again we assume that the correct solution is that of a very dense mesh of displacement-based elements.

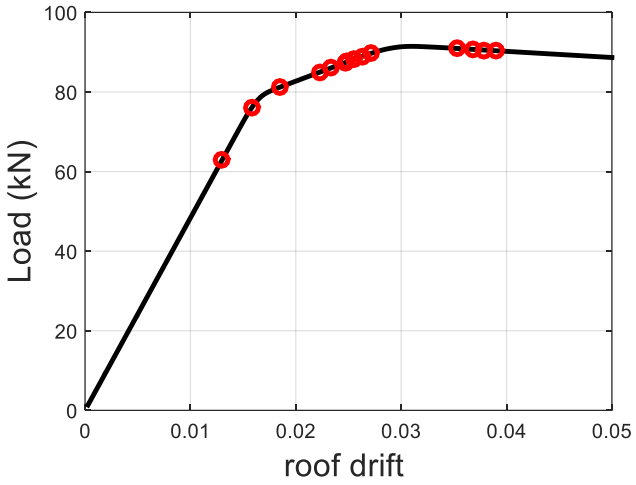

Figure 6: Roof drift demand of the natural ground motion records (red circles) plotted on the capacity curve of the frame (solid line).

All response history analyses are performed with fifteen ground motion records. The records cover a broad spectrum of seismic intensities in order to evaluate the structural behavior at different levels of seismic demand. All records are scaled with a uniform scaling factor equal to 2, to guarantee that some of them will yield the frame. Figure 6 shows the maximum drifts demand for every record plotted against the capacity curve of the frame, assuming the mean value of every random parameter. Significant record-to-record variability is expected due to the different frequency content and duration of the ground motions.

The accuracy of the proposed method is examined considering the first three statistical moments. Figure 7 shows the mean storey drift (θ_{max}) for four values of the correlation length. The proposed force-based modeling provides results that are practically identical to the "correct" solution. Note that in Figure 7, the records are sorted from left to right according to the maximum expected drift demand of Figure 6.

Figure 8 shows the effect of stochastic material properties on the COV of θ_{max} demand. For all b values considered, the accuracy of the force-based formulation is again very close to the correct solution. The errors observed are small proving that the discretization with 20 sections is sufficient. Furthermore, records that do not cause large inelastic displacement demand (records on the left) have smaller COV values than records that caused inelastic damage on the building (records towards the right). Still, the COV values are very sensitive to the record characteristics while, for most ground motions, the COV of the response is lower than the variance of the stochastic input parameters. The effect of the correlation length is small compared to the significance of the ground motion properties, while large correlation lengths tend to increase the COV.

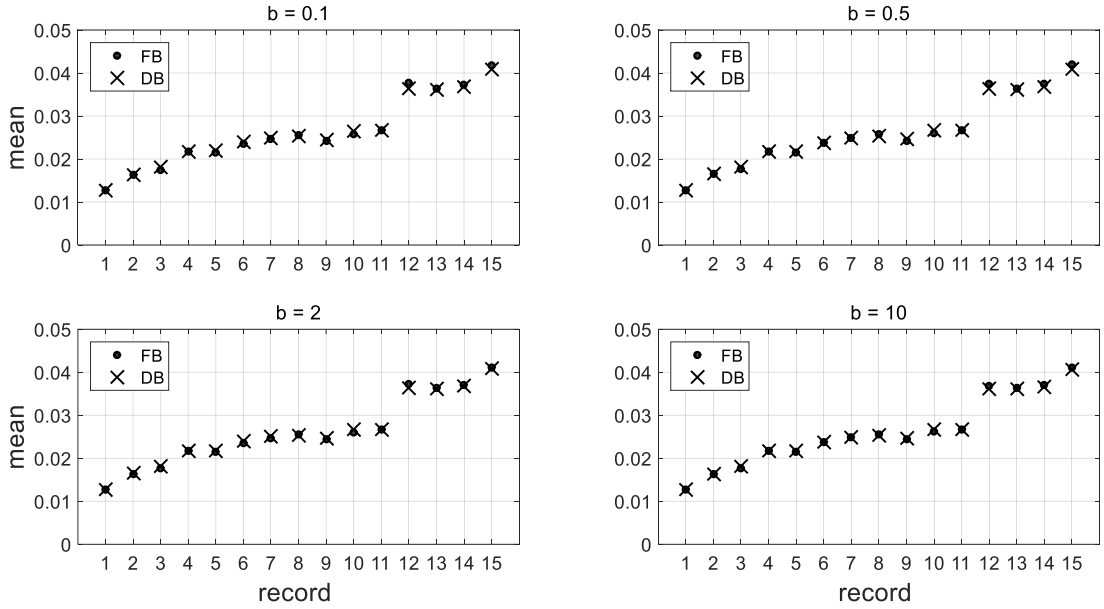

Figure 7: Mean drift demand for correlation values equal to *b*=0.1, 0.5, 2 and 10.

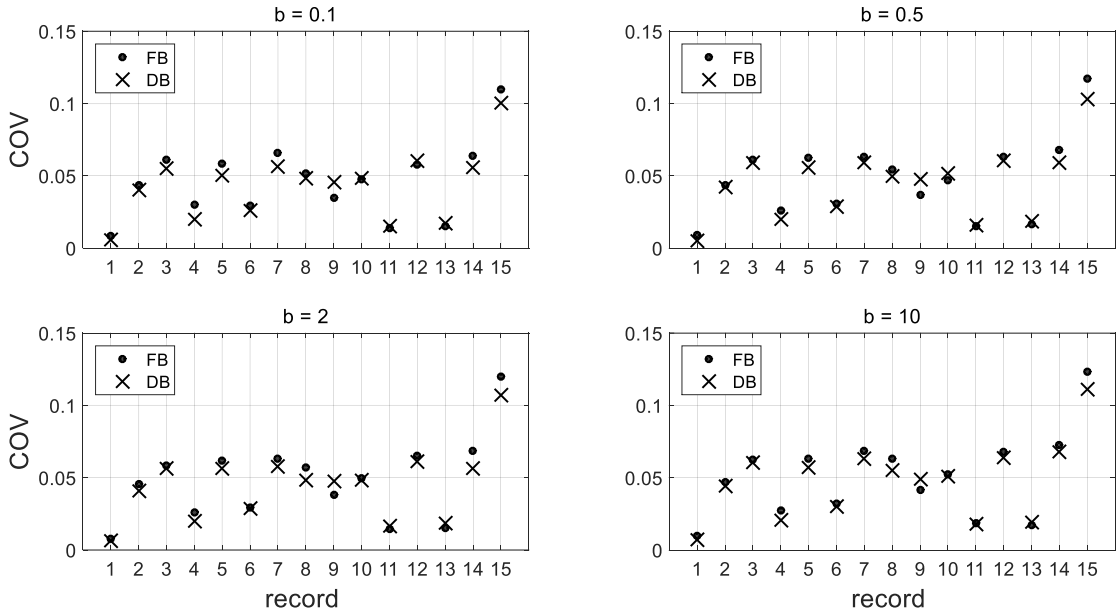

Figure 8: COV of drift demand for correlation values equal to *b*=0.1, 0.5, 2 and 10.

Figure 9 shows the skewness (third statistical moment). The skewness provides a measure of the asymmetry of the sample's cumulative distribution function. Contrary to the COV, the skewness is quite sensitive to the correlation length and varies with the record properties. For many records the skewness differs considerably for different *b* values and doesn't follow the properties of the lognormal material/input properties. Furthermore, samples of opposite skewness for the same natural record, e.g. records 11 and 15, were found. In all cases, the proposed modeling gave excellent estimates of the skewness.

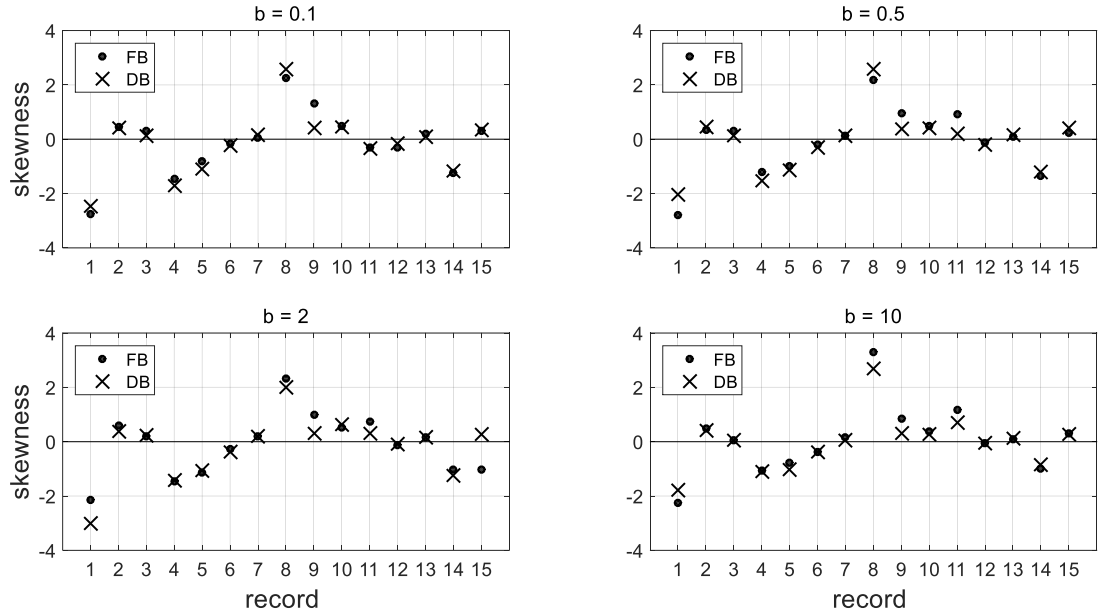

Figure 9: Skewness of drift demand for correlation values equal to *b*=0.1, 0.5, 2 and 10.

Apart from accuracy, the proposed method also reduces considerably the computing cost. Figure 10 compares the computational cost of the proposed element to that of the displacement-based formulation for both static and dynamic analysis. An Intel Core 2 Duo processor required more than double time to run 500 Monte Carlo simulations for the nonlinear static case. For the response history analysis of a single record, the proposed methodology required approximately 10% of the time of the displacement-based element for the same number of simulations. Although the computational effort of the displacement-based element can be reduced using a more coarse mesh, Figure 10 provides a clear indication of the exceptional performance of the force-based element which can be therefore adopted for the simulation of real-scale problems without having to modify the mesh of fiber elements.

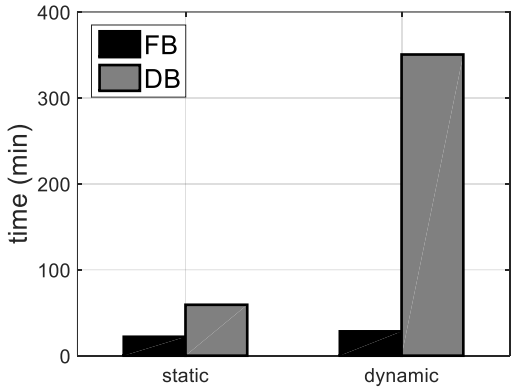

Figure 10: Computing cost of 500 Monte Carlo simulations of the portal frame for the force-based and the displacement-based formulation.

6 CONCLUSIONS

A novel modeling approach for the probabilistic seismic assessment of frame structures with stochastic system properties is proposed. The proposed method extends the use of flexi-

bility-based fiber elements to the stochastic finite element method, offering the possibility of applications to real-scale problems due to the remarkable computational performance and stability of these elements. The performance of the proposed modeling is demonstrated on a one-storey steel portal frame. The study provides a valuable guidance for the analysis and the design of structures with non-Gaussian system properties and its main conclusions are here summarized:

- The choice of the number of integration points is essential. The integration should be able to capture the spectral characteristics of the input stochastic field.
- The proposed modeling offers remarkable accuracy and reduced computing numerical effort, even for very small values of the correlation length parameter (highly uncorrelated stochastic fields).
- The computational performance was exceptional, especially for the case of response history analysis where the proposed modeling reduced the required computing effort by 90%. This allows the implementation of the method to real-scale problems.

Keywords: Architecture Trade-Off, Collaborative Simulation, Multidisciplinary and Multi-Level optimization, TOICA EU FP7 Project.

Abstract. *Evolution toward more complex electrical systems on board of commercial aircrafts to be fitted in smaller containment areas of composite lightweight structures have raised challenges in respect of thermal optimization in a multi-disciplinary context. It is so crucial to OEMs that it motivated the assembly of a consortium from 32 companies around an R&D project, named "Thermal Overall Integrated Conception of Aircraft" under the umbrella for Framework Program 7 with a focus on:*

- *Closing the gap between architectural view and domain specific simulations*
- *Enabling multi-level, multi-disciplinary approach for flexible architecture trade-offs*
- *Developing new integrated architecture aiming to thermally optimize aircraft*

Among others activities along this project, MSC is engaged to sustain one of the selected use cases conducted by Airbus and referenced here as new power plant integration.
Specifically, an environment enabling architects to conduct a trade-off study collaboratively with domain specialists has been developed. It is tightly integrated with Airbus simulation environment built on the top of heterogeneous solutions from Siemens, Cenaero and MSC. TOICA outcome so far have focused on:

- *Trade Study Process Management capitalizing on former projects developments like the "Modeling and Simulation information in a collaborative Systems Engineering Context" (MoSSEC) introduced in Crescendo*
- *Multi-Level and Multi-Disciplinary Optimization tightly linked to the concept of agile behavioral model generation*

This paper exposes maturity of the proposed solution validated by real plateaus execution involving all actors of the targeted study.

1 INTRODUCTION

Among critical capabilities required by architects and chief engineers, managing efficient trade-off studies of thermal energy has become a number one priority. The efficiency and management are needed because the aircraft manufacturers work collaboratively with their extended enterprise to propose competitive solutions.

Indeed, if early evaluation of more alternatives is key to avoid late recognition of "low-performing" design solution and facilitate faster time to market demands, then better understanding of the thermal behaviour has emerged because of the growth of inter-related challenges at sub-component level:

- Shift from hydraulic and pneumatic systems to more electrical ones in modern aircrafts has highly affected the overall thermal load; the thermal load has increased five-fold over the two last decades. No reduction in such a trend being expected for the foreseeable future.
- Further, confinement of equipment to address payload increase (cargo and passengers) has raised issues related to sensitivity of new generation batteries to ambient temperature.
- Effort to lighten Aircraft Structures through use of composite materials, whose insulation power is higher by 2 orders of magnitude, created more thermal constraints. However, the mechanical properties of composites might also drop drastically beyond their glass transition temperature. The gap between composite and thermal expansion coefficients can also induce critical constraints at the junctions of some components assembly.

To overcome these thermal challenges, it is key that the aerospace industry performs thermal trade management as early as possible in the development process. Therefore, a consortium of 32 companies, coordinated by Airbus, launched an R&D project, named "Thermal Overall Integrated Conception of Aircraft" (TOICA [8]) that has been awarded for funding by the European Community's Seventh Framework Programme (FP7/2007-2013, under grant agreement n°604981).

The focus of this project is on:

- Closing the gap between architectural view and domain specific simulations validation
- Enabling multi-level, multi-disciplinary approach for preforming flexible architecture trade-off analyses.
- Developing new integrated architecture/solutions aiming to thermally optimize aircraft

Among the partners and their associated contributions:

- Airbus leads several Use Cases and drive their implementation through "plateaus". Plateaus are technical working sessions where thermal trade-off studies are operated using the TOICA capabilities and where business benefits are assessed.
- MSC contributes to the development of TOICA capabilities like:
    - Specific Aircraft Architect Environment to empower the architects with means of assessing their architectures in early design phases, through trade-off studies and reviews.
    - Collaborative data and process management capitalizing on previous project outcomes like Behavioural Digital Aircraft matured by CRESCENDO.
    - Parametric Model Generation to enable end users to build objects serving as inputs in studies of configurations and their evaluations along trade off process.

- Coupling simulation approaches in Multi Discipline and Multi-level context.

This paper intends:

- To share the status of the proposed methods, elaborated with partners using Technology Readiness Level, reviewing Airbus's use case relative to Pylon Architecture trade-off for new power plant integration.

  Specifically, the TOICA collaborative richness will be described showing how the Flexible Model Generation capability, capitalizing on Pyramid of Model and Super Integration concepts, is used either to address needs of the simulation experts or as a trade-off generator engine serving the architect platform.

  MSC, as work package leader, is coordinating the Flexible Model Generation capability; Siemens/LMS is orchestrating the Pyramid of Model concept.

- To map the proposed methods to TOICA use case driven by Airbus and focusing on management of power plant integration trade off from a multi-disciplinary perspective.

2 TOICA AT A GLANCE

TOICA is a 3-year European project, coordinated by Airbus that was launched in 2013. Its contributors comprise a consortium of 32 partners from 8 countries associated with a budget of nearly 30M€.

R&D effort is balanced amongst eleven industrial companies, seven IT vendors, five small and medium enterprises, four research centers, and five universities.

Capitalizing on results (Figure 1) of the CRESCENDO European project (2009-2012), where the concept of the Behavioural Digital Aircraft (BDA, now referred to as the MoSSEC standard [7]) architecture was specified, developed and validated, TOICA aims to introduce the next generation approach to sustain aircraft thermal studies throughout the design cycle. The proposed path is to develop simultaneously the systems, equipment and components by utilising the exchange of their behavioural representations amongst the stakeholders.

In that respect, the TOICA members have agreed on four High Level Objectives (HLO):

- HLO1: Develop customized collaborative simulation capabilities improving the generation, management, and maturity of the BDA dataset.
- HLO2: Develop new concepts for improved thermal load management within aircraft components, systems and equipment, which will integrate innovative cooling technologies and products.
- HLO3: Assess and validate the developed capabilities and technology concepts against different common reference aircraft targeting both "Enter into Service (EIS) 2020" and EIS 2030+ Thermal Concept Aircraft".
- HLO4: Optimise aircraft design by enabling highly dynamic allocation and association between requirements, functions and product elements (Super integration) for product innovations.

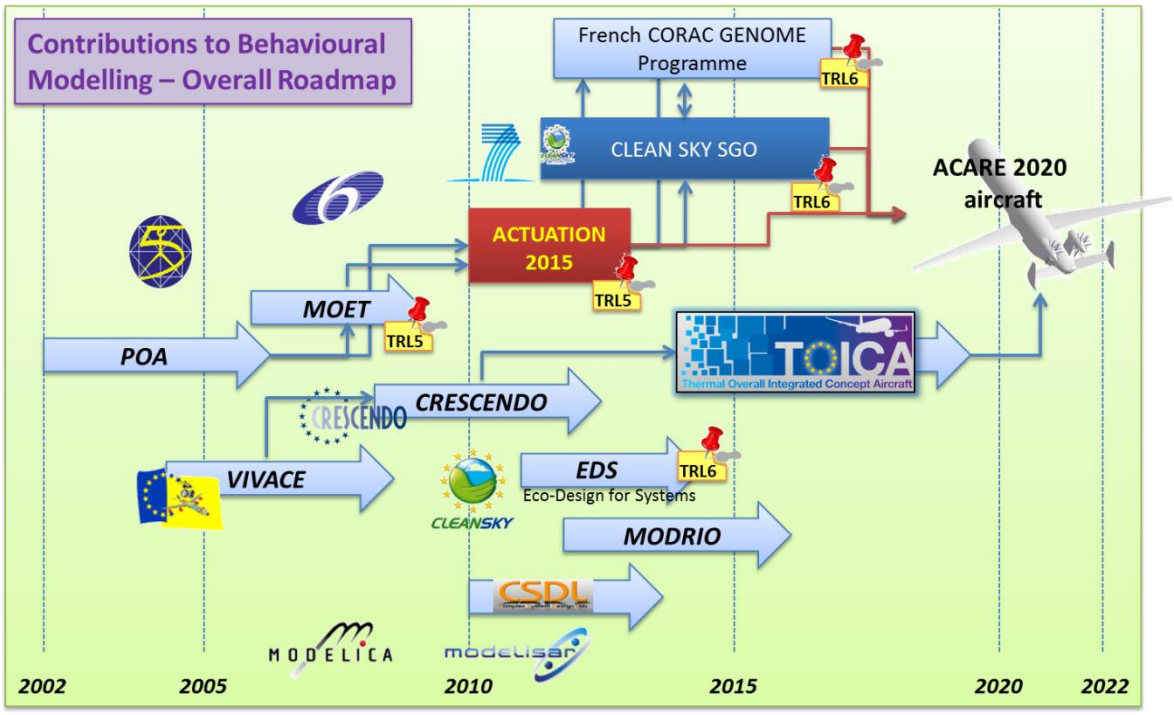

Figure 1: TOICA History

In order to deliver applicable results on time, TOICA relies on its Use Case driven organization; with a progress monitoring scheme derived from a realistic aircraft design cycle that is drum beat by regular Milestone plateaus (MSP). In other words, real actors, in the context of their design activity, test any capability developed, which allows them to check a proposed method and review its Technology Readiness Level (TRL) validation. Further, it allows them to evaluate the gap between the expectations and the evidence produced.

Six main use cases, illustrated in Figure 2, have been retained:

- Manage Future Aircraft Architecture
- Integrate Equipment Thermal
- Research new cooling Technologies
- Manage Aircraft Heat Load via Heat Sink
- Optimize Overall Thermal (Energy) for Systems
- Integrate Power plant

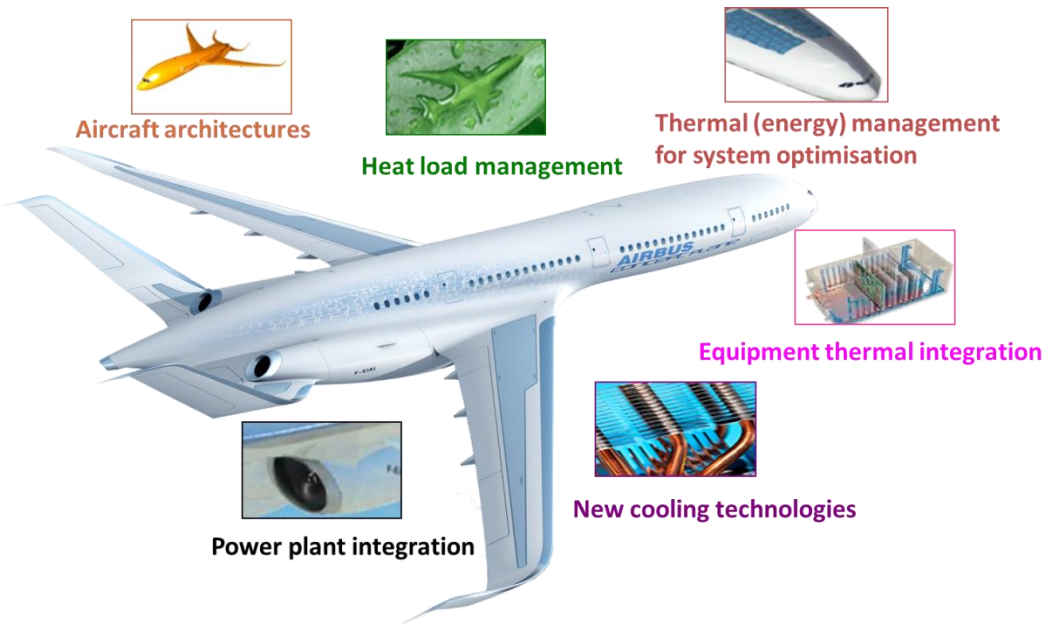

Figure 2: TOICA Use Cases

TOICA partners target to contribute to "Challenge 3 – Competitiveness through innovation" of the ACARE SRA2 High Level Target Concept (HLTC) "High Efficient Air Transport System", enhancing:

- Aircraft development cost
    - Reducing by 10% equipment development impact via a more robust specification process allowing equipment supplier, or risk-sharing partners, to design systems and equipment according to more realistic margins.
    - Reduce the costs and time associated with integration and installation of systems and equipment in aircraft by strongly reducing the need for late rework
- Supply chain efficiency
    - Reduce by 50% the lead time of an aircraft thermal architecture assessment.
    - Shorten by 6 months the equipment development process by improving the exchanges of thermal requirements with the suppliers and sharing the overall thermal view information across the supply chain.
- Aircraft operational costs:
    - Reduce by 5% the energy/power consumption used for active cooling or controlling (heating) of systems
    - Increase the Mean Time Between Failure (MTBF) by 15% as the direct impact of more equipment-dedicated specifications

In the following chapter, we focus on a specific study related to the future architecture associated to Airbus New Engine Option (NEO). For the sake of this study, we will pay special attention to TOICA developed capabilities: Architects' Cockpit, and Flexible Model Generation. We will highlight how the overall study is already benefiting from the MoSSEC standard [7] and the multi-level coupling, mechanisms. Finally we will elaborate on how it will be fully delivered using additional TOICA developed capabilities like Super Integration.

3 NEO USE CASE

3.1 Business Challenges and benefits

Maximum re-use of equipment is expected in order drastically reduce program development costs.

However, for various reasons like hotter engine and reduced space allocation the thermal environment of equipment, thermal constraints on new configuration raise. This trend is even accentuated by new nacelles and engines design orientations like:

- Increase of the engine by-pass ratio impacting cooling efficiency
- Shorter nacelles impacting space allocation
- More electrical function generating more heat sources.

This leads to a strong need for efficient thermal trade-off means of equipment, required to face such an emergence of thermal challenges.

The required capabilities to be delivered by TOICA should:

- Enable early trades on power plant and pylon integration considering thermal integration & ventilation as well as re-use of constrains.
- Enable trade on bleed architecture that includes all the driving parameters: ventilation, thermal impact and exhaust section, bleed performance, etc…
- Analyze the close aero-mechanical-thermal coupling impact to pylon design.

3.2 Trade off scenario

In this case, the evolution of the aircraft configuration follows a process composed of the following key steps:

- Define Top level aircraft requirement;
- Define Mission;
- Derive Neo Power Plant architecture constraints from aircraft baseline including
    - Aircraft level requirements
    - System level design requirements
    - Functional definition
    - Baseline architecture definition
- Analysis at aircraft and system level of the baseline configuration
- Review and challenge of the baseline configuration
- Evolve the configuration in a iterative process

In particular, the introduction of baseline variants or alternatives hypothetically takes place during the review and leads to the evolution of the configuration.

The evolution of the configuration will generate a variant dataset, linked to the baseline dataset to ensure traceability of the entire evolution process. This is because the dataset is linked to the configuration

Specifically, as shown in the workflow views reported above, the main actors' interactions with the dataset can be summarized as follows:

- Power Plant Architect: Defines the trade-off study He specifies the study objectives and populates the dataset by creating/importing the
    - TLAR
    - Operational definition
    - Aircraft configuration and zoning
    - Objectives
- Thermal Expert: Receives the study request from the Power Plant Architect and enriches the dataset by defining the thermal objectives and constraints before to split the request in two branches:
    - The first one, the analysis of cooling and packing of engine integration compartments
        - In turn this sub-study will involve additional actors like the Engine Architect and his thermal team, at integrator partner's level.
    - The second one, relative to pylon thermally constrained design trade off
        - Equally to the previous one, this branch will grow into a distributed and collaborative study coordinated by a thermal leader

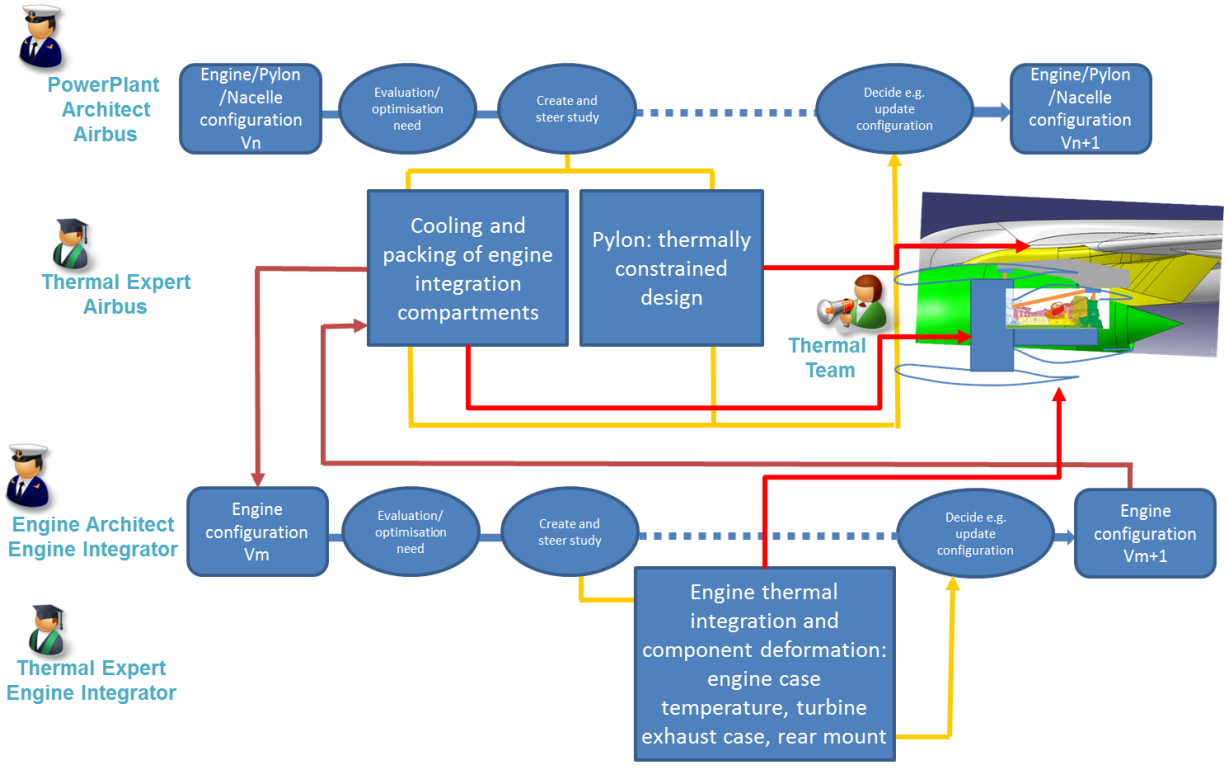

Figure 3: TOICA Neo Use Case Scenario

The sub-study dedicated to pylon trade-off will be detailed along the next paragraph to illustrate how thermal expert will leverage most of the TOICA developed capabilities to col-

laborate with the architect. This expert will orchestrate a multidisciplinary and multi-level optimization process for the engine pylon, where this process takes into account thermal, flutter and detailed stress constraints (Figure 4).

The goal in that case being to assess the sensitivity of the main performance indicators with respect to variations of the pylon width along three different of its sections. The considered performance indicators will be mass of the pylon and the drag coefficient; proposing a set of design solutions that are optimal in the sense of both aerodynamics and structure disciplines.

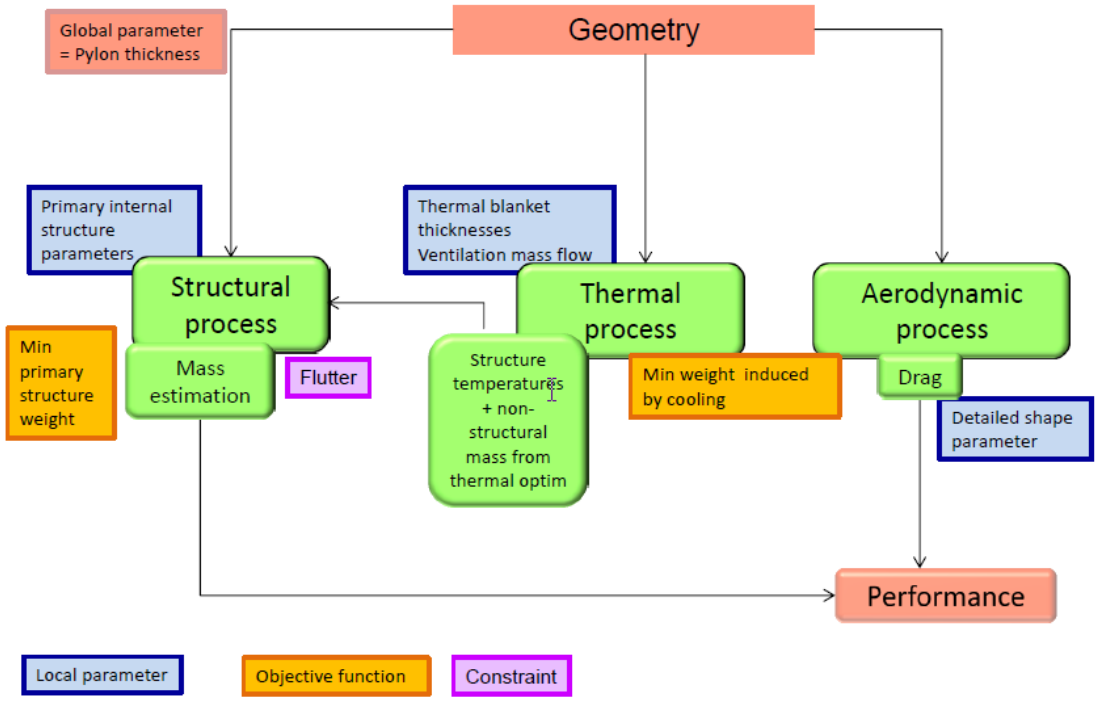

Figure 4: Multi-Disciplinary scenario overview

Technically this will be reached by leveraging a bi-level approach:

- At global level: each discipline feeds the global process with shared parameters (pylon width, material choice…), constraints and objectives (minimum drag and mass).
- At local level: specific parameters and constraints for each discipline are addressed, and are not shared among the disciplines.

3.3 To-Be process requirements mapping to TOICA capabilities

In order to address the business objectives defined in 3.1, the "As-Is" process needs to be enhanced in a way that the workflow, highlighted by Figure 3, can be executed by the actors.

Initial requirements direct us to an environment where the architects can (Figure 5)

- Define their domain architecture at aircraft level, (the Power Plant level in the specific case of TOICA), or at Engine Integrator level. Forthwith these objects are called models because:
    - Conceptually they are supported by the idealization from various perspectives, being for instance functional; logical, 1D to 3D views.

- Such models are essentially assembly of sub-models: from the requirements and objectives within an operational scenario to physical representations that can co-exist at different levels.

- Edit/Author the architecture model, meaning:
  - Populating datasets for a certain view
  - Updating view representation while development matures
  - Deriving alternatives from a baseline, or an existing library of architectures. At this stage, it corresponds to trade variable definition converted to parameters of the architecture model, where a parameter can encompass many representations like
    - Geometrical (change of a dimension or a zone)
    - Functional (choice in function to perform)
    - Architectural (requirements & objectives balance scope)
    - Behavioural (selection of Idealization level & method to assemble possible components of overall object)
- Explore a proposed architecture through visualization of the
  - Requirements space (requirements, objectives, constraints)
  - Alternatives, as an initial means of comparison
- Instantiate and manage trade off request from previous variants:
    - Defining and distributing tasks to various stakeholders across the extended enterprise; while retaining Intellectual Property Rights in the context of heterogeneous domain tools and infrastructures.
    - Monitoring based on selected key indicators throughout the project by tracing
    - Assumptions
    - Uncertainties
    - Results
    - Decisions

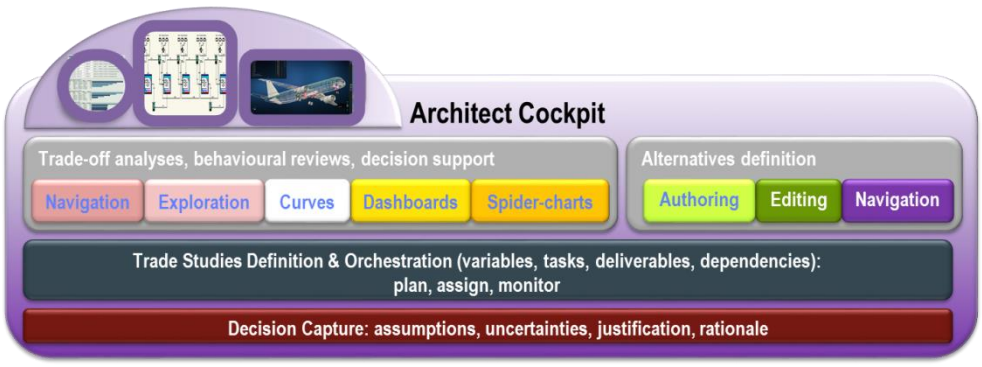

Figure 5: Architects' Cockpit functional scope

Beyond natural interest into an Architects' Cockpit from the NEO scenario, two additional TOICA developed capabilities will consolidate the benefits delivered to the end users. In the latter scenario, many stakeholders are engaged in a collaborative effort. The foreseen deployment does anticipate multiple lifecycle management platforms (Airbus legacy and /or partner's heterogeneous infrastructure constraints). Therefore, the communication and exchange scheme with the extended enterprise require some level of standard format and services to work collaboratively with them. In that respect, TOICA contributes to the MoSSEC [7] standard, by working on necessary BDA objects expanding the thermal collaborative scenario that were already validated during CRESCENDO project [1].

Keeping in mind the Architects' Cockpit requirements, and switching to the Modeling and Simulation (M&S) toolbox, it is now easy to understand why and how it has to be "powered inside" with Flexible Model Generation technology. Indeed, its purpose is to enable the assembly of componentized models: what an architecture definition is; and to introduce parameters to enable creation of variant models: what a tradeoff requires.

At such a stage, we do not even need to know what the sub-model components will be. Their representation will be populated with richer models while the development cycle of the aircraft progresses. In paragraph 3.4, we will show examples like top-level aircraft requirements (TLAR); operational scenarios, functional or system models and surrogate simulation models or 3D CAD models. However, at this stage it is important to emphasize that if Flexible Model Generation allows you to select a sub component and/or parameterized it along the global model assembly, it does not affect the possible choices among level representations.

Indeed, if a choice does not exist at the start of the aircraft project it is important to organize the way we make a particular choice when several options become available. Do I select a surrogate representation of the structure, or a full 3D model? Does a 3D model derives from a preliminary simplified representation, or vice versa: surrogate versus 3D is not only a difference in the maturity of the study; it can be a preference in respect of the analysis performance associated with the precision on the expected result. The M&S workgroup in charge of this capability has developed the Pyramid of Models organization that can be seen at process-oriented libraries of models that the Flexible Generation aspect will query when a possible choice occurs.(Figure 6)

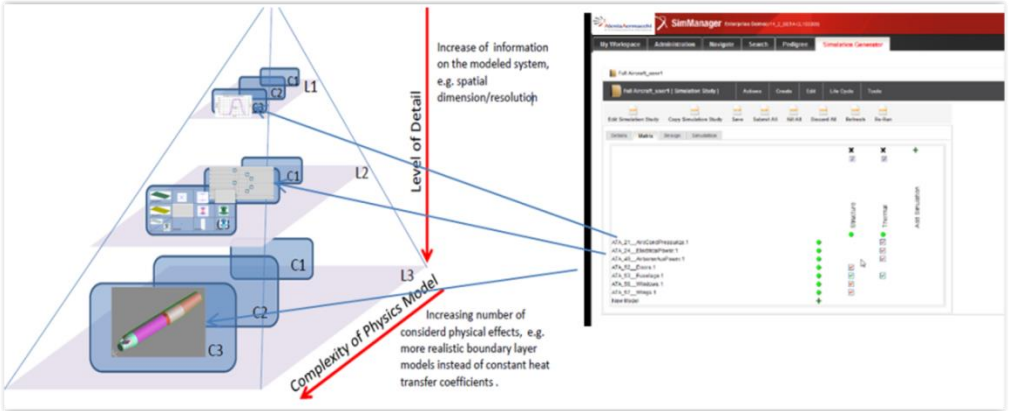

Figure 6: Pyramid of Models Serving the Flexible Model Assembly Generation

This coupled solution enables framework of model usage to sustain NEO scenario with the Multi-Disciplinary architectural/behavioral representation of the complete aircraft, in any operating conditions.

During the implementation of NEO use case detailed in this paper, we will see a second aspect of Flexible Model Generation directly applied to a more commonly understood geometry parameterization, driving a parametric simulation model. In that respect TOICA has capitalized on methodology introduced by Airbus and enhanced in a European project from framework program seven named MAAXIMUS [3].This approach is to use external shapes and add Design Parametric Objects (DPOs) of structural components like, ribs, holes, stiffeners or corners piece reinforcements

Then for each DPO an excel design table (DT) is created with associated parameters and each parameter of the DTs can be linked through excel with others if needed, or with parameters associated to an external shape and logged into an xml format.

Diving more into the details: we know that the scenario has to be driven by a Multi-Disciplinary Optimization (MDO) and Multi-Level as well as accounting for optimization and coupling aspects, using the TOICA M&S capabilities. We will not elaborate this optimization method because it is covered by a "conventional" Design of Experiment approach. Therefore, we focus attention to the fashion in which simulations are coupled.

Indeed, we have already described benefits of Flexible Model, assembling components from libraries organized as a Pyramid of Models. What we have dropped so far was the magic to make dissimilar idealization components compatible for the execution of a coupled run. In the context of NEO such integration has been performed by the creation of behavioural libraries and surrogate models that will enable exchange though "MoSSEC" connectors. This "interface" component, in the generation of the model, becomes one of the possible "variability" or parameter of the Flexible Model. It means here that if Architect view of the aircraft is:

- Pylon Structure +Interfaces+ Equipment + Operational Scenario

The representation for a simulation of a trade study can be for instance upon choice of equipment partner's CAE preferred domain tools:

- Pylon Structure(Solver A) + Interface (Solver A to B) + Equipment(Solver B) + Loads &Boundary Conditions
- Pylon Structure (Solver A) + Interface (Solver A to C) + Equipment(Solver C) + Loads & Boundary Conditions

As we need to enlarge Flexible Model to the concept of Architectural Model, the method needs to sustain not only coupling of models via an "interface component" but also functional models for which one change is going to impact more than, for instance the definition of model itself (more electrical components…) . Flexible Model will then be supported by Super Integration, which will be demonstrated in future TOICA plateaus.

Finally, we will close this presentation of TOICA capabilities complementarity, as well as their mapping to the use case needs pointing onto risk reduction one. It is the final touch to empower stakeholders and ultimately architects to trace information and decision associated with the KPIs.

3.4 Scenario implementation example

Consistently with capability mapping, the cornerstone component of the scenario implementation has been the Architects' Cockpit. Choice has been made on MSC SimManager interacting with SimManager as the SLM for the pylon multi-disciplinary trade-off and another PLM technologies representing legacy or extended enterprise platforms. This will enable the demonstration of TOICA collaborative philosophy, throughout the exposure of a communication to a SimManager server across APIs that are MoSSEC compliant, as demonstrated in CRESENDO [2]. Then a key core product functionality known as "Assemble&Simulate" that

enables in the simulation context to glue model components together for a particular simulation scheme(parts idealization, connectors ,loads, constrains, materials, solver parameters, key results to extract, report to generate) before to automatically submit a job and retrieve the outputs, has been extended to an "Assemble&WorkRequest". As such it is behaving in the same way in respect of an architecture model to define, populate with datasets and associate to a trade study, requests to be sent to other actors.

Knowing that SimManager work request are by design mapped to MoSSEC model network representation, the solution can be implemented in a context of the extended enterprise for which the trade study demand is conveyed then to the partner by a MoSSEC web service.

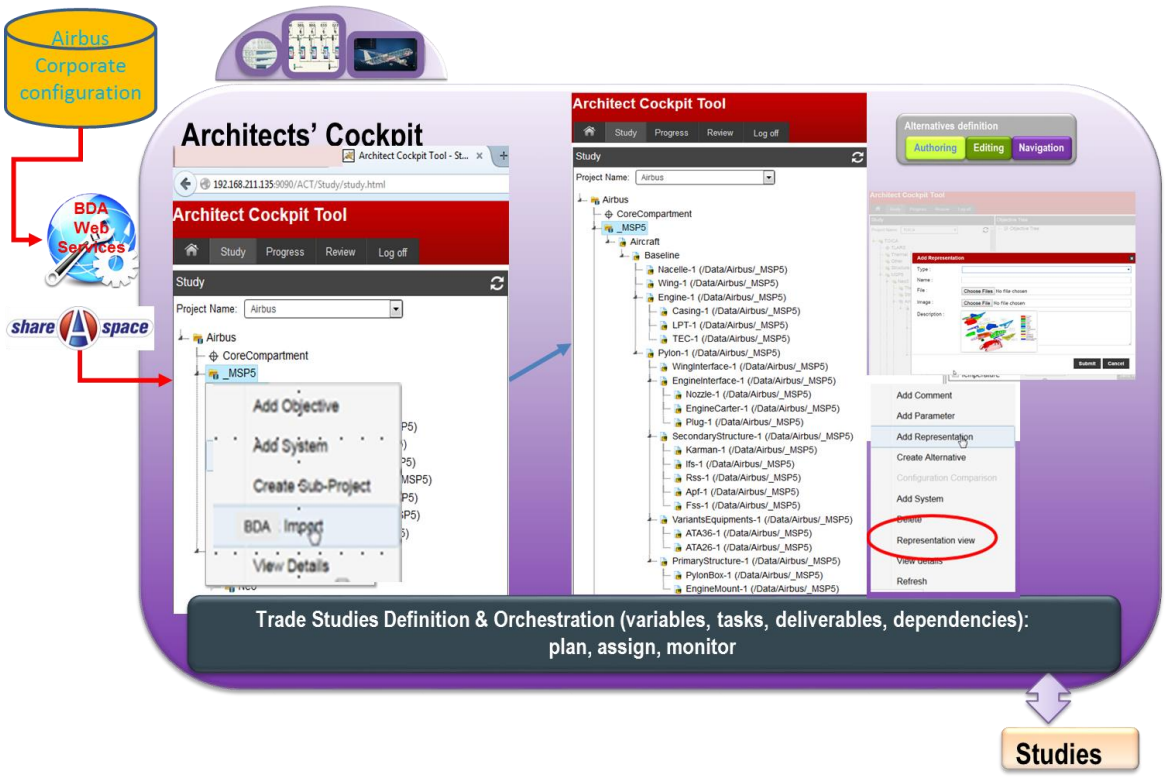

Figure 7: Illustration of Architects' Cockpit leveraging Flexible Model Assembly from functional architecture vs scenario

Representation can be updated by right clicking on a model component in order to browse the "MoSSEC" libraries (Pyramid of Model & Super Integration) and select the preferred available level to be used in the study. User interface also allows for variant generation for instance by dragging and dropping an existing instance prior to define the variable parameters and update the master consequently. (Figure 7)

Same kind of sequence is applicable to any layer of architects in the scenario, knowing that each time a request is made to actors, a notification is send which allows next stake holder to update the detail of the model in respect of its domain of concerns.

And finally, Architects' Cockpit will monitor study request execution, checking each task status (pending, running, completed, aborted…) in respect of planning. Each task can report objects, returned to the requester by the actor in charge of a particular aspect of the study. Of course, a result (temperature, width impact…), or a report of combined information can help to sustain a documented decision, in between additional milestone feedback like validation gates can also be controlled. Knowing that communication here again is managed by

MoSSEC associative model network (AMN) [2], it is possible to sink two activities with a filter on the granularity of details, and the representation of information exchanged.

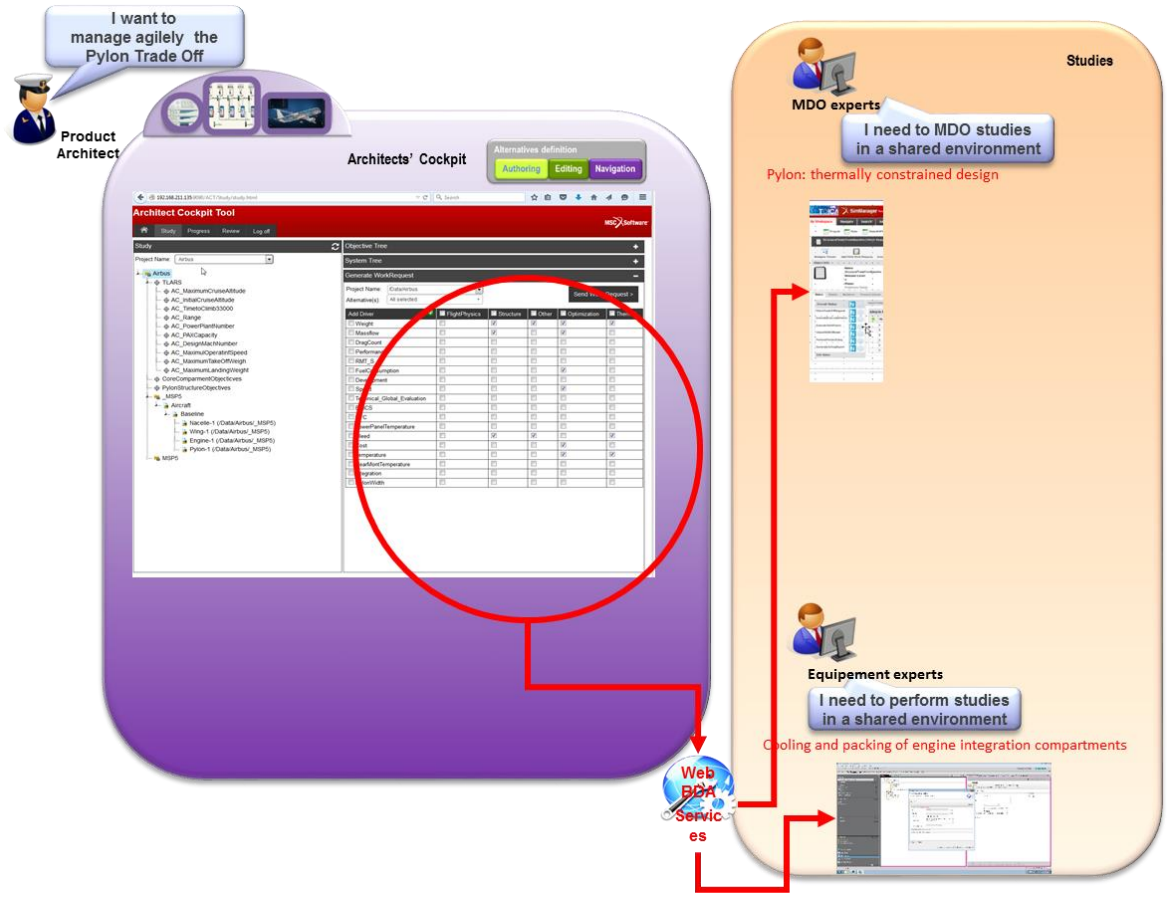

Figure 8: Multi-Level process granularity from Architects' Cockpit to SLM

The first use of AMN allows architect to safely trace simulation expert answers without any burden on CAE domain know how has shown in Figure 8, while the second way of use empowers Intellectual Property Right preservation by the mean of behavioral representation along the collaboration.

The second enabler, we will detail is the Flexible Model Generation applied this time to Simulation domain. In order here to address need for multiple variant on a geometrically parameterized model, we have developed around MSC SimXpert, a tool that can (Figure 9):

- Read an aircraft geometry and associated parametrization relying on DPOs as introduced in chapter 3.3
- Leverage the Airbus patented ways in associating them to Parameterized Geometric Support (PGS): a child CAD model of the DMU associated to DTs representing part of the physics [5].

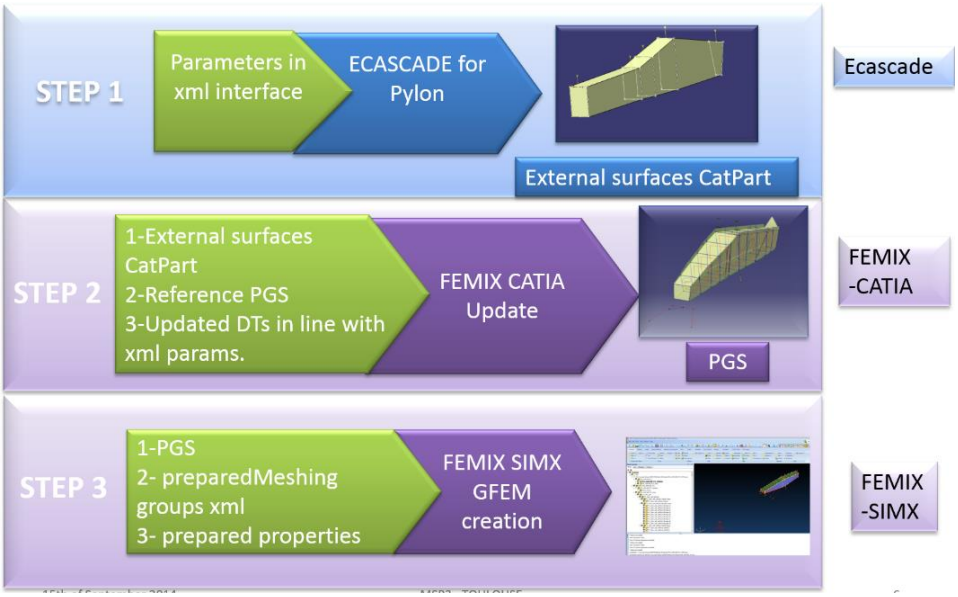

Figure 9: Airbus FEMIX based Flexible Model Generation

Multi-Level Coupling is managed then by an extension of FEMIX capabilities to the DPOs relevant to the various additional domains like thermal one (by the way FEMIX for non-purely structural solution has been demonstrated as well in CRESCENDO for Acoustics), and the optimization "block" is implemented by coupling a Nastran SOL200 Finite Element Model run to the Sizing process (second level of optimization) within Airbus Sizing legacy environment by the mean of Nastran DRESP3.

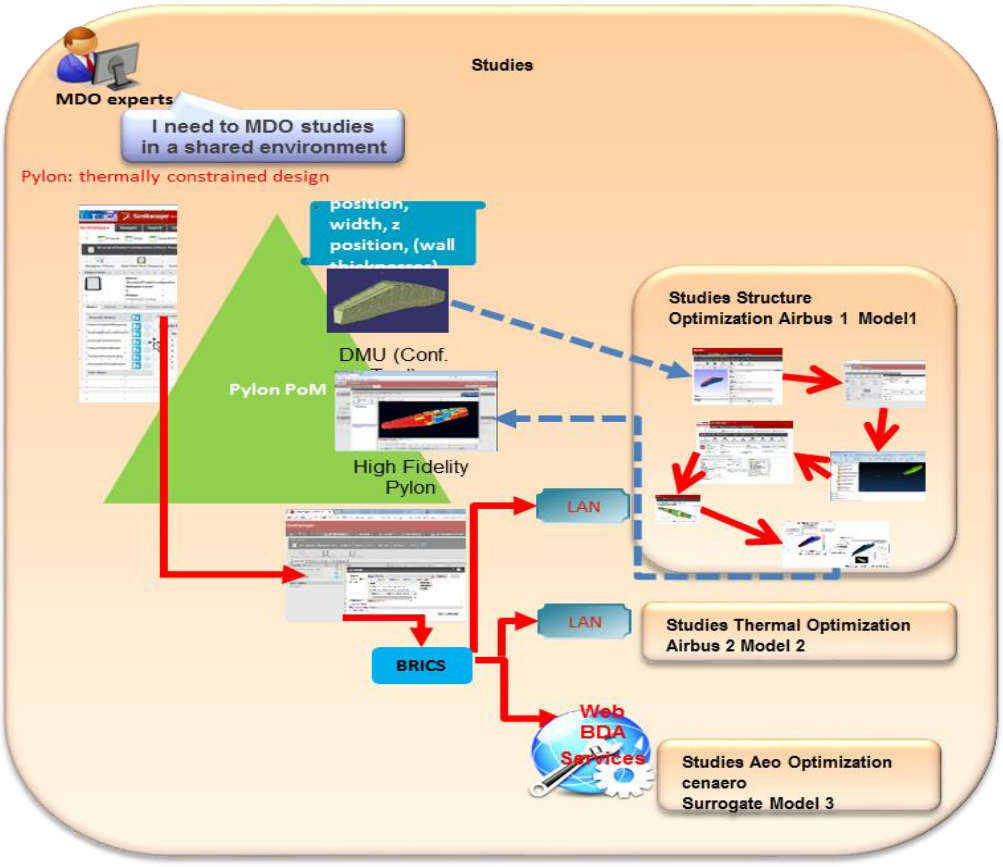

Figure 10: Multi-Level Multi-Disciplinary process

Along the 5th plateau (MSP5) execution, SimManager took into account the collaborative MDO distribution of surrogate models for the structural, thermal and aero domains in one hand, while it was driving on the other hand, the structural optimization to sizing process. As illustrated in Figure10. This was achieved with support from NLR's tool named BRICS [6] and Cenaero's platform known as MINAMO. The flexible model capability from SimXpert has matured and will execute a full automatic coupling of the structural optimization process with thermal and aero surrogate models at horizon of 6th plateau.

In that scenario, the post processing with architects' cockpit and risk reduction associated to value assessment were also demonstrated for MSP5. (Figure 11)

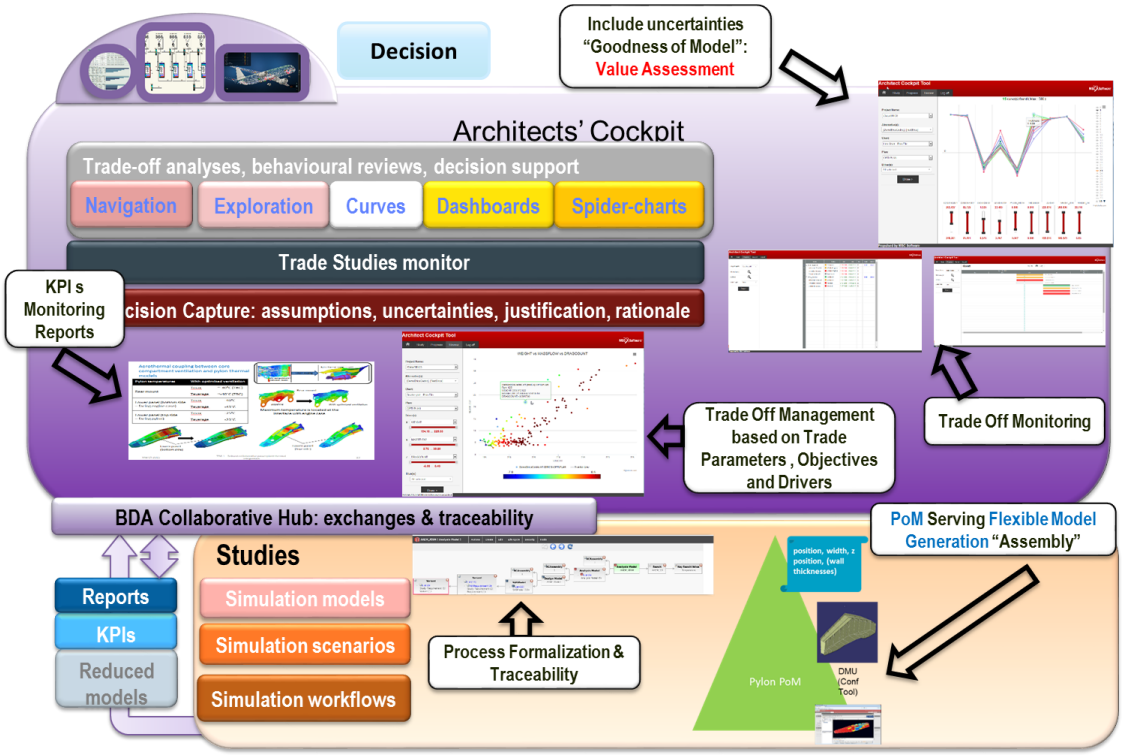

Figure 11: Trade-off decision and value assessment interaction

4 CONCLUSIONS

Through the review of one of the Airbus Use Cases, we have illustrated the relevance and benefit of TOICA capabilities, whether it relates to their interactions through MoSSEC as a standard for collaboration, or independently operating as M&S innovations.

A strong point has been made on the fact that TOICA capabilities, though split by project WBS to optimize consortium knowhow and resources, are not totally independent and conjointly contribute to TOICA high-level objectives.

In particular Flexible Model associated to Pyramid of Models and Coupling in the simulation world; as well as Super Integration from Architecture perspective is a Key enabler of Architects' Cockpit: a pillar of TOICA.

It is important to notice that between mid-term project presented in previous papers [9] and outcome of 5th plateau detailed in chapter 3, the solutions have matured to higher level of maturity. Indeed the referenced demonstration executed by end users themselves, within an IT infrastructure exact image of their industrial working environment, enabled validation of a

TLR4, for Architect's Cockpit and Flexible Model capabilities acting here in a tight interaction. This trend is expected to mature even more for the last plateau to be held just before this paper is publicly presented.

5 ACKNOWLEDGEMENT

The authors from Airbus and MSC thank their colleagues and partners involved in the use cases described, for their contribution to this work. Namely we were able to capitalize on NLR's technology for the distribution of MDO request, while Design of Experiment was conducted by Cenaero's framework.

We also would like to show our gratitude to Sanjiv Sharma (Airbus Operations Limited), Jean-Claude Dunyach and Pierre Arbez (Airbus Operations SAS) for their contribution to the project description within this paper.

Keywords: Collaborative Simulation, Thermal Analysis, TOICA EU FP7 Project, Cross-Organisation Workflow, Surrogate Modelling, Fuel Tank Thermal Modelling.

Abstract. *The TOICA EU FP7 project focuses on developing capabilities that support aircraft manufacturers and their supply chain in jointly performing thermal analyses of aircraft architectures. Collaboration capabilities and related multi-disciplinary modelling and simulation technologies are key pillars for joint thermal analyses. The paper describes two such capabilities: surrogate modelling and smooth cross-organisation workflow execution. These capabilities have been further developed based on TOICA needs. The integrated application of the capabilities is illustrated in the context of an aircraft wing fuel tank thermal analysis conducted in TOICA.*

1 INTRODUCTION

Aeronautics research and technology development programs generally involve collaboration among different organisations, in order to include all required skills from the supply chain, to share risks and costs and to timely and efficiently develop innovative products. To achieve the challenging objectives of contemporary and future aeronautics, and to maintain global industrial leadership [1], a high level of integrated system design of the aircraft and its subsystems is needed. This requires a continuously increased level of collaborative engineering through modelling and simulation along the supply chain in order to improve cost and time efficiency and to reduce the integration risk in later phases. Teams of engineers from various disciplines and organisations are supposed to collaborate across organisational and geographical boundaries. The size and complexity of aircraft programs, the market demands, and the competition in the market require the collaboration to be effective and efficient, while obeying security constraints and preserving the intellectual property of the supply chain members.

To achieve a step change in the way multi-disciplinary teams in an extended enterprise carry out modelling and simulation processes, several capabilities that support collaboration and multi-disciplinary modelling and simulation were developed in the context of the TOICA EU FP7 project. TOICA develops these capabilities for application in the thermal analysis of aircraft architectures and validates them on realistic thermal use cases. The need for thermal analysis of aircraft architectures has emerged from the increased application in aircraft of technologies that strongly impact the thermal behaviour of the aircraft.

Collaborative engineering through modelling and simulation along the supply chain has to deal with two opposite goals. Firstly, the supply members want to protect their intellectual property rights (IPR) amongst each other, whereas more integrated simulation may ask for more and agile exchange of data among the supply chain. Secondly, security policies at the supply chain members limit access to simulation resources, whereas increased collaboration asks for well-established simulation workflows across the supply chain that support reproducibility and traceability of simulation data and processes.

In the TOICA project, the Netherlands Aerospace Centre NLR developed and applied two innovative technologies that enable collaborative engineering through modelling and simulation, while respecting IPR and security policies among the supply chain: the Brics capability and surrogate modelling. Brics enables multi-disciplinary and multi-partner engineering teams achieving cross-organisational simulation workflows while dealing with security constraints and measures of the involved organisations. Surrogate modelling is an effective method for reducing a complex simulation model to a ‘light’ version, which may respect IPR policies and can be exchanged easily among the supply chain. A surrogate model is specifically useful for extensive trade-off studies at aircraft level during conceptual design (as in TOICA), since a surrogate model requires low computational efforts.

The two innovative technologies are illustrated on the realistic use case of fuel tank thermal modelling, which was set up in the abovementioned TOICA project. This use case is driven by the needs to investigate the potential of fuel as heat sink and to support certification of a wing fuel tank that is made from non-aluminium materials. The potential of fuel as heat sink is limited by thermal constraints due to certification requirements. In case of novel materials for the fuel tank extensive testing and/or detailed thermal analysis is necessary to determine the bulk fuel tank thermal behaviour for different flight cases.

Section 2 will introduce the TOICA project, the fuel tank thermal modelling use case, and the problems and challenges that have led to the development of the Brics and surrogate modelling technologies. Sections 3 and 4 describe the backgrounds, details, and realistic example

applications of Brics and surrogate modelling, respectively. Section 5 describes the integrated application of the two technologies to the fuel tank thermal modelling use case. Section 6 presents conclusions.

2 OUTLINING THE CONTEXT

This section describes the context and rationale of the study of which the results are presented in this paper. Subsection 2.1 introduces the TOICA project. Subsection 2.2 introduces the fuel tank thermal modelling use case. Subsection 2.3 describes the problems and challenges that have led to the development of the two innovative capabilities addressed in this paper.

2.1 Introduction to TOICA

Thermal behaviour has become a crucial topic in the development of modern aircraft. This is due to the increasing number of complex systems required by modern, more electric commercial aircraft, the introduction of hotter engines with higher by-pass ratios, the increased use of composite material in aircraft structures, and the confinement of highly dissipative equipment and systems in smaller areas, to save space for passengers and cargo. New advanced techniques to manage the aircraft thermal behaviour at the early stages of development are essential to take the right configuration decisions while meeting market demands.

The 'Thermal Overall Integrated Conception of Aircraft' (TOICA) EU FP7 project intends to change the way thermal studies are performed within the aircraft design processes [2]. The project focuses on the creation and management of new aircraft architectures, including thermal analysis and trade-off studies of such architectures, via a so-called "Architect's Cockpit" as depicted in Figure 1. The thermal analyses require collaborative effort from the supply chain involved in the development of modern aircraft. The TOICA project develops advanced capabilities to support the collaborative analyses.

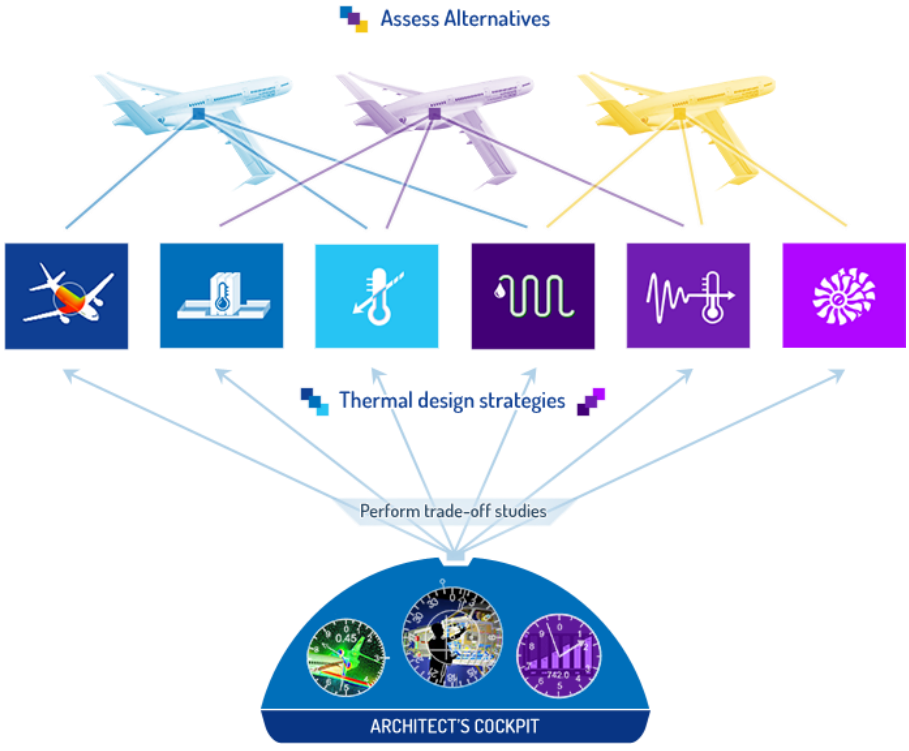

Figure 1: Depiction of the TOICA Thermal Architect's Cockpit that enables collaborative thermal trade-off studies (source: [2])

2.2 The fuel tank leading edge case

The use case addressed in this paper is related to one of the use cases of the TOICA project: using fuel as a heat sink for waste heat from other systems. This may raise certification issues with regards to the fuel tank, especially if innovative, non-aluminium materials are involved. Therefore, part of the TOICA use case is dedicated to the integrated analysis of the thermal behaviour of a wing fuel tank. The applicable wing fuel tank thermal model is part of the Alenia Thermal Aircraft Model lead by Finmeccanica's Aircraft Division. To comply with certification standards of a wing fuel tank that is made from non-aluminium materials, extensive testing and/or detailed thermal analysis is necessary to determine the bulk fuel tank thermal behaviour for different flight cases. The methodology for the fuel tank thermal characteristics evaluation shall indicate - during the aircraft preliminary design phase – whether or not a flammability reduction means (FRM) is needed.

Figure 2 depicts a 3D schematic view of a wing fuel tank and leading edge. The tank is filled with fuel up to a certain level. Consequently, there remains a part of the tank that is not filled with fuel, but which may contain fuel vapour. This part is called the 'ullage'. The tank compartment is separated from the leading edge compartment by a spar. Within the leading edge compartment a bleed pipe resides that transports hot air from the engine. The bleed pipe causes the fuel and the ullage to heat up when the engine is switched on. Furthermore, other heat sources such as solar radiation on the wing may cause the fuel and the ullage to heat up. All such heat sources need to be taken into account into the integrated thermal analysis of the wing fuel tank.

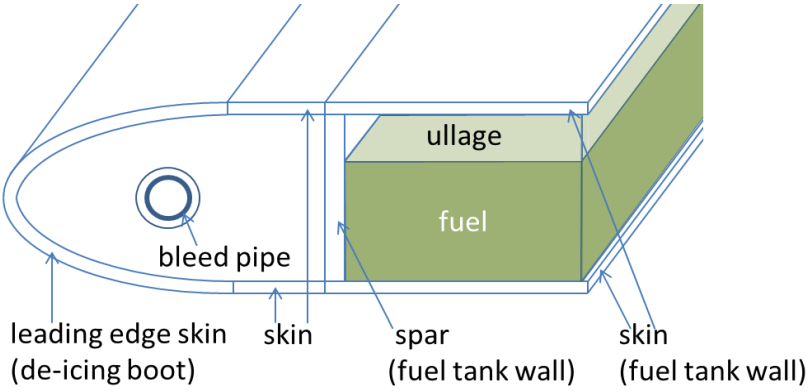

Figure 2: Schematic of the wing fuel tank. The bleed pipe is located in front of the wing fuel tank. The bleed pipe causes the fuel and ullage, i.e., the unfilled part of the tank, inside the tank to heat up.

The thermal analyses are performed at two levels:

- Detailed thermal analysis by calculating the three-dimensional temperature profiles via structural Finite Element Analysis (FEA) and Computational Fluid Dynamics (CFD).
- Quick thermal analysis and prediction of the bulk temperature via a nodal model, applying a thermal network approach. The nodal model must be validated by the detailed thermal analysis. An efficient and sufficiently accurate model is needed for applying the analysis during the aircraft predesign phase.

Both analysis levels rely on accurate boundary condition estimations for the fuel tank structure. Therefore, the effect of heat sources that are located close to the tank (e.g. the bleed pipe) is modelled to identify hot spots on the boundary of the fuel tank due to external heat sources.

On the detailed level this estimation is supported by a model of the wing leading edge. This model is described in further detail in subsection 5.1. On the quick analysis level the estimation is performed by a surrogate model of the wing leading edge. The derivation of the surrogate model is described in subsection 5.2.

Figure 3 provides a scheme of simulation models that are involved in the fuel tank thermal analysis together with their interrelations and thermal coupling. The different simulation models depicted in Figure 3 have been developed by different partners with different tooling: University of Padova using StarCCM+ for the fuel tank CFD model, Siemens Industry Software using LMS Imagine.Lab Amesim™ for the fuel tank nodal model, and NLR using Abaqus for the fuel tank structure FEA model and for the leading edge FEA/CFD model. The latter model is addressed in this paper. In the ideal situation these models run all at one physical location: at the aircraft manufacturer. However, if this is not the case, collaborative engineering technologies can facilitate an efficient integration workflow/process. Various reasons for such collaborative multi-partner approach will be explained for the general case in the next section.

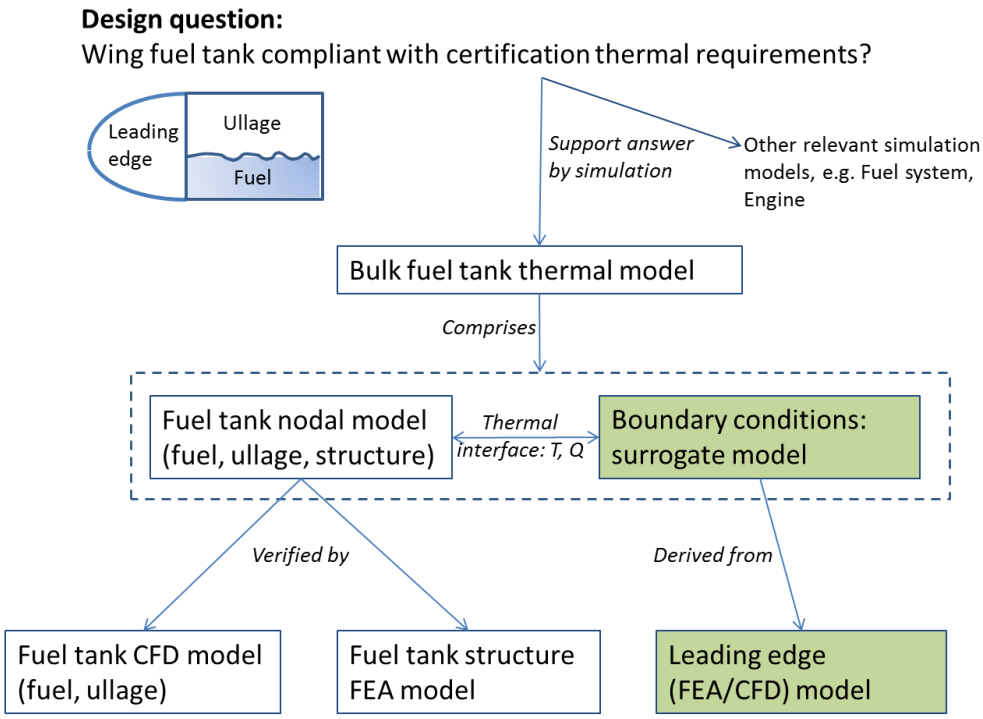

Figure 3: Model coupling and relation scheme of the fuel tank thermal analysis. The models in the green blocks will be further detailed in this paper (see section 5).

2.3 Problem description and challenge

Collaborative modelling and simulation in aeronautical industry with a multi-disciplinary, multi-organisational and multi-site engineering team are commonly hampered by security constraints, protection of intellectual property, and dependency on simulation tools and complex simulation models that are expensive to run. Several research projects in the EU framework programmes, such as VIVACE, CESAR, and CRESCENDO have been dedicated to development of innovative concepts and technologies that support collaborative engineering processes in the aerospace context. In the context of TOICA, NLR addressed two particular aspects: distributed collaboration technologies and cost and time efficient simulation technologies.

With respect to distributed collaboration, NLR investigated the limitations of cross-organisation collaborative engineering resulting from the fact that organisations are protective with respect to access to their own assets. Due to a variety of security constraints imposed by the connected organisations, running a simulation workflow that comprises tools at the different organisations is not obvious. Organisational rules and fire wall settings seem to make participation of a partner in a cross-organisation simulation workflow difficult or even impossible. NLR's challenge in this respect is to facilitate and smoothen the execution of cross-organisation workflows while dealing and complying with the policy and rules of the involved organisations. The approach is outlined in section 3.

NLR also focussed on cost and time efficient simulation technologies. These are often a challenge within aeronautic design. Models that describe the behaviour of an aircraft component in detail are usually expensive to run. They may be dependent on specific simulation tools and difficult to interface with other models. This makes it difficult to apply them in trade-off studies on aircraft level. Furthermore, they may not be shared with partners in order to protect the company's knowledge that lies behind the model. Surrogate modelling can provide a solution to these challenges. In order to achieve cost and time efficient simulation technologies NLR's objective is to develop surrogate models in such way that:

- the generated models have an appropriate accuracy (fit for purpose),
- the generated models are efficient (computationally cheap),
- intellectual property of the detailed model owner is protected,
- integration and model derivation effort is minimal, and
- both transient and steady-state thermal behaviour can be simulated.

This capability is presented in section 4.

Both capabilities will be illustrated by separate application examples in the frame of TOICA. Furthermore, their integrated application in the context of the fuel tank leading edge use case is described in subsection 5.3.

3 SMOOTH EXECUTION OF CROSS-ORGANISATION WORKFLOWS

This section introduces Brics as capability for the support of smooth execution of cross-organisation workflows. A quick, high-level introduction to Brics, describing its rationale and a global overview is given in subsection 3.1. A more detailed description of Brics is given in subsection 3.2. Implementation aspects of Brics are described in subsection 3.3. A first realistic example application of Brics in the context of a distributed MDO study is briefly presented in subsection 3.4. The application of Brics in the context of fuel tank thermal modelling is described in subsection 5.3.

3.1 Cross-organisation collaboration challenges

Collaborative engineering activities and simulation workflows are largely supported by information and communication technology and software tools. But making cross-organisation collaborative engineering efficient and effective in practice requires a step change. For example, collaborative workflows typically span the networks of the collaborating organisations. The workflows would ideally run seamlessly across the networks of these organisations. However, with the current complexity of design, analysis and simulation tools and workflows it is difficult to be compatible with the varying security settings and the variety thereof. Engineers are facing unintended security restrictions due to security rules, fire walls and proxy servers. These restrictions help organisations protecting their assets and intellectual properties and obeying legislation and regulations. In practice, aircraft collaborative design teams end up in using standard facilities, such as e-mail and FTP servers, and in dealing with IT depart-

ments and security officers that seem unwilling to cooperate. From an aircraft program technical point of view, effective and efficient collaboration in the jungle of security rules, measures and technologies is a big challenge. This challenge has been the point of departure for the development of Brics.

NLR has long history of experiences in supporting the realisation of cross-organisation workflows. The knowledge, expertise and reusable solutions have been collected in, and are being deployed through Brics. In a nutshell, Brics targets to achieve smooth and secure execution of cross-organisational multi-partner collaborative workflows. It enables all engineering partners to participate, even if they are "network access restricted" because of security measures [3]. At the same time, Brics complies with the security constraints of the organisations involved. Brics also aims to allow each partner to have full control over its own resources, including computing resources, on-line data, and software tools. This means that organisations do not have to put their resources under management of Brics, any cross-organisation workflow nor any umbrella authority. The resources may be deployed on behalf of cross-organisation workflows only under full control of the organisation's own employees. Brics caters for a "man-in-the-loop", as is shown in Figure 4.

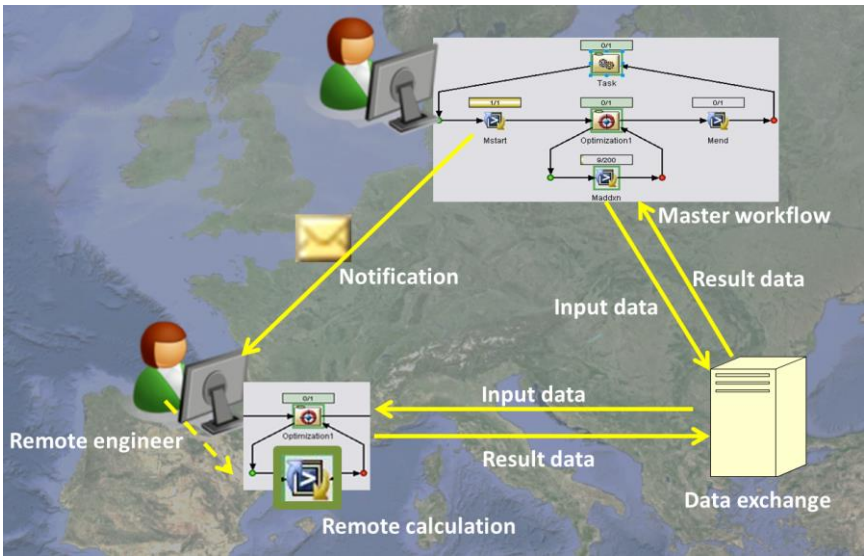

Figure 4: Schematic overview of the basic idea behind Brics: performing a remote calculation from within a "master" workflow by sending a notification to a remote engineer, who may decide on whether or not perform an action or a series of similar actions. Brics in addition facilitates the orchestration of the remote job and the data exchanges involved.

The "evolution" of Brics started more than ten years ago, in research projects aimed at establishing virtual or extended enterprises in the support of collaborative engineering activities (VIVACE[4], CESAR[5], CRESCENDO[6]). Cross-organisation collaboration used to be mainly based on the exchange of data files via e-mail, FTP servers, websites for information exchange and collaboration (e.g., SharePoint), product lifecycle management and support systems, telecon and videoconference systems. In some cases it involved the shared use of tools, workflows and data on centralised systems. Commercial workflow management tools are available to support cross-organisation workflows but generally put heavy demands on the interconnectivity of the systems and organisation networks involved. They usually enforce the collaborating partners to install and use the same tool.

Brics has evolved and still is evolving "on the job". This means that it is being developed in projects that target or apply collaborative engineering activities and workflows. Its devel-

opment is fed by needs and requirements that come from projects, use cases, and engineering teams that involve more and more cross-organisation collaborative engineering while facing ever increasing security constraints. Through the years, the security rules and mechanisms have become and still are becoming stricter. At the same time, partners in collaborations want to persist using their own processes, methods and tools, even while fulfilling their role in collaborations and collaborative workflows. This will enable them to fully exploit their own expertise and to pursue their own way of working, but on the other hand leads to more and more heterogeneous environments to be dealt with in collaborations. The two growing barriers of security and heterogeneity have fed and still feed the ongoing evolution of Brics.

3.2 Brics technology to support cross-organisation collaborative workflows

Brics comprises protocols and supporting middleware that facilitate remote execution of tools and workflows. The remote execution involves sending of notifications to remote engineers, exchange of data, and synchronisation of distributed activities. Brics is based on default and standard network protocols, tools and facilities. Application of Brics has minimum "connectivity" requirements: being able to send and receive e-mail messages and to upload and download files to a file or data server that is accessible to at least one other partner. To avoid misunderstandings, Brics does not "penetrate" fire walls nor rely on known bugs in networking software or in other security means. The communication related to Brics-enabled cross-organisation workflows is fully transparent and can be explained easily to the involved IT departments and security officers upon request. Brics respects the security rules of the collaborating partners. It supports the application of secure communication technologies, it involves remote engineers explicitly and it enables the collaboration partners to have full control over their own resources. Brics can be used complementary to existing engineering tools and workflows, and does not require changes of tools, methods, and processes in organisations. These properties contribute to the possible deployment of Brics with minimum impact on the business of the connected organisations.

Brics is based on a simple protocol that arranges the execution and data flow between an orchestrating (or "master") workflow in one organisation and a remote engineer in another organisation who is assigned to execute a tool or a part of the workflow. The protocol comprises the uploading of data files that are input for a remote process, sending a notification to a remote engineer requesting the execution of a task, the synchronisation with the remote task, and the downloading of the data files that are output of the remote task; cf. Figure 5. The 'single-task' protocol is suitable for the execution of a single remote task. If the same protocol were applied in a loop, the remote engineer would repeatedly be notified to execute the same task again with slightly different input data. The handling of a consecutive series of similar notifications is cumbersome, time consuming and error prone. Brics has an extended protocol for gracefully dealing with such multi-task jobs. The 'multi-task' protocol centralises the triggering of the remote engineering into a single notification, requesting the remote engineer to execute a series of equal tasks. The protocol furthermore deals with handling the series of equal tasks and the graceful termination thereof. The protocols are described in detail in [7].

The middleware provide software methods to support the protocols. The methods can be plugged in easily as commands in scripts and tools in workflows and hence enable the use of the protocols from within scripts and workflows. The middleware supports the use of various existing mechanisms for notifications and data exchanges. It includes mechanisms to deal with proxy servers and to use permitted communication channels with the required level of security. It also includes mechanisms for relaying data files and notifications, to cater for situations in which partners have no access to particular data, file or e-mail services. The middle-

ware furthermore supports engineers in providing specific parametric calculations "as a service", for use by (possibly remote) engineers and workflows [8].

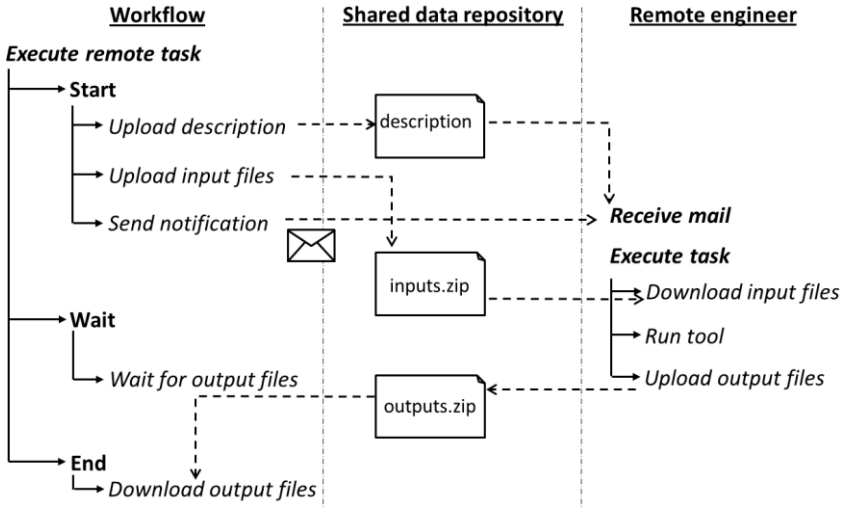

Figure 5: Simplified sequence diagram of the Brics single-task protocol.

3.3 Implementation

The Brics middleware comprises a set of Java packages with a small number of 'main' programs and interfaces. As such, Brics is operational on a variety of operating systems, including Windows, Linux, and UNIX. The Java packages enable easy integration of the middleware in Java applications and existing products. Brics has been successfully integrated in COTS and open-source workflow management and optimisation tools such as Boss Quattro, Isight/FIPER, RCE, and Optimus. The main programs include simple command interpreters that cater for interactive use of Brics as well as use of Brics from within script languages such as UNIX and Linux command scripts, Windows BAT scripts, Python, and Matlab.

To support data exchange, Brics is capable of interacting with a variety of data and file servers. Examples are FTP, MS SharePoint, Share-A-space, and shared file systems. Interfaces to other, including new and organisation-specific data exchange services, such as Airbus' FTS+ service, can be added easily at the Brics developer's level. Brics' default mechanism for notifications is e-mail. Brics has also provisions for dealing with product-specific notification mechanisms.

As might be clear from the above, Brics includes many interfaces. The middleware is also capable of communicating through a variety of – secure as well as insecure – internet communication channels. Use of Brics requires some configuration, which includes the specification of what data server and e-mail interfaces to use, web addresses and authentication information for the services, and proxy servers to deal with. The configuration information can be provided as parameters at the Java level as well as via environment variables and configuration files for the main programs and interfaces. The light-weight configuration means makes Brics an agile tool in the various collaboration settings.

3.4 Example application in a distributed MDO process

Brics has been installed in industry, research institutes, software vendors, and SMEs. It has been, and still is being applied for the implementation of cross-organisation distributed workflows in several EU and national research projects (VIVACE, CRESCENDO, CESAR, TOICA). In these projects, Brics has proven to be a valuable tool through which partners can

experience collaborative working in a flexible and easily accessible way, even in an early stage of the development of multi-partner scenarios and workflows.

Brics facilitates the transformation and integration of local workflows into cross-organisation collaborative engineering workflows, by supporting the replacement of a tool by a 'stub' that handles the remote execution of the tool as if it runs locally. Section 5.3 describes the application of Brics in thermal analysis of an aircraft wing fuel tank. A realistic example application was set up and demonstrated live in the context of TOICA [9]. In this use case, Brics has been used for the realisation of an automated multi-partner and cross-organisation distributed multidisciplinary design optimisation (MDO) workflow; see Figure 6.

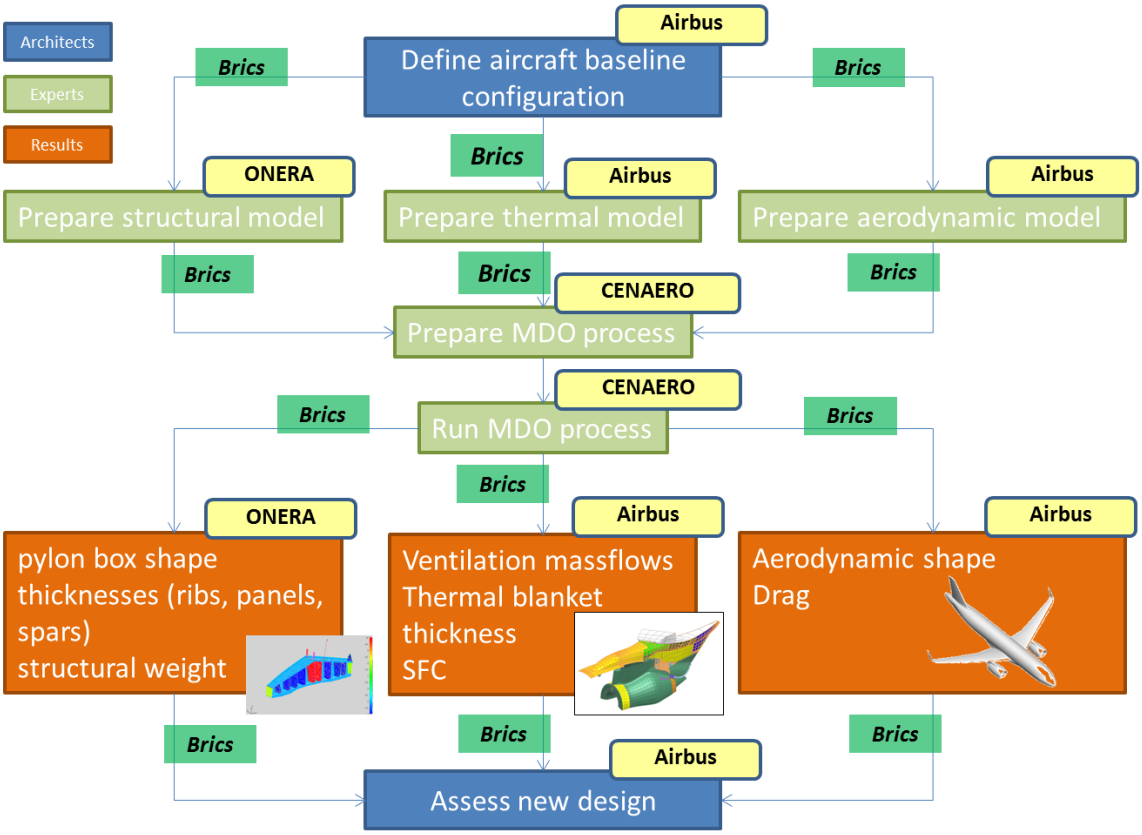

Figure 6: Overall process of preliminary design of power plant structures under thermal constraints. The process includes a distributed cross-organisation MDO workflow. The yellow boxes indicate the different partners. Note that different departments from Airbus were involved. The small green boxes indicate the role of Brics for orchestration and data exchange.

The MDO workflow serves to support the preliminary design of aircraft power plant structures under thermal conditions. The optimisation requires multiple disciplines and tools available from the aircraft OEM as well as the suppliers. The MDO workflow concerns the optimisation of an aircraft pylon design using structural, thermal as well as aerodynamic simulations. The so-called "master" workflow drives the MDO process and is operated from the OEM's site by a simulation expert. The progress of the optimisation process can be monitored by the simulation expert as well as the architect. The master workflow uses Brics to initialise the optimisation and simulation processes (tools and workflows) at the different partners. The optimisation process uses Brics to orchestrate the simulations and to manage the data exchanges in between. The remote partners use Brics to respond to the series of simulation re-

quests and to manipulate the data to be exchanged. Notifications are sent by e-mail messages, and data exchanges take place via a single shared data server located at the OEM.

Subsection 5.3 describes the application of Brics in the fuel tank modelling case introduced in section 2.2. In that case, Brics has been used in combination with the surrogate modelling techniques that are discussed in the next section.

4 SURROGATE MODELLING

This section describes the details of NLR's surrogate modelling capability. An introduction is provided in subsection 4.1. The general surrogate modelling process is presented in subsection 4.2. Subsection 4.3 focusses on surrogate modelling of time-dependent models. A first realistic TOICA application of the surrogate modelling capability is discussed briefly in subsection 4.4. The application of the capability in the context of fuel tank thermal modelling is described in subsection 5.2.

4.1 Capability introduction

A surrogate model is an approximating model that replaces a more complex simulation model. The terminology "surrogate model" is used in the context of behavioural models. It is also referred to as "reduced model". Similarly to the complex simulation model the surrogate model is a representation of the behaviour of a system. The surrogate model however aims at reducing the complexity needed to compute the system behaviour. There are several possible reasons for creating a surrogate model from a complex model:

- Numerical efficiency – A surrogate model requires less computational power than the complex model. This is specifically useful in case the model needs to be used in an optimisation loop and therefor executed many times
- Protection of intellectual property (IP) – The complex model may not be distributed to other parties because of the protection of IP. A surrogate model may be an alternative for this as it can be implemented as a black-box. The contents of the original complex model are not visible anymore.
- Ease of integration – Running a complex model may require the specific tool, which it was developed with. In several cases the model needs to be integrated with other models, developed with other tools at other organisations. These tools do not necessarily interface with each other. A surrogate model – being a simplified representation of the original complex model – can usually be integrated more easily into other tools.

One can consider two broad families of surrogate/ reduced models. First, data-fitted surrogate models are data-driven models that emulate the responses of a complex simulation model (see Figure 7). This type is applicable to this paper. Second, simulation models can also be reduced in a physics-based way. This type is not treated in detail in this paper, but is considered in TOICA e.g.:

- Model reduction by means of geometry simplification of the original CAD model; see [10] and [11].
- Model reduction by means of thermal nodal modelling; see [12] for an explanation.

In aeronautic design surrogate models are usually applied as part of a design optimisation loop. In some cases the surrogate models are adapted on the fly as part of the optimisation algorithm: so-called adaptive surrogate models. Another frequent application is the creation of surrogate models as part of data analysis and statistics. A surrogate model is then directly derived from experimental data in order to predict a certain behaviour that is under investigation [13].

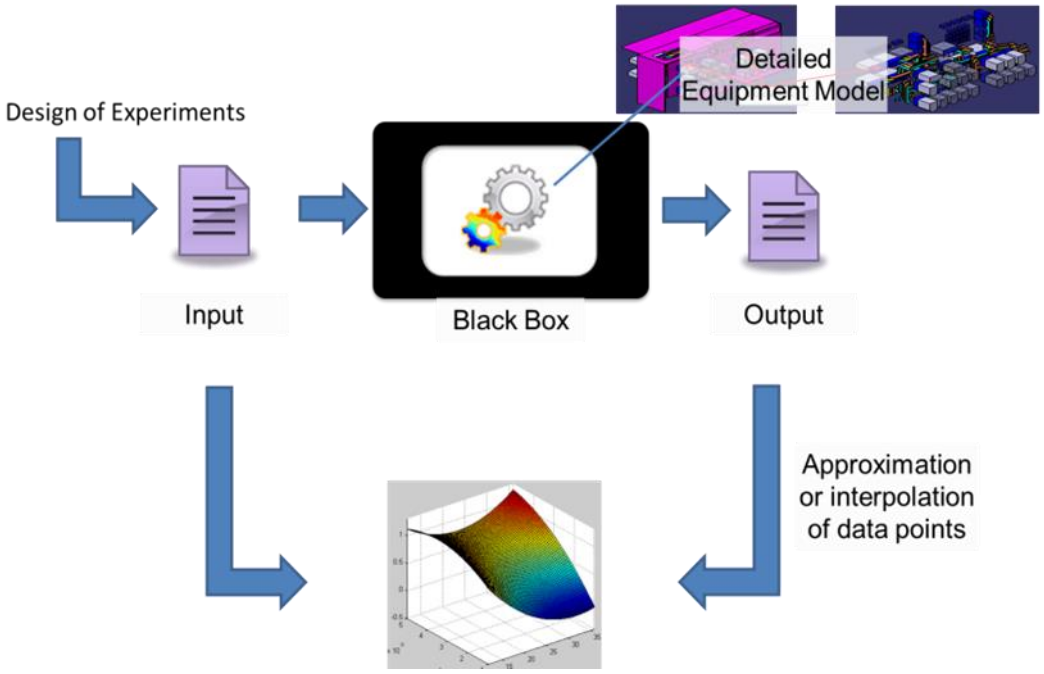

Figure 7: Illustration of data-fitted surrogate model derived from a detailed model of an equipment behaviour.

Organisations that need to create surrogate models develop their own tools for it or use commercial-off-the-shelf (COTS) software packages. Several steps in the surrogate modelling process can indeed be performed automatically (see also subsection 4.2), but to derive a surrogate model that is fit for purpose the involvement of experts is still essential. Expert judgment is needed as the choice for the most appropriate data fitting method depends very much on the data set that is to be fitted. NLR has long experience in developing and applying surrogate models based on data fitting from various EU research projects (e.g., POA[14], ICE[13], VIVACE[15], CRESCENDO[16], MAAXIMUS[17]).

4.2 Workflow for surrogate model derivation

The derivation of a surrogate model comprises several steps. When a surrogate model is derived from a set of input/output data of the complex model, the sampling of the data points is based on a so called Design of Experiments (DoE). The DoE is a crucial ingredient of the surrogate generation process, especially when the function evaluations are expensive. It should provide sufficient variation in the input values to cover the desired input range because it must contain as much information as possible. Examples of DoE methods are full or fractional factorial designs, Latin Hypercube Sampling (LHS) or D-optimal methods. Based on the DoE a database is derived that contains the results (input and output data) of the sequence of simulations with the complex model.

The surrogate model itself is derived by fitting the set of input-output data. For this several fitting techniques exist. The most common is polynomial regression, also referred to as response surface method. Other methods have been developed with more complicated analytical expressions like artificial neural networks, kriging, radial basis functions, splines, etc. The methods can be divided in *interpolation* and *approximation* methods. In case of interpolation the resulting surrogate model exactly matches the data points from which it was created with estimations in between those data points. In case of approximation the surrogate model does not exactly match the data points but approximates them as well as the space in between. The feasibility of a fit method depends on the nature of the data set: high or low dimensional,

sampled in a grid or scattered, noisy or clean, sampled in a sparse or dense manner (referring to the DoE), etc.

The fitting process is usually supported by dedicated software tools that statistically analyse and pre-process the data set, provide multiple fit methods and facilitate a fit assessment to select the best method with the appropriate settings. At NLR the MATLAB based in-house fitting tool MultiFit[15] is used. The assessment of a candidate surrogate model is performed by excluding a number of points of the data set from the fit and reserving them for validation afterwards by comparing the surrogate prediction in these points with the true values. This validation data set can be shifted across the complete data set to have a better validation range: cross-validation Several error metrics are available to represent the validation, e.g. Root Mean Square Error (RMSE), Mean Absolute Percentage Error (MAPE), R-squared test and quantile tests.

Figure 8 shows the identified steps that constitute the generic surrogate modelling workflow. Almost all steps are implemented using MATLAB. Only the runs with the high-fidelity model depend on its particular enabler (e.g. CFD or FEA computations). These runs can be orchestrated and linked into the surrogate modelling workflow using Brics. Such integration is detailed in subsection 5.3.

The resulting surrogate models are represented with analytical functions, calculating an output prediction in one step. As such they require very low computational effort.

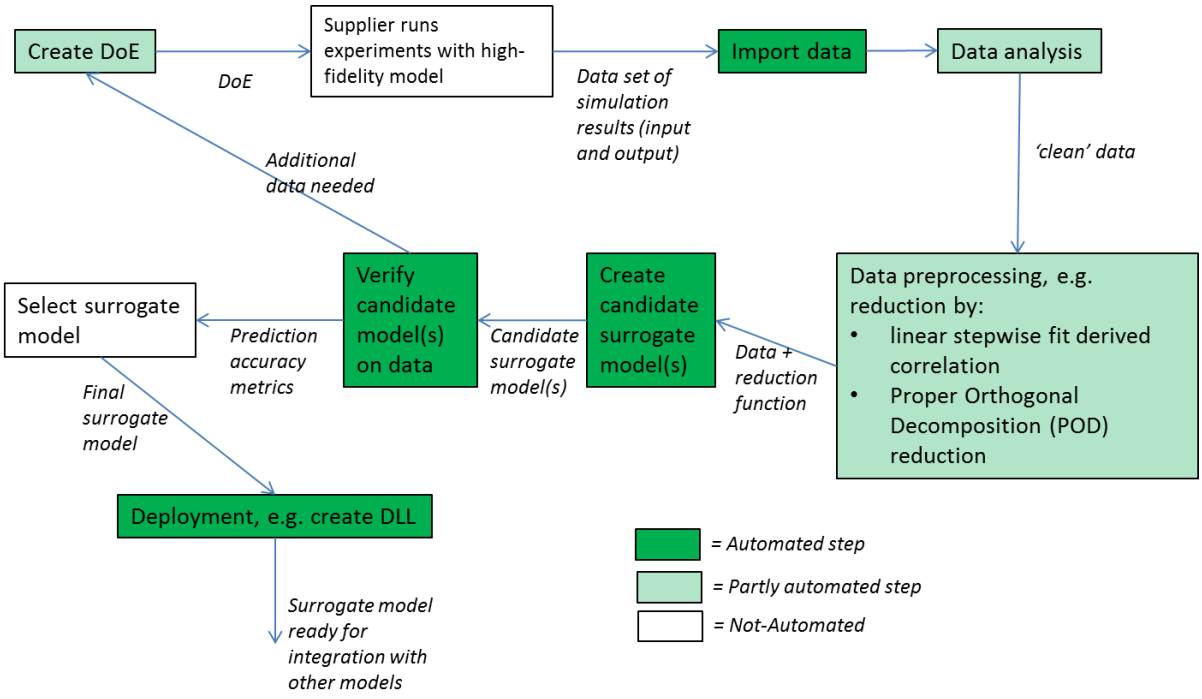

Figure 8: Generic workflow for deriving a surrogate model.

The surrogate models are by default available as MATLAB analytical functions, since they were created in the MATLAB environment. They have been exported as C type DLL or executable file using the MATLAB Coder. The export makes the model a black box and easy to integrate with other simulation tools, e.g. as Functional Mock-up Unit [18].

4.3 Transient surrogate modelling

In most cases data-based surrogate models are applied in the context of a steady-state analysis of system behaviour. During TOICA a method has been developed for creating transient surrogate models. This means that the surrogate model is able to capture time-dependent behaviour, specifically in short intervals of time (dynamic behaviour). The transient surrogate modelling problem is formulated as follows. Derive a function *f* such that

$$y(t) \approx f(y(t-\Delta t), u(t), u(t-\Delta t), \Delta t), \tag{1}$$

with *y* the vector of output variables, *u* the vector of input variables, *t* the simulation time and Δt a time step. For simplicity reasons only one time delay Δt of *u* and *y* is added in equation 1 but one could also consider multiple time delays here. In the context of thermal analysis *y* usually represents a temperature field whereas *u* represents boundary temperatures and/or heat flows.

The creation of a transient surrogate model gives rise to a significant increase of data, because complete time histories of the model inputs and outputs are needed to derive a surrogate model. Furthermore the dimensions of *u* and *y* may be very high, e.g. if complete temperature fields on a structure are to be predicted. In general, the more input dependencies need to be taken into account by the surrogate model, the more data points are needed. In many cases a large number of simulations is not feasible, because of the computational cost (e.g. CFD runs). In such cases it is useful to analyse whether the dimensionality of the inputs and outputs can be reduced. In the context of a thermal analysis this reduction can be applied to the temperature field y. As such a data pre-processing step is performed in which a transformation of the data is created that affects the eventual surrogate model. The transformation function will become part of the final surrogate model. The data pre-processing step has been performed using Proper Orthogonal Decomposition (POD) [19]. With this method the dimension of the data is reduced by finding the (spatial) coherence in the simulated time histories of *y* by performing a singular value decomposition of the snapshot matrix and retaining the singular vectors that correspond with largest singular values. These POD vectors derived from the simulation results form a reduced basis for *y*. Then a function *g* is to be fitted such that

$$c(t) \approx g(c(t-\Delta t), u(t), u(t-\Delta t), \Delta t), \tag{2}$$

with *c* the predictions of the POD coefficients (i.e., the representation of *y* in the new basis), *u* the vector of input variables, *t* the simulation time and Δt a time step. Typically *c* has a dimension that is orders of magnitude smaller than *y*.

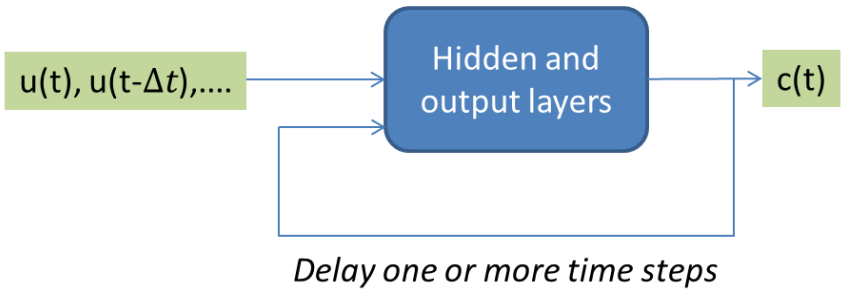

Figure 9: Top-level view of a recurrent artificial neural network that fits the POD coefficients *c(t)*.

A suitable method for deriving the function *g* is a recurrent artificial neural network (ANN). This method supports fitting of time series [20]. The recurrent ANN fits the values *c(t)* of the POD coefficient matrix as a function of the inputs *u(t)* -including a number of time delays of

u(t) - and it feeds the predictions of *c(t)* back into the network with one or multiple time delays. This is illustrated in Figure 9. A recurrent ANN is applied as surrogate modelling method in the fuel tank use case described in subsection 5.2.

With a recurrent ANN the time step Δt is assumed to be fixed. In some cases the data set may contain time series with different time step values, e.g. when the data set is assembled from other data sets. In those cases a feed-forward ANN can be used instead, in which the histories of *c(t)* and the time step Δt are to be treated as inputs as well. Such ANN is illustrated in Figure 10, and has been applied in the example described in subsection 4.4.

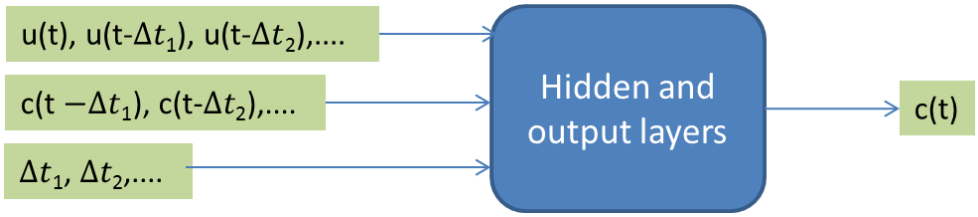

Figure 10: Top-level view of a feed-forward artificial neural network that fits the POD coefficients *c(t)*, for time histories with variable time steps

The steps for creating transient surrogate models have been automated as much as possible using the generic workflow depicted in Figure 8.

4.4 Example application in equipment thermal integration

The application of the transient surrogate modelling method to the fuel tank analysis use case is detailed in subsection 5.2. Earlier during TOICA, the method has been applied in the context of equipment thermal integration. That realistic application is summarised in this subsection.

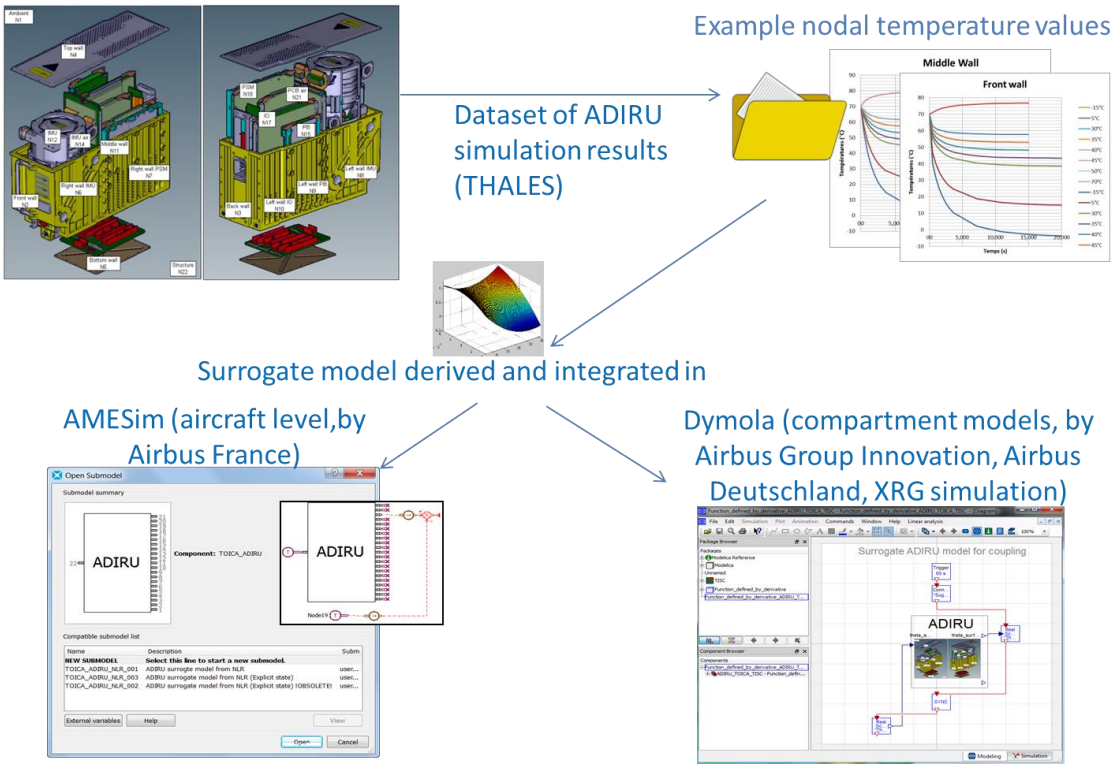

Figure 11: Illustration of surrogate modelling in the context of equipment thermal integration.

A data set has been provided of the transient thermal behaviour of the Air Data Inertial Reference Unit (ADIRU), by Thales (see Figure 11). The data set contains a number of time histories of 21 nodal temperatures on the equipment with varied initial conditions and a varied ambient temperature. The nodal temperatures represent the vector of output variables *y* to be predicted and the ambient temperature represents the input variable *u* (see equation 1). The data set consists of 5448 records in total. The dimensions of the data set have been reduced using POD. Five singular vectors have been retained. The POD coefficients have been predicted by a feed-forward ANN, taking the time history of the POD coefficients at the previous time step, the ambient temperature and the time step as input (see also Figure 10). The ANN consists of 2 hidden layers of size 12 and 8 respectively. Training has been performed using Bayesian regularisation. The resulting surrogate model has a temperature prediction error of order 1-2 ^{o}C (measured on the full data set used for fitting).

The surrogate model has been exported as a C type DLL which has been integrated with the system simulation tools (representing equipment thermal integration, see Figure 11):

- Amesim, used for integration of the surrogate ADIRU model on aircraft level.
- Dymola, used for integration of the surrogate ADIRU model on avionics compartment level.

5 THERMAL SIMULATION OF A FUEL TANK LEADING EDGE

This section details the case of thermal simulation of a fuel tank leading edge, which is related to one of the use cases of the TOICA project: using fuel as a heat sink for waste heat from other systems. Part of the TOICA use case is dedicated to the integrated analysis of the thermal behaviour of a wing fuel tank. The applicable wing fuel tank model is part of the Alenia Thermal Aircraft Model lead by Finmeccanica's Aircraft Division.

In subsection 5.1 the thermal model of a hot spot close to the fuel tank is described. The model is used to simulate the thermal effect of a bleed pipe on the tank wall. Furthermore, in subsection 5.2 a surrogate model is created from the results obtained in subsection 5.1. This surrogate model is then shown to produce comparable results of thermal history as the original model of subsection 5.1. Finally, in subsection 5.3, the simulation and surrogate creation steps are integrated into the collaborative engineering chain. All simulations have been performed by NLR.

5.1 Thermal modelling

Thermal analysis of an aircraft wing fuel tank consists of an internal and external temperature simulation. External temperature analysis covers the wing structure and structural heat sources, e.g. bleed pipe. Internal temperature covers the fluid and ullage (cf. Figure 2).

To identify the effect of heat sources external to the wing tank, a thermal model is necessary that is able to capture convection, conduction and radiation effects of these heat sources. Such heat sources are typically components that are running through the wing where the fuel tank is located. These components may not be directly in contact with the wing fuel tank. However, their supports are typically connected to the wing spar that is part of the fuel tank structure, causing the wing spar to locally heat up. Furthermore, the air inside the bay where the heat source is located is heated up. Therefore, a fluid-structure model is created that models the effect of heat sources and e.g. cooling effects of vents that are present in front of the fuel tank wall. The present case consists of a hot spot in the form of a bleed pipe located in the wing leading edge in front of the fuel tank; see Figure 2.

The thermal model for fuel tank external heat sources consists of two individual models that are coupled. The first model is a structural thermal model using a Finite Element ap-

proach and simulates the structural thermal loading. The second model consists of a fluid thermal model using a Finite Volume approach and models thermal behaviour of the air inside the leading edge. The two models are coupled to exchange temperature and heat flux values. These models are simulated in Abaqus standard (Finite Element) and Abaqus CFD (Finite Volume), and are coupled through Abaqus co-simulation engine [21].

In Figure 2, an overview is given of the wing structure consisting of skin, spar, and bleed pipe. The fluid model consists of the air inside the wing leading edge bounded by skin, spar and bleed pipe. Hence, the hot air inside the bleed pipe is not part of the CFD model but modelled as boundary conditions for the structural FE model. Furthermore, the front spar is the boundary of the structure model. The fuel and ullage section is not modelled in this fluid-structure model and is taken into account via a boundary condition. Modelling of the fuel and ullage are carried out by another TOICA partner, the University of Padova, using a CFD program.

Structural model

The upper and lower skins as well as the wing spar are made of composite material with different thermal properties in plane 6.7 W/mK and out of plane 0.7 W/mK, a density of 1.60 g/cm^3 and specific heat of 1.4 J/gK. The curved part of the leading edge consists of a de-icing boot. Inside the leading edge is a bleed pipe made of aluminium. The structure model is shown in Figure 12.

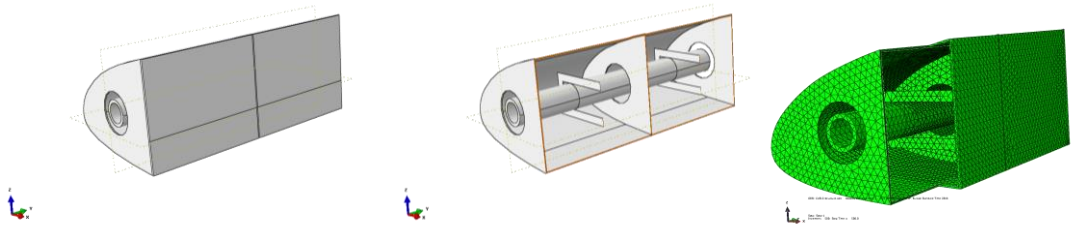

Figure 12: Wing structure part for which an FEA model is created. Left: the closed wing leading edge. Middle: a cut-out to show the internal structure showing the ribs, bleed pipe and bleed pipe supports. Right: the finite element mesh of the leading edge structure, bleed pipe and supports. Via a cut-out the internals are shown.

Hot air coming from the engine is running through the bleed pipe. This bleed pipe is then heated up and releases its heat via radiation to the surrounding walls. Additionally, via convection with the air inside the leading edge and finally via conduction with the bleed pipe supports, the walls are heated up. Air is running through the wing leading edge via ventilation holes. As can be seen in Figure 12 the bleed pipe radius is smaller than the hole in the rib section. Through this open area air is entering the wing leading edge in the model. On the opposite side air is leaving the wing leading edge via the space between the rib and the bleed pipe.

For meshing the structural model, linear tetrahedron elements are used and mesh seeding is chosen such that it more or less corresponds to the mesh seed that is used for the fluid domain. Boundary conditions are fixed temperatures on the wing top and bottom skin (including the de-icing boot). Thermal interaction of the front wing spar with the fuel is modelled via a heat transfer coefficient that was obtained from a CFD analysis conducted by the University of Padova for the fuel tank internals, i.e. ullage and fuel. The interaction with the air inside the leading edge is modelled via a fluid-structure interaction. Calculated wall temperatures on the FEA nodes are transmitted to the fluid calculations and the fluid calculations return heat trans-

fer coefficients on the CFD nodes. Interpolation of the calculated values is used to map results of the FEA onto the CFD and vice versa.

Fluid (air) model

To model the thermal interaction via convection of the wing leading edge structure and the air inside the leading edge, a fluid (air) model is created of the leading edge internals. In Figure 13 the geometry is shown. To summarise, all the empty space inside the leading edge is used for the volume mesh.

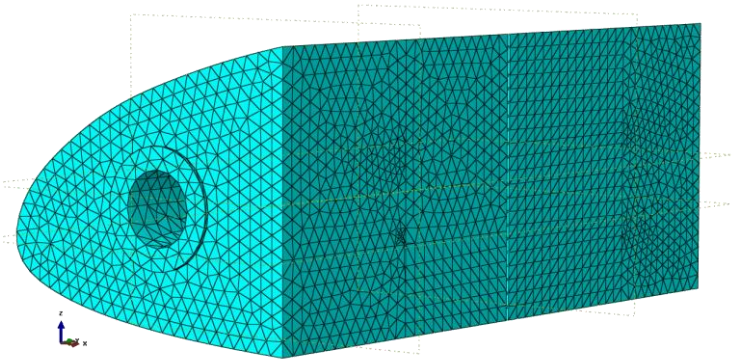

Figure 13: Wing leading edge air model showing the mesh of the air inside the wing leading edge that is modelled via a finite volume approach.

The fluid model is meshed using fluid linear tetrahedron elements. The mesh seed is chosen such that it more or less corresponds to the mesh seed that is used for the structure domain. The Spalart-Allmaras turbulence model is applied that uses wall functions to avoid very fine meshes near the walls. Boundary conditions are no slip conditions where the air touches the structure. Furthermore, a constant fluid flow is prescribed on one side of the leading edge.

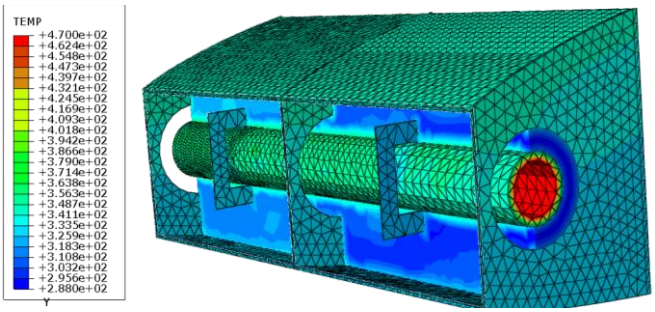

Figure 14: Temperature plot in degrees Kelvin of a cut-out of the Finite Element model for the structure filled up with a cut-out of the Finite Volume model for the fluid (air) in the leading edge.

The air intake is located on the front side of the leading edge shown in Figure 14. The ventilation is taken into account in the model using a constant 1kg/s airflow running from left to right through the ribs. There is an opening in the rib that is larger than the size of the bleed pipe. On the back side of the leading edge the rib has an opening and here a constant pressure of 1 bar is applied. The result is a flow of air that cools the leading edge and prevents the leading edge internal from heating up too much by the bleed pipe.

Co-simulation approach

A transient analysis is carried out with an initial time step of 1 for both FEA and CFD. For the CFD model an automatic time stepping scheme is used called Courant-Friedrichs-Lewy

(CFL) time increment method and the time integration method is Galerkin. The numerical procedure to solve the pressure equation is using Bi-Conjugate Gradient, stabilised with a pre-conditioner algebraic multigrid. Furthermore, the inflow of air is smoothly introduced over a period of ten seconds.

The FEA model uses a fixed time increment, a direct solver and Full Newton. The maximum allowable temperature change per increment is 10 degrees and the maximum allowable emissivity change per increment is 0.1.

The Co-simulation agent uses a Gauss-Seidel coupling algorithm (FEA and CFD are solved sequentially). The target time step for both analyses is the FEA time step. The FEA uses so-called fixed time stepping, i.e. lockstep, and the CFD uses so-called subcycling, i.e. multiple time stepping within a targeted time step.

Main results

The heat flow in the leading edge is simulated for a situation where the aircraft is on ground with engine on. Several ambient temperatures are chosen as starting condition. Furthermore, cooling of the leading edge is accomplished via a constant mass flow of ambient air into the leading edge. The top part of the leading edge is heated up by a constant solar radiation that leads to a 344K temperature of upper skin. The bottom part of the leading edge is heated via reflection of solar radiation from the ground leading to a 327K temperature of lower skin. Hot air (473K) is heating up the bleed pipe which is modelled via sink temperature and convection coefficient. The right tank compartment is full of fuel at a temperature of 324K while in the left tank compartment the fuel has a temperature of 321K. In addition, the left tank compartment has a fuel level of 12cm from the tank bottom. The ullage space in the left tank compartment has a temperature of 326K.

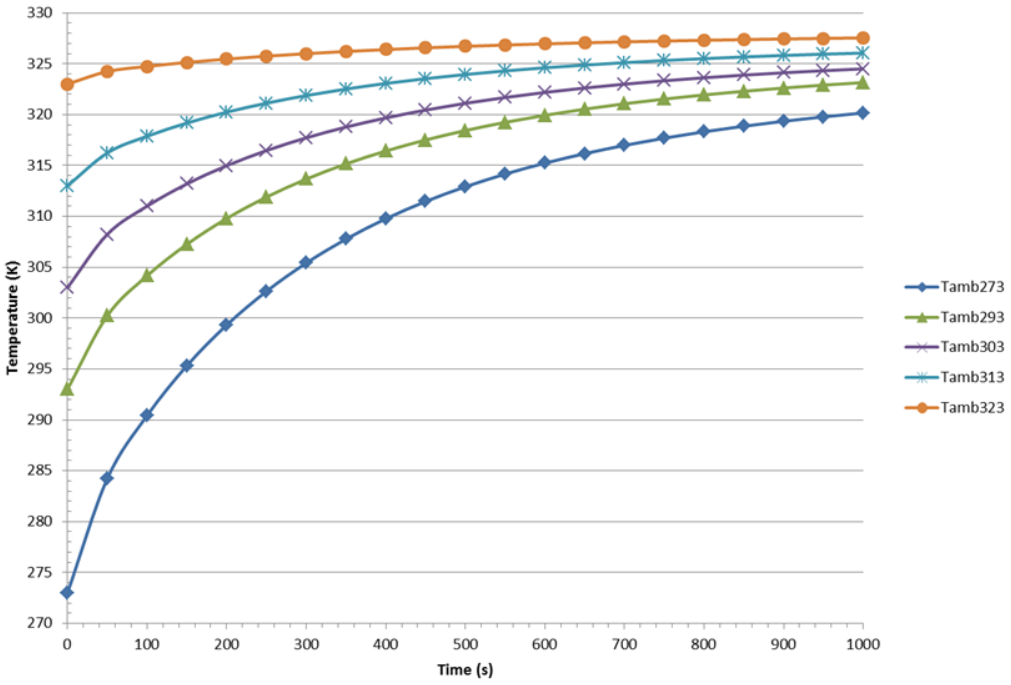

Figure 15: Temperature history of the front spar for different ambient starting conditions. The average temperature of the entire front spar is plotted.

Figure 15 shows the temperature history of the average temperature of the front spar with an output time step of 50 seconds. For different ambient starting conditions the final tempera-

ture approaches a value between 320K and 327K. Hence the effect of the hot bleed pipe is sufficiently compensated for by the cooling effect from outside venting air. Not all transient simulations have reached a final steady-state within 1000 seconds, but for all cases the steady-state temperature of the front spar is not expected to be significantly higher than that of the fuel inside the tank. Nevertheless, Figure 15 shows that the time it takes to reach the steady-state temperature depends on the ambient temperature, ranging from approximately 700 seconds for an ambient temperature of 323K more than 1000 seconds for 273K. The simulations are time consuming. A single analysis can take up to 2 days to run on a single cluster node with 20 cores. Application of such simulations is not practical for long transient simulations and in case the transient behaviour is to be predicted for ambient starting conditions additional to the ones depicted in Figure 15, e.g. during extensive trade-off studies at aircraft level in the early design stages. This is where a surrogate model of the transient behaviour is an added value.

5.2 Surrogate model

With the thermal model of the leading edge transient simulations can be performed. However the calculation time of one transient simulation is very long, e.g. up to 2 days for a simulation of 1000 seconds. The high computational effort makes it difficult to apply such simulation as part of efficient thermal analysis during the early design stage. Therefore a surrogate model has been derived using the transient surrogate modelling capability as described in subsection 4.3. The surrogate model of the leading edge predicts the wing spar temperature field at a certain time as a function of the wing spar temperature field during the previous time step and of the ambient air temperature. Equation 1 has been adapted to:

$$\vec{T}(t) \approx f\left(\vec{T}(t-\Delta t), T_{ambient}(t), \Delta t\right), \tag{3}$$

with $\vec{T}$ the temperature field in K, $T_{ambient}$ in K, t the simulation time, Δt the time step and f the analytical function representing the surrogate model. The ambient temperature remains constant during one transient simulation. Therefore a time delay of $T_{ambient}$ – like applied in equation 1 on the input u – is not considered relevant here.

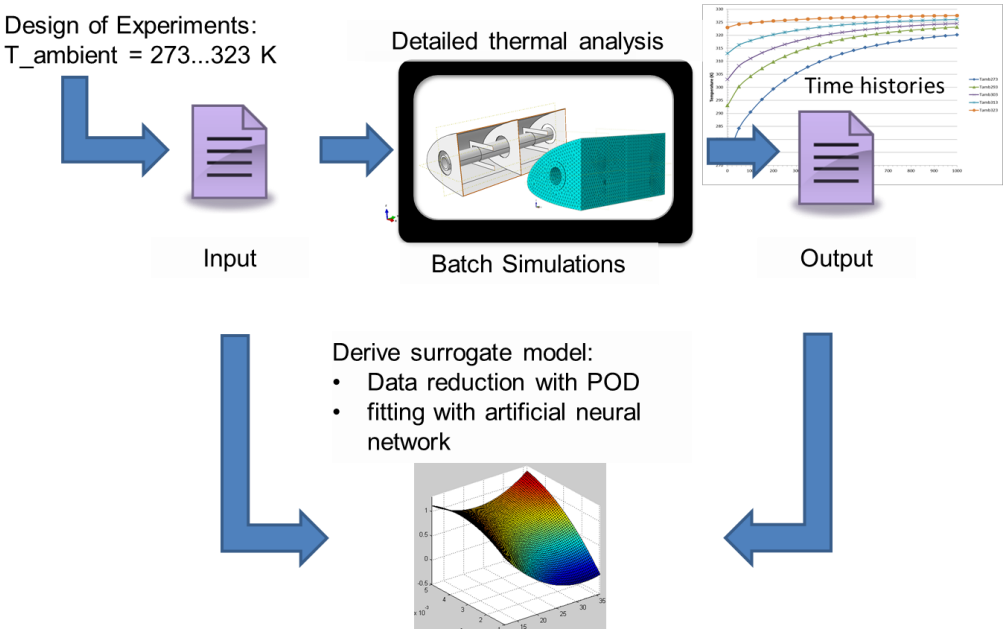

Figure 16: Surrogate modelling process scheme of the leading edge model.

Figure 16 illustrates the process of deriving the surrogate model. Five transient simulations have been performed, starting at different ambient temperatures. The ambient temperature has been varied between 273K and 323K. It is assumed that the temperature of the ventilation air through the leading edge is equal to the ambient temperature. Each transient simulation runs for 1000 seconds with an output time step of 50 seconds (cf. Figure 15). The resulting data represents the temperature field on the wing spar, calculated by the FEA analysis on 2700 nodes.

The spatial dimension of the data has been reduced using POD. The dimensionality has been reduced from 2700 nodes to 5 POD vectors that represent the relevant spatial behaviour over time. The data fitting problem is now reduced to fitting the time history of the POD coefficients, see also equation 2. A recurrent artificial neural network has been applied using a hidden layer of 5 nodes (see also Figure 9). The POD transformation functions have been integrated into the surrogate model such that the surrogate model predicts the complete temperature field at the 2700 spatial nodes. The predictions have a maximum error of 1.6K measured over the full data set of nodal temperatures.

Figure 17 depicts the surrogate model predictions over time together with the FEA data points compared by their spatial mean values. The transient predictions by the surrogate model have been extended to 2000 seconds in order to test the prediction of the steady-states. Within the time interval between 1000 and 2000 seconds the results have been compared with a number of simulation results from additional transient runs with the detailed FEA/CFD model, with output time step 250 seconds. Figure 17 shows that the predictions by the surrogate model between 1000 and 2000 seconds are close to the FEA data points, even though the surrogate model is extrapolating in this region. Close to 2000 seconds the extrapolation starts to give undesired effects: the curves bend downwards again. However, the surrogate model provides a useful means to estimate the steady-state temperatures and the times when they have been reached.

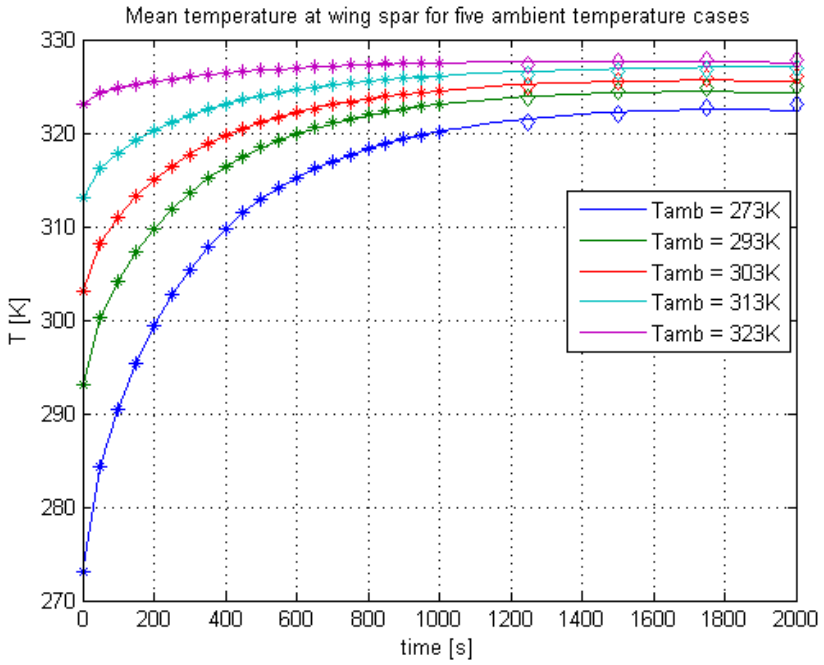

Figure 17: Spatial mean values of the surrogate model predictions (solid lines), fit data points provided by FEA (stars) and additional verification data points provided by FEA (diamonds) for the five simulation cases with ambient temperature variations.

5.3 Integrating the collaborative engineering capabilities

The integrated thermal analysis of a wing fuel tank usually involves experts from different disciplines and possibly different departments and organisations. Disciplines involved could concern fuel systems, wing structure, pylon, fuselage, and thermal analysis (FEA/CFD and systems). Organisations involved could be aircraft manufacturers, system and component suppliers, and simulation solution providers. This distributed process can be performed as a collaborative workflow, using Brics for orchestration and data exchange, and using surrogate modelling to bridge the gaps between different simulation tools of the disciplines and organisations. To demonstrate such distributed process a part of it has been realised, namely the derivation of the leading edge surrogate model as described in the previous section.

The calculation of the simulation FEA/CFD data set for creation of the leading surrogate model is a time-consuming process. Furthermore it may be challenging to obtain time slots and permissions for performing the simulation on appropriate computer hardware while using the specific software licenses that are needed. And when all simulations have been performed the generated data may be contained in very large files which are difficult to handle and access. Extraction of the relevant data needed for fitting is still to be performed in a post-processing step. It has been experienced that structuring the whole data calculation process into a workflow improves the efficiency of deriving the surrogate model. Brics supports the implementation of such a workflow, especially when the FEA/CFD thermal simulations are to be calculated by another partner than the one who derives the surrogate model. Figure 18 illustrates the implementation of the workflow. The detailed thermal analysis by means of batch simulations as illustrated in the upper part of Figure 16 is now realised through a distributed process with Brics. This process results in a data set from which the surrogate model can be derived.

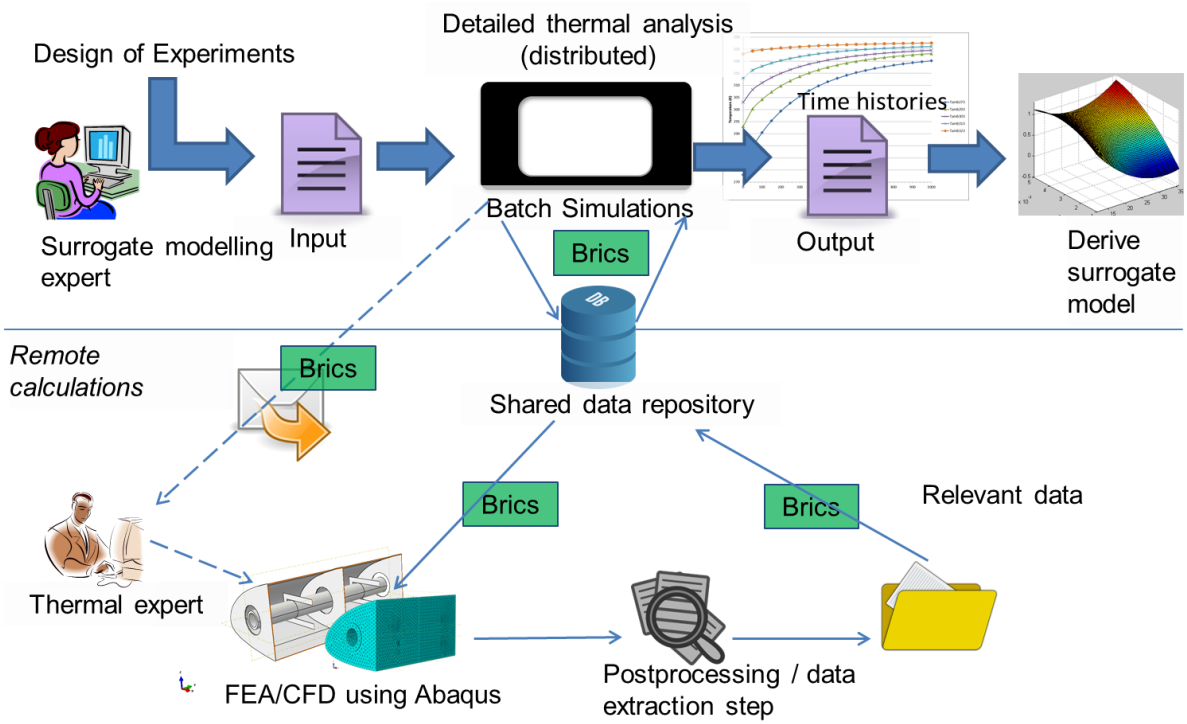

Figure 18: Distributed process for obtaining the data for a surrogate model of the leading edge. The upper half covers Figure 16, while in this figure the detailed thermal analysis is performed in a distributed way.

The surrogate modelling expert does not need to worry about how the data set of thermal behaviour of the leading edge is derived (and how the relevant parts are accessed). This is being performed by a thermal expert who may be part of another organisation or another department. The orchestration of the distributed calculation process and the exchange of the data is performed by Brics. At NLR thermal analysis, surrogate modelling, and distributed collaboration with Brics have been combined in order to derive a surrogate model of the leading edge thermal behaviour in an efficient way.

6 CONCLUSIONS

In the paper, we presented two collaborative engineering capabilities that support the need for high level of integrated system design of the aircraft and its subsystems: surrogate modelling and smooth cross-organisation workflow execution. The development of the capabilities took place in past projects, driven by needs and requirements from and discussions with stakeholders, and based on experiences gained with collaborative engineering and simulation solutions built. The capabilities have been further developed based on needs and distributed multi-partner simulation scenarios in the TOICA project. The application of the technologies has been illustrated by realistic examples of collaborative thermal analysis conducted in TOICA. An integrated application of the technologies has been demonstrated in a specific use case: wing leading edge thermal simulation for the thermal analysis of fuel tank.

Based on the experiences with solutions for distributed multi-partner scenarios based on Brics, and successful demonstrations thereof, we conclude that Brics enables the smooth cross-organisation execution of engineering workflows in a world full of security rules and measures, while still complying with the overall and organisation-specific security policies. Through its flexible integration with a variety of standard and COTS software, Brics also demonstrated to be applicable through the various organisations with minimum effort. The impact on the business of the individual organisations is kept to a minimum, apart from the ability to connect to extra-organisation workflows. As such, we conclude that Brics responds to the challenges of distributed cross-organisation collaboration, and hence contributes to effective and efficient collaboration among aircraft manufacturers and their supply chains.

As demonstrated in the fuel tank thermal modelling case, surrogate modelling has proven to make expensive, time-consuming and typically complex simulations of aircraft component behaviour available for quick thermal analysis. In collaborative simulations, it also caters for use of models that may not or cannot be shared with partners for intellectual property preservation reasons or that are restricted by their implementation tools. As such, surrogate modelling has proven providing valuable technology for cost and time efficient simulation during the preliminary design phase.

Furthermore, the detailed modelling of the thermal behaviour of a wing leading edge, based on FEA and CFD analysis, has been described. Such thermal modelling capability caters for detailed analysis of aircraft components that are to be manufactured with innovative materials, such as composites, in order to support certification of these components.

The capabilities have been further developed and demonstrated in the context of collaborative thermal analyses orchestrated by the aircraft manufacturer and performed throughout the supply chain, including small to medium enterprises. More generally, the capabilities can be applied beyond thermal analysis to support modelling and simulation for high level of integrated aircraft design in general, which increases the competitiveness of the European aeronautics industry. The generic character of the capabilities suggests investigating the applicability in other areas, such as automotive and ship-building.

The research leading to the results described in this paper has received funding from the European Community Seventh Framework Programme (FP7/2013-2016) under grant agree-

ment no. 604981 (TOICA, [2]). The authors would like to acknowledge all colleagues from the TOICA project partners who contributed to the success of the collaborative engineering and simulation studies that provided valuable input for the research described in this paper.

Abstract. *Many traditional engineering design processes in industry have evolved, and nowadays they are supported by computational tools and methods. As a consequence, apart from the quantity of information and data, a network of simulation methods produces information at various level of detail and nature. Furthermore, human interactivity is an essential consideration when building and designing such computational systems, simply because there is a requirement to process and understand this information that is produced during an engineering project effectively in real time.*

We introduce here a Visual Analytics perspective in computational engineering design process, as well as tightening the interactive analysis of engineering data with Parallel Coordinates and Scatter plots. To demonstrate the benefits of the proposed approach we use a case study that describes the design of an aero engine component critically suffering from the operating conditions but at the same time from the change of specifications and customer requirements.

Some of the benefits include minimisation of rework through early identification of behaviour in selected Value Dimensions, as well as the ability to trade product performance (e.g. weight, minimum expected life) with internal stakeholder expectations (e.g. higher overall productivity of aircraft, low degree of aircraft modifications, faster design convergence). Furthermore, the proposed method develops the ability to identify architectural options that align with Value Creation Strategies, but also the evaluation of design options in advance of physical trade studies.

1 INTRODUCTION

These days, people perceive for granted complex engineering products, such as an aircraft, and most importantly use them in their daily routine. As a result, the requirements and specifications should meet the expectations of the customers and stakeholders simultaneously. In other words, the technical and engineering objectives that usually drive a design process, should now reflect the impact of customer satisfaction. In our example, a passenger would wish to have more leg space for comfort, better quality of air in the cabin, and cheap ticket price, and expect to be able to reach at the airport and spend minimum amount of time during security control and boarding. But how do these expectations translate to engineering performance indicators? How these metrics can be modelled? What are the relationships between such properties? We believe Visual Analytics and Big Data management can assist towards finding answers to these questions, and perhaps more importantly to create new questions that weren't thought before, but will further support the human imagination and creativity.

In an engineering design process, as illustrated in Figure 1, we start with the description of a problem, which we then need to formulate and model, often, in a computational/simulation environment. The same problem can have many model instances depending on the level of detail that is described, or even the point of view of the analysis. Each of these problem formulations are then explored, almost simultaneously through design optimisation studies, simulation and analysis tools, or similar. Before we are able to cascade this information downstream in the process for decision making, we need to collect, synthesise, and process the data.

The process to collect this data, most of the times, has a complex structure, since many different analysis and simulation tools are used during an engineering design project. Furthermore, in many cases they are located in geographically different sources.

The mere amount of aspects that need to be considered simultaneously when making decisions during product development is one of the main reasons why synthesis in engineering design relies on experienced and advanced human cognitive skills. Since the introduction of computational support, the ability to design and optimise products have made several leaps forward. As one example, the actual definition and representation of a compressor, or turbine blade is no longer possible to be defined by hand. Advances in Computational Fluid Dynamics and the following ability to optimise such designs have enabled efficiency of compressor design to advance from 9X% to over 99% in just a couple of decades. A second aspect is that to differentiate on the marketplace, success is increasingly determined by how well the product performs from multiple perspectives.

From an industrialist's perspective, we are now at a point where we no longer create a single concept with small variations of forthcoming products, but rather exploring entire design spaces using advanced computer tools. Engineers have the capability to produce more data per instance, for more variants and for more situations than ever before.

There is a need to visualise the data and more importantly to be able to interpret and understand what these data mean in a sensible way. Traditional ways of the representation of the behaviour of a design solution include the use of animations of e.g. deflection and distortion of a product (modal analysis, stress plots, etc.). Where the engineer could display results of one, or few alternatives, now is no longer feasible due to the multitude of variants and circumstances (loads) that the product is exposed to. Many aspects need to be explored for a range of alternative solutions. As a consequence, even if it is possible to generate such information, the analysis of a multi-parameter design space for many alternatives drive the need to interact and understand much richer and more complex dataset.

Hence, we need to complement other visualisation techniques to enable rich understanding of many alternatives subject to variation to many variables or aspects. This is also another major contribution of this paper.

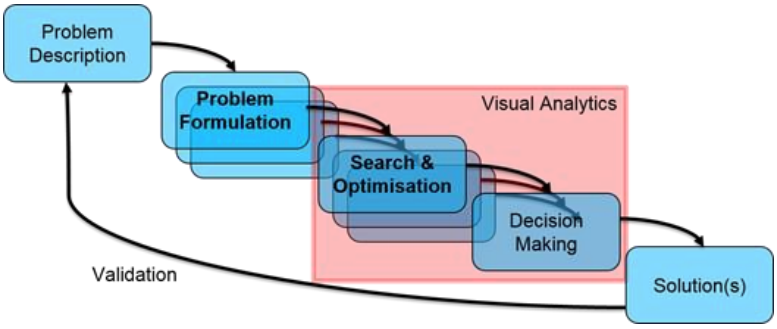

Figure 1: High level view of an engineering design process supported by visual analytics tools and methods.

2 BACKGROUND AND LITERATURE

Decision making during development is by nature multi-disciplinary, and several authors have proposed ways on how to explore design spaces in many dimensions. The MOVA framework by Woodruff et.al. [6] extended a finite dimensional design strategy to a more general framework to include multiple objectives, and compared the approach with alternative decision making strategies. Keim et al [15] summarised the area of Visual Analytics as a result from a three year European project, and concluded that assisting designers using visual analytic systems was one of the key challenges for the future.

In Figure 2 it is shown a schematic representation of a concept of how to facilitate human interactivity within the automated computational engineering design cycle.

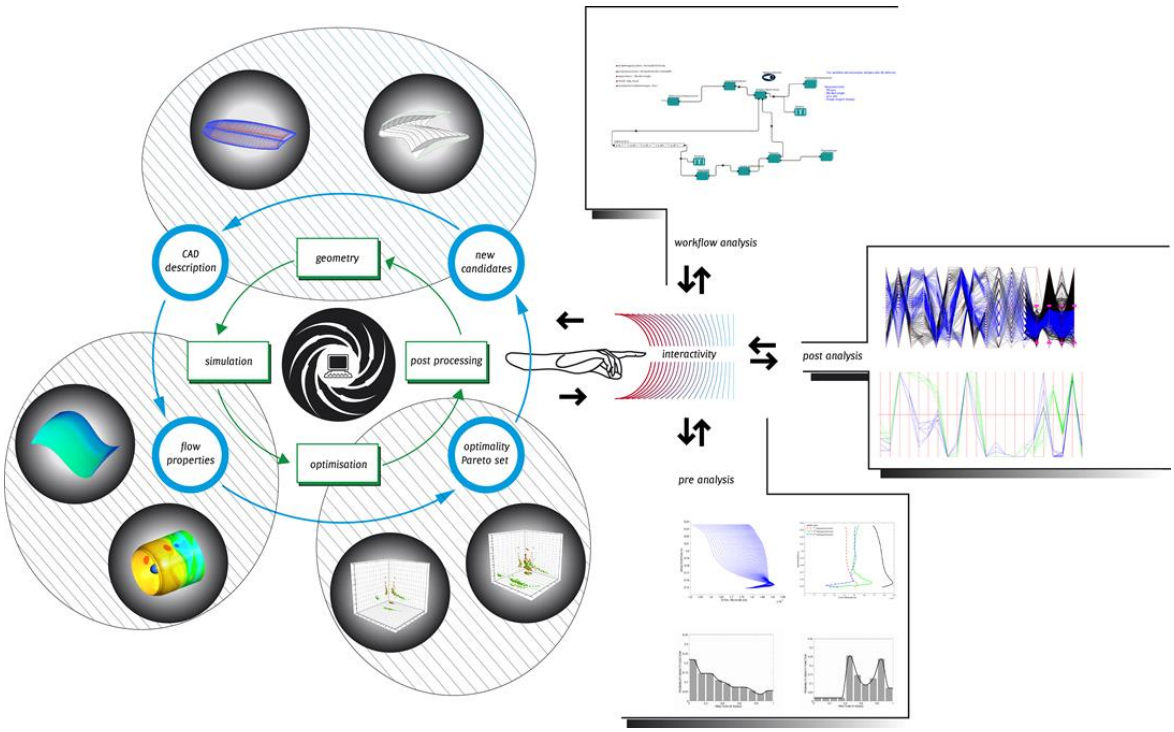

Figure 2: Schematic representation of an interactive optimisation engineering design process [10].

The automated computational design cycle is shown on the left, and at the heart of the overall process is the human, who interactively analyses the results of the process, understands the complexities and infuses this knowledge in real-time into the automated process.

Although engineering design largely relies on the use of numerical and computational analysis tools, the synthesis and insights enabling design decisions still expect design engineers to understand the breadth of the design problem. There is a human aspect on decision making where the influence of appearance and visualisation has been shown to affect decision making in design situations. The influence of colours in visualising results has been previously applied in the area of Value Driven Design [16]. It has further been demonstrated the effect of contextual information of product oriented data and observed the effect on engineering team attention to how data was visualised [14]. The ability to interact with alternatives and changing conditions, such as product requirements changes and/or preference changes are clearly emphasised.

Engineering Design is a highly iterative activity, where the definition of forthcoming products is typically matured through managing iteration and changes. Any decision support method needs to facilitate the study of variation, trading, etc. Data is typically produced in engineering tools, but also in less quantitative manner. Subjective metrics such as confidence, appearance, risk, etc co-exist with quantifiable aspects such as stresses, strains etc.

Parallel coordinates (||-coords) can support and facilitate the possibility to identify trends and relationships between technical properties and specification characteristics when these are simultaneously represented in a multi-dimensional domain.

There are platforms and frameworks under investigation and development that facilitate the human interaction and drive/guide optimisation studies. But also offer visual representation of the product in an auxiliary engineering analysis environment (i.e. Workways [12]).

3 AN ENGINEERING EXAMPLE

The initial aim and objective of this work was to identify the means to connect high level stakeholder and customer expectations and requirements to actual technical key performance characteristics and indicators. We use the Value Assessment method as introduced in [2] and expanded in [1]. Here, we only provide a brief description of the main stages of the Value Assessment process. For more details the reader should refer to [1] and [2].

3.1 Value Driven Design Methodology

A Value Assessment process can be best described within the Value Driven Design process as shown in Figure 3.

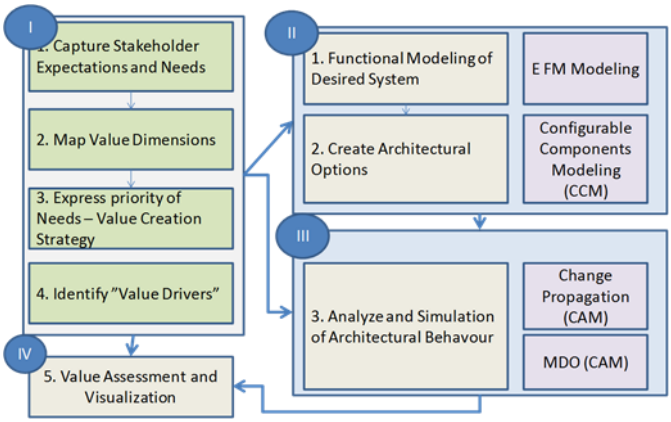

Figure 3: The four phases of the Value Driven Design methodology.

In phase I the stakeholder expectations and needs are captured and linked with Value Dimensions and Value Drivers. The often tacitly expressed expectations are organised into a Value Creation Strategy (VCS), this is the prioritised set of stakeholder needs that can be influenced in design via the Value Drivers. The Value Drivers are consequently aspects wherein it is possible to define the design parameters to explore. Typically, the breadth of information in phase I is vast. Explicit and numerically defined expectations, such as expected range or target weights are mixed with tacit and ill-defined expectations, such as being "sustainable" or "easily maintainable", "easy to integrate into a system" etc. Explicit and quantifiable modeling may not be feasible, not at least in early phases, but may still be necessary to include in decision making.

The second phase takes the VCS as input and serves to support the design synthesis stage. Searching for solutions in the design space is divided into an architectural modeling phase, in this case using an extended function means modeling approach, where the functionality of the systems is modeled and the alternative design solutions are defined. At this phase, the characteristics of the forthcoming design is modeled for all relevant candidate design solutions. One way of representing an architectural option is via Design Structure Matrices (DSM's), where the pattern of internal dependencies of design objects provides a quantifiable pattern of the architectural option (Figure 4).

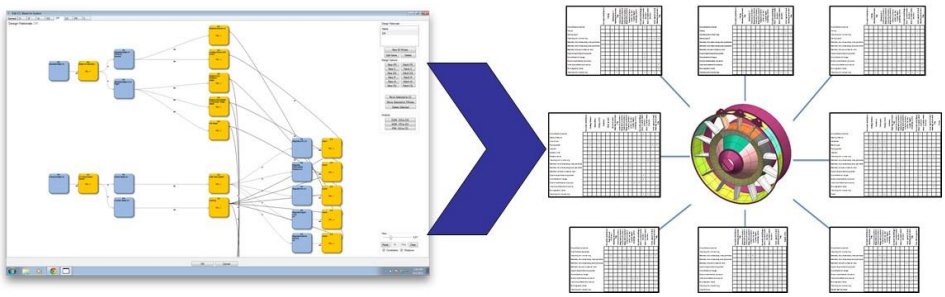

Figure 4: Through Function-Means modeling in CCM (Configurable Components Model) environment [17], alternative architectures of a RTS engine component are exported as DSM's.

The third phase introduces analytical tools that analyse the behaviour of the alternative architectures along with the evaluation of the properties identified as Value Dimensions in phase I. One efficient method to understand and explore the behaviour of the product is the Change Propagation Method (CPM) [18], where dependencies between the architectural objects are assigned with probability and impact information. Change propagation analysis then generate information of how an architectural definition reacts to changes and perturbations (Figure 5). It has been demonstrated that it is possible to define first order relations to several stakeholder needs, such as "integration ability" and "development process efficiency" [1]. Of course, more traditional methods such as Finite Element Analysis (FEA) and Computational Fluid Dynamics (CFD) are also possible to be applied at this stage of the Value Driven Design methodology.

The focus of this paper is the fourth phase where the results from the simulated behaviour of all alternative architectural studies are collected and organised. Using ||-coords as a means of visualisation, the experience and intuition of the designer can be combined with the patterns discovered using analytical methods. Since multiple aspects and multiple architectural options are studied, the pattern recognition abilities of humans is used to facilitate interactive exploration and search for suitable combinations of input and output.

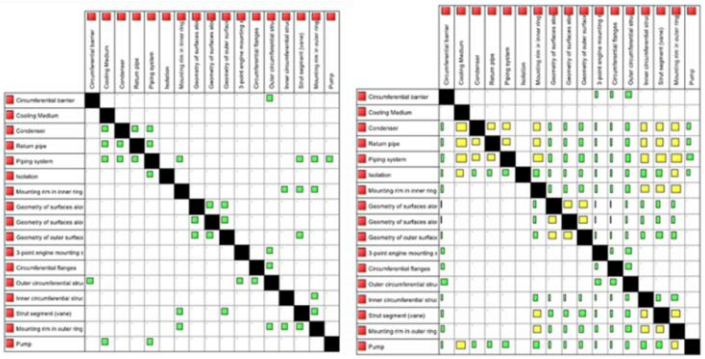

Figure 5: A DSM representation of the product and the combined risk matrix as calculated in CAM (Cambridge Advanced Modeller) environment.

3.2 A Brief Description of the Case Study

The method using visual analytics is applied onto a case study. The product studied is a sub system of an aircraft jet-engine, a rear turbine structure (RTS) as shown in Figure 6. From an applied perspective, the RTS is a tightly integrated structural component of the jet engine used to propel the aircraft and provide power to the aircraft also for other purposes. A re-engine scenario where the aircraft manufacturer wishes to upgrade the performance of the aircraft by replacing and/or upgrading the existing engine type is considered here. The engine manufacturing consortia consisting of the jet engine OEM and its design partners need to understand the new consequences and assess what design options exist that are necessary to satisfy the ambitions of the re-engine scenario.

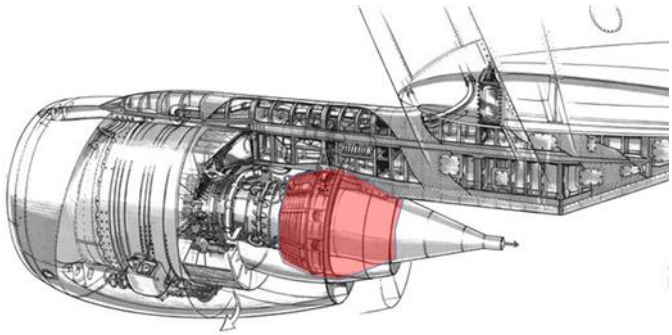

Figure 6: Re-engine scenario: turbine exit structure (*illustration from Flight Magazine).*

In the European project TOICA, the scenario is defined as a context, wherein the Value Assessment Methodology, described in [1] and introduced above has been followed. In this paper we focus on phase IV but capture portions of the dataset for clarification and to present the sources of information used when assessing value in the interactive way using ||-coords. From phase I, a range of Value information is captured, each linking Stakeholder Expectations to Value Drivers. In Figure 7 this is illustrated for the "Higher Productivity of Aircraft" Stakeholder Expectations. This expectation eventually is influenced by weight since this has a first order influence on payload, and on minimum expected life which has an equal direct influence in the operating cost of an aircraft.

Stakeholder Expectations	Stakeholder Needs	Value Dimensions	Value Drivers
Higher productivity of aircraft	Increased payload	Mission performance	Weight
	Reduced operating cost		Minimum expected life

Figure 7: Expression of generic stakeholder expectations and needs, and the mapping to value dimensions and value drivers.

Since the stakeholder expectation of "Higher productivity of Aircraft" and both of its Stakeholder Needs are attributed to the operation of the aircraft, the property of "Mission Performance" was the right classification of value dimension. Notably, there are other Value Dimensions, addressing other aspects of stakeholders, such as how costly the products are to integrate into a system etc.

The weight of a component is a good example of a Value Driver that can be assigned as a firm and quantifiable target. It can equally be related to the impact on productivity of the aircraft, since frequently is the case in aerospace that weight is given a direct relation to productivity of the aircraft. In design phases, it is equally common to formulate penalty relations in monetary terms if target weights are not met.

In a similar manner, there are relations with the expected life and the productivity of operating the aircraft. Maintenance schedules, repair and inspection costs are directly related to the satisfaction of a minimum expected life.

Both minimum expected life and weight of components are examples of quantifiable value drivers. To evaluate weight and expected life, there is effectively no mature way of analysing this impact for new alternative designs without modeling the CAD definition (calculation of volume) and making physics based evaluations using computational techniques such as finite element analysis (calculation of the stresses and strains) and some life analysis technique (such as crack propagation and/or fatigue analysis).

The actual relations between weight and performance, or minimal life and operating cost are business sensitive data and not disclosed explicitly in this paper.

4 INTERACTIVE ANALYSIS WITH PARALLEL COORDINATES

4.1 Methodology

The inputs to the interactive analysis for Value Assessment are initially the results from the functional analysis and CPM analyses, as well FEA and CFD analyses. Parallel coordinates are used to display simultaneously the results onto each value dimension in the same plot as the design variables. The architect can work interactively with the data set, and filter out architectures in several ways, either via filters on the parameters or via a graphical plot in 2D where two selected parameters are compared to each other. As the concepts are refined, more advanced modeling and analysis tools can be used to predict the behaviour or the concept.

The first step (to the left below) operate on the pre-embodiment DSM data. In this step alternative variants are down-selected, and the most promising variants are selected for further refinement. Selection of variants allow physical and parametric geometrical modeling and finite element analyses to be conducted. The same tool and interactive analysis is re-used with a richer data set. This is described to the left in Figure 8.

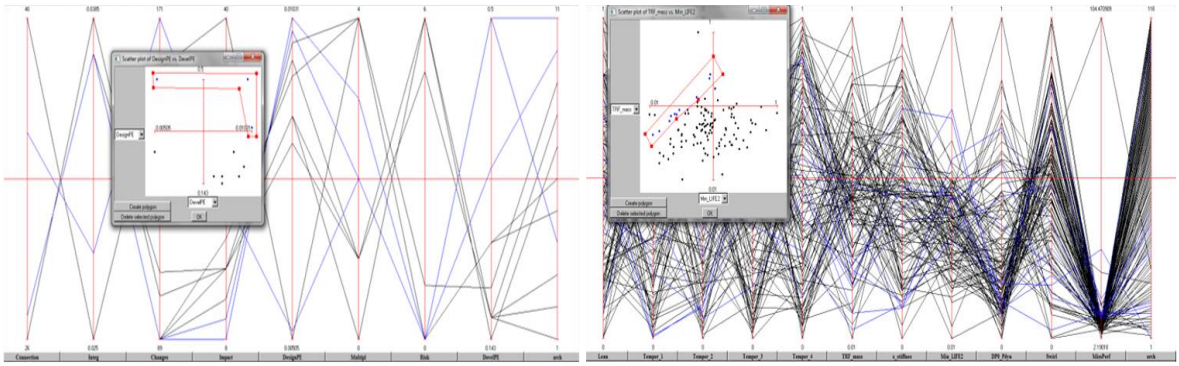

Figure 8: Parallel coordinates and interactive analysis and visualisation of impact of stakeholder needs and value dimensions enabled using multi-disciplinary analysis and design tools.

Similar examples and methods of interactive analysis can be found in [7], [8], [9], [10], [11], [12], and [13].

5 FUTURE WORK AND CONCLUSIONS

The approach presented, and the interactive way of analysing datasets was used to assess initial architectural descriptions based on DSM representations and CPM as analysis method. The same visual analytics tools is re-used as the data set is enriched through more detailed and refined models of the architectures. In particular, the visual and interactive tool has been demonstrated effective as a means to facilitate the communication between architects and different engineering design teams. The ability to link "high level" objectives through the Value Creation Strategy, to the design variables characterising the various architectures has been demonstrated successfully. Since information in complex product development typically engage many disparate competences and specialist teams, the value of communicating the expectations and technical results are decisive. The Visual Analytics methods and tools are highly suitable to combine data from different sources and of different nature.

In particular, the ability to analyse the often extensive data sets by filtering, selecting and searching for combinations of parameter values is an important feature. This is typically the task for multidisciplinary optimisation specialists, whereas through the visual analytics approach different stakeholders can analyse the datasets simultaneously. Based on this type of interaction during the development of the methods and tools in the TOICA project, engagement and critical understanding were aspects that were significantly improved.

Here we also list the identified benefits so far, and emphasis is given on further potentials and contributions in the engineering design field.

These include:

- Ability to represent many design alternatives that were evaluated simultaneously for many variables
- Aggregation of information, where dynamic navigation in resolution and underlying assumptions can be done interactively
- Analysis supported by the ability to search for better and more suitable solution areas
- Describe the logic-disciplinary development via computational tools
- Ability to combine disciplines (multi-physics)
- Ability to process large amount of data (computational power)

- Ability to automatically generate the necessary designs and their variation (design automation, KBE, etc)
- Differentiation in business by tailoring and customising products and services (i.e. more variations and aspects ageing)

But also other enabling means to support decision making:

- Impact of component performance to global performance
- Identify meaningful trade-offs between requirements and design parameters
- Understand the design space and find answers to the questions:
    - What are the important parameters?
    - How the requirements compete?
    - Where are the most promising solutions?
- Manage risk

For further work there are several directions of interest. One is to further strengthen the interaction with different scientific communities, such as the engineering disciplines, computer science, visual analytics communities, mathematics and cognitive decision making specialists.

Secondly, already in its current state of maturity, there is an exploitation track to explore. The needs and contexts prevailing in decision making situations during product development can already now benefit from the ability to bring in complex data sets, link them to high level objectives and increase interaction with specialists. There is a route to more clearly understand, demonstrate and implement support for decision making in complex product and production development situations. The ability to represent and characterise architectures via internal and external dependencies is a promising area, where research is needed to enhance representation, definition and evaluation methods and tools. It is likely that the actual decision making process throughout a development project will continue to develop new practices. One of which is the facilitation of more interactive, visual and analytical tools.

Keywords: Continuous Adjoint, RBF Morphing, Aeronautical Optimization

Abstract. *In this paper, the continuous adjoint method, developed by NTUA in the OpenFOAM® environment, is coupled with an RBF-based morpher developed by UTV to tackle optimization problems in low-speed aeronautics. The adjoint method provides a fast and accurate way for computing the sensitivity derivatives of the objective functions (here, drag, lift and losses) with respect to the design variables. The latter are defined as a set of variables controlling a group of RBF control points used to deform both the surface and volume mesh of the computational domain. The use of the RBF-based morpher provides a fast and robust way of handling mesh and geometry deformations, facing two challenging tasks related to shape optimization with the same tool. The coupling of the above-mentioned tools is used to tackle (a) the minimization of the cooling losses for an electric motor installed on a lightweight aircraft, by controlling the cooling air intake shape and (b) the shape optimization of a glider geometry targeting maximum lift-to-drag ratio by mainly optimizing the wing-fuselage junction. Regarding problem (a), a porous media is utilized to simulate the pressure drop caused by the radiator; the adjoint to this porosity model is developed and presented. This work was carried out in the framework of the EU-funded RBF4AERO project and the presented methods are available through the RBF4AERO platform (www.rbf4aero.eu).*

1 INTRODUCTION

During the last years, CFD-based aerodynamic shape optimization has been attracting the interest of both academia and industry. The constituents needed for executing an automated shape optimization loop include the flow solver, the geometry parameterization (the parameters of which act as the design variables), an optimization method capable of computing the optimal values of the design variables and a way to adapt (or regenerate) the computational mesh to each candidate solution.

Nowadays, a great variety of in-house and commercial flow solvers exist. In the study presented in this paper, the steady-state flow solver of the open-source CFD toolbox, OpenFOAM®, is used to numerically solve the Navier-Stokes equations for incompressible, turbulent flows.

Shape parameterization techniques can be divided into two categories, i.e. those parameterizing only the surface to be optimized and those which also deform the surrounding mesh nodes. In the context of an optimization method, the former rely on, among others, the normal displacement of surface wall nodes [14], the displacement of control points of Bézier–Bernstein or NURBS curves or surfaces and the variation in CAD parameters [15, 17]. The latter include volumetric B-splines or NURBS [9], Radial Basis Functions (RBFs) [6, 4], the harmonic coordinates method, etc. The great advantage of this category is that the interior of the computational mesh is also deformed, avoiding, thus, costly re-meshing and allowing the initialization of the flow field from the solution obtained in the previous optimization cycle, since the mesh topology is preserved. In this paper, a number of parameters controlling the positions of groups of RBF control points are used as the design variables, using technology and methods developed in the context of the RBF Morph software [3].

Gradient-based optimization methods require a high effort to develop and maintain but can have a cost per optimization cycle that does not scale with the number of design variables, when the adjoint method is used to compute the gradients of the objective function. Both discrete and continuous adjoint methods, [5, 12], have been developed. In this work, a continuous adjoint method implemented on the NTUA in-house version of the OpenFOAM® software is used.

The above-mentioned tools are combined in order to form an automated optimization loop, targeting the maximization of the lift-to-drag ratio for a glider plane and the cooling losses minimization caused by the cooling system of a small electric airplane.

The work presented in this paper was carried out in the framework of the RBF4AERO Project which aims at developing the RBF4AERO Benchmark Technology, namely a numerical platform conceived to face the requirements of top-level aeronautical design studies such as multi-physics and multi-objective optimization, fluid-structure interaction (FSI), adjoint-driven optimization and ice accretion simulation. Based on the RBF mesh morphing technique, the platform allows to significantly boost the aerodynamic design process and a relevant impact is then expected in the ever-growing technological demand posed by aeronautical manufacturers in relation to the performance and reliability of aircraft components.

2 THE CONTINUOUS ADJOINT METHOD

In this section, the formulation of the continuous adjoint PDEs, their boundary conditions and the sensitivity derivatives (gradient) expression are presented in brief. The interested reader could find more about the adjoint method used in [18, 19, 13]. Since both geometries to be studied operate at low air speeds, the development is based on the incompressible RANS equations.

2.1 Flow equations

The mean flow equations read

$$R^p = -\frac{\partial v_i}{\partial x_i} = 0 \tag{1a}$$

$$R_i^w = v_j \frac{\partial v_i}{\partial x_j} + \frac{\partial p}{\partial x_i} - \frac{\partial \tau_{ij}}{\partial x_j} + f_i = 0 \tag{1b}$$

where v_i are the velocity components, p is the static pressure divided by the constant density, $\tau_{ij} = (\nu + \nu_t)\left(\frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i}\right)$ are the components of the stress tensor, ν and ν_t the kinematic and turbulent viscosity, respectively. In eq. 1b, term f_i stands for any external force acting on the fluid. In one of the applications studied in section 5, a non-linear, anisotropic porosity model is used based on the Darcy-Forchheimer law, [1]. In this case, f_i reads

$$f_i = r_{ij} v_j \quad , \quad r_{ij} = \nu D_{ij} + \sqrt{v_k^2} E_{ij} \tag{2}$$

where D_{ij} and E_{ij} are constant Darcy and Forchheimer tensorial coefficients.

Eqs. 1 along with the turbulence model PDE(s) comprise the primal or state equations. In the applications presented in section 5, the Spalart-Allmaras, [16], and k-ω SST, [10], models are used. Though the continuous adjoint to both turbulence models has been developed by some of the authors, [18, 13, 8], the remainder of the continuous adjoint formulation will neglect their differentiation in the interest of space.

2.2 General objective function

Let F be the objective function to be minimized by computing the optimal values of the design variables $b_n, n \in [1, N]$. A general expression for an objective function defined on (parts of) the boundary S and the computational domain Ω is given by

$$F = \int_S F_{S_i} n_i dS + \int_\Omega F_\Omega d\Omega \tag{3}$$

where $\mathbf{n}$ is the outward facing normal unit vector.

Differentiating eq. 3 w.r.t. to b_n and applying the chain rule yields

$$\begin{aligned}\frac{\delta F}{\delta b_n} = &\int_S \left(\frac{\partial F_{S_k}}{\partial v_i} n_k + \acute{F}^v_{S,i}\right) \frac{\partial v_i}{\partial b_n} dS + \int_S \left(\frac{\partial F_{S_i}}{\partial p} n_i + \acute{F}^p_S\right) \frac{\partial p}{\partial b_n} dS + \int_S \frac{\partial F_{S_k}}{\partial \tau_{ij}} n_k \frac{\partial \tau_{ij}}{\partial b_n} dS \\ &+ \int_{S_W} n_i \frac{\partial F_{S_i}}{\partial x_k} \frac{\delta x_k}{\delta b_n} dS + \int_{S_W} F_{S_i} \frac{\delta (n_i dS)}{\delta b_n} + \int_{S_W} F_\Omega n_k \frac{\delta x_k}{\delta b_n} dS + \int_\Omega \acute{F}^v_{\Omega,i} \frac{\partial v_i}{\partial b_n} d\Omega + \int_\Omega \acute{F}^p_\Omega \frac{\partial p}{\partial b_n} d\Omega\end{aligned} \tag{4}$$

where S_W is the parameterized part of the solid wall boundaries and $\acute{F}^\Phi_\Omega$ includes the partial derivative $\partial F_\Omega / \partial \Phi$ plus any term resulting from the use of the Green-Gauss theorem for integrals of the form $\int_\Omega \frac{\partial}{\partial b_n}\left(\frac{\partial \Phi}{\partial x_j}\right) d\Omega$. Terms $\acute{F}^v_{S,i}$ and $\acute{F}^p_S$ are non-zero only if F_Ω includes differential operators of v_i or p. In eq. 4, $\delta\Phi/\delta b_n$ is the total derivative of any quantity Φ while $\partial\Phi/\partial b_n$ is its partial derivative. These are related by

$$\frac{\delta \Phi}{\delta b_n} = \frac{\partial \Phi}{\partial b_n} + \frac{\partial \Phi}{\partial x_k} \frac{\delta x_k}{\delta b_n} \tag{5}$$

To avoid computing variations in the flow variables, the adjoint method as presented in the next subsection, is used.

2.3 Continuous adjoint formulation

Starting point of the continuous adjoint formulation is the introduction of the augmented objective function

$$F_{aug} = F + \int_{\Omega} u_i R_i^v d\Omega + \int_{\Omega} q R^p d\Omega \tag{6}$$

where u_i are the components of the adjoint velocity vector and q is the adjoint pressure. For the development of the adjoint to the turbulence model PDEs, the reader is referred to [13]. The differentiation of eq. 6, based on the Leibniz theorem, yields

$$\frac{\delta F_{aug}}{\delta b_n} = \frac{\delta F}{\delta b_n} + \int_{\Omega} u_i \frac{\partial R_i^v}{\partial b_n} d\Omega + \int_{\Omega} q \frac{\partial R^p}{\partial b_n} d\Omega + \int_{S_W} (u_i R_i^v + q R^p) n_k \frac{\delta x_k}{\delta b_n} dS \tag{7}$$

Then, the derivatives of the flow residuals in the volume integrals on the r.h.s. of eq. 7 are developed by differentiating eqs. 1 and applying the Green-Gauss theorem, where necessary. This development can be found in [18, 8, 13].

In order to obtain a gradient expression which does not depend on the partial derivatives of the flow variables w.r.t. b_n, their multipliers in (the developed form of) eq. 7 are set to zero, giving rise to the field adjoint equations

$$R^q = -\frac{\partial u_j}{\partial x_j} + \acute{F}_{\Omega}^p = 0 \tag{8a}$$

$$R_i^v = u_j \frac{\partial v_j}{\partial x_i} - \frac{\partial (v_j u_i)}{\partial x_j} - \frac{\partial \tau_{ij}^a}{\partial x_j} + \frac{\partial q}{\partial x_i} + \acute{F}_{\Omega,i}^v + f_i^a = 0 \tag{8b}$$

where $\tau_{ij}^a = (\nu + \nu_t)\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right)$ are the components of the adjoint stress tensor and f_i^a is the adjoint to the external force term. The adjoint to the Darcy-Forchheimer porosity force term reads

$$f_i^a = u_k (r_{ki} + E_{kj} v_j v_i) \tag{9}$$

The adjoint boundary conditions are derived by treating the flow variations in the boundary integrals (of the developed form of) eq. 7. This development is presented in detail in [13].

In industrial applications, the wall function technique is used routinely in analysis and design. When the design is based on the adjoint method, considering the adjoint to the wall function model becomes necessary. The continuous adjoint method in problems governed by the RANS turbulence models with wall functions was initially presented in [19], where the adjoint wall function technique was introduced for the $k-\varepsilon$ model and a vertex–centered finite volume method with slip velocity at the wall. The proposed formulation led to a new concept: the "adjoint law of the wall". This bridges the gap between the solid wall and the first node off the wall during the solution of the adjoint equations. The adjoint wall function technique has also been implemented in flow solvers based on cell-centered finite-volume schemes, for the Spalart–Allmaras , [18], and $k-\omega$ *SST*, [8], models.

After satisfying the adjoint PDEs and their boundary conditions, the remaining terms in eq. 7

yield the sensitivity derivatives

$$\begin{aligned}\frac{\delta F_{aug}}{\delta b_n} = &-\int_{S_W}\left[(\nu+\nu_t)\left(\frac{\partial u_i}{\partial x_j}+\frac{\partial u_j}{\partial x_i}\right)n_j - qn_i + \frac{\partial F_{S_{W,l}}}{\partial v_i}n_l + \acute{F}^v_{S_{W,i}}\right]\frac{\partial v_i}{\partial x_k}\frac{\delta x_k}{\delta b_n}dS \\ &+\int_{S_W} n_i\frac{\partial F_{S_{W,i}}}{\partial x_k}\frac{\delta x_k}{\delta b_n}dS + \int_{S_W} F_{S_{W,i}}\frac{\delta(n_i dS)}{\delta b_n}dS + \int_{S_W}(u_i R^v_i + qR^p + F_\Omega)\frac{\delta x_k}{\delta b_n}n_k dS \\ &-\int_{S_W}\left[\left(-u_{\langle n\rangle}+\frac{\partial F_{S_{W,k}}}{\partial \tau_{lm}}n_k n_l n_m\right)\left(\tau_{ij}\frac{\delta(n_i n_j)}{\delta b_n}+\frac{\partial \tau_{ij}}{\partial x_m}n_m\frac{\delta x_k}{\delta b_n}n_k n_i n_j\right)\right]dS \\ &-\int_{S_W}\left[\frac{\partial F_{S_{W,k}}}{\partial \tau_{lm}}n_k t^I_l t^I_m\left(\tau_{ij}\frac{\delta(t^I_i t^I_j)}{\delta b_n}+\frac{\partial \tau_{ij}}{\partial x_m}n_m\frac{\delta x_k}{\delta b_n}n_k t^I_i t^I_j\right)\right]dS \\ &-\int_{S_W}\left[\left(\frac{\partial F_{S_{W,k}}}{\partial \tau_{lm}}n_k(t^{II}_l t^I_m + t^I_l t^{II}_m)\right)\left(\tau_{ij}\frac{\delta(t^{II}_i t^I_j)}{\delta b_n}+\frac{\partial \tau_{ij}}{\partial x_m}n_m\frac{\delta x_k}{\delta b_n}n_k t^{II}_i t^I_j\right)\right]dS \\ &-\int_{S_W}\left[\frac{\partial F_{S_{W,k}}}{\partial \tau_{lm}}n_k t^{II}_l t^{II}_m\left(\tau_{ij}\frac{\delta(t^{II}_i t^{II}_j)}{\delta b_n}+\frac{\partial \tau_{ij}}{\partial x_m}n_m\frac{\delta x_k}{\delta b_n}n_k t^{II}_i t^{II}_j\right)\right]dS \end{aligned} \tag{10}$$

New symbols appearing in eq. 10 are explained in [13]. The deformation velocities, $\delta x_k/\delta b_n$, included in eq. 10 express the dependency of the boundary wall nodes on the shape modification parameters. This can be computed by differentiating the surface parameterization scheme presented in the next section.

3 RBF-BASED MORPHING

In this section the mesh morphing algorithm based on RBFs is described. The background theory of RBFs and details of its application in the mesh morphing field are presented; the industrial implementation of the method, as provided by the stand alone version of the software RBF Morph, is then described; finally, the coupling of the mesh morphing tool with adjoint-based sensitivities is explained.

3.1 RBFs background

RBFs are mathematical functions able to interpolate data defined at discrete points only (source points) in an n-dimensional environment. The interpolation quality and its behavior depends on the chosen radial basis function.

In general, the solution of the RBF mathematical problem consists on the computation of the scalar parameters of a linear system of order equal to the number of considered source points. The RBF system solution, determined after defining a set of source points with their displacement, is employed to operate mesh morphing to the discretized domain of the computational model. Operatively, once the RBF system coefficients have been computed, the displacement of an arbitrary node of the mesh, either inside (interpolation) or outside (extrapolation) the domain, can be expressed as the sum of the radial contribution of each source point (if the point falls inside the influence domain). In such a way, a desired modification of the mesh nodes position (smoothing) can be rapidly applied preserving mesh topology.

RBFs can be classified on the basis of the type of support (global or compact) they have, meaning the domain where the chosen RBF is non zero-valued.

An interpolation function composed of a radial basis function φ and a polynomial h of order $m-1$, where m is the order of φ, introduced with the aim to guarantee the compatibility with

rigid motions, is defined as follows

$$s(x) = \sum_{i=1}^{N} \gamma_i \varphi \left(\| x - x_{k_i} \| \right) + h(x) \tag{11}$$

where N is the total number of contributing source points. The degree of the polynomial has to be chosen depending on the kind of RBF adopted. A radial basis fit exists if the coefficients γ_i and the weights of the polynomial can be found such that the desired function values are obtained at source points and the polynomial terms gives no contributions at source points, i.e.

$$s(x_{k_i}) = g_i, 1 \leq i \leq N \ , \ \sum_{i=1}^{N} \gamma_i q(x_{k_i}) = 0 \tag{12}$$

for all polynomials q with a degree less or equal to that of polynomial h. The minimal degree of polynomial h depends on the choice of the RBF. A unique interpolant exists if the basis function is a conditionally positive definite function [11]. If the RBFs are conditionally positive definite of order $m \leq 2$ [2], a linear polynomial can be used

$$h(x) = \beta_1 + \beta_2 x + \beta_3 y + \beta_4 z \tag{13}$$

The subsequent development will assume that the aforementioned hypothesis is valid. The values for the coefficients γ_i of RBF and the coefficients β of the linear polynomial can be obtained by solving the system

$$\begin{pmatrix} \mathbf{M} & \mathbf{P} \\ \mathbf{P^T} & \mathbf{0} \end{pmatrix} \begin{pmatrix} \gamma \\ \beta \end{pmatrix} = \begin{pmatrix} \mathbf{g} \\ \mathbf{0} \end{pmatrix} \tag{14}$$

where g are the known values at the source points and $\mathbf{M}$ is the interpolation matrix defined by calculating all the radial interactions between source points

$$M_{ij} = \varphi \left(\left\| x_{k_i} - x_{k_j} \right\| \right), 1 \leq i \leq N, 1 \leq j \leq N \tag{15}$$

P is a constraint matrix that arises to balance the polynomial contribution and contains a column of "1" and the x, y, z positions of the source points in the other three columns

$$\mathbf{P} = \begin{pmatrix} 1 & x_{k_1} & y_{k_1} & z_{k_1} \\ 1 & x_{k_2} & y_{k_2} & z_{k_2} \\ \vdots & \vdots & \vdots & \vdots \\ 1 & x_{k_N} & y_{k_N} & z_{k_N} \end{pmatrix} \tag{16}$$

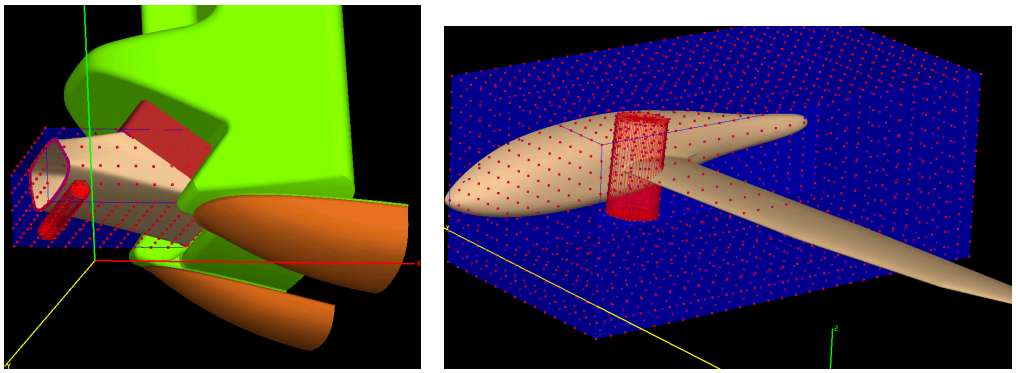
RBF interpolation works for scalar fields, hence a system of the form of eq. 14 has to be solved for each of the three spatial directions.

The RBF method has several advantages that make it very attractive for mesh smoothing. The key point is that being a meshless method only grid points are moved regardless of which elements are connected to them; this make the method suitable for parallel implementation. In fact, once the solution is known and shared in the memory of each processing node of the cluster, each partition has the ability to smooth its nodes without taking care of what happens outside, because the smoother is a global point function and the continuity at interfaces is implicitly guaranteed. Though meshless, the method is able to exactly prescribe known deformations onto the surface mesh: this effect is achieved by using all the mesh nodes as RBF centres with prescribed displacements, including the simple zero field to guarantee that a surface is left untouched by the morphing action.

3.2 RBF Morph tool

The industrial implementation of the RBF mesh morphing poses two challenges: the numerical complexity related to the solution of the RBF problem for a large number of centers and the definition of suitable paradigms to effectively control shapes using RBF. The software RBF Morph allows to deal with both as it comes with a fast RBF solver capable to fit large datasets (hundreds of thousands of RBF points can be fitted in a few minutes) and with a suite of modeling tools that allows the user to set-up each shape modification in an expressive an flexible way.

RBF Morph allows to extract and control points from surfaces and edges, to put points on primitive shapes (boxes, spheres and cylinders) or to specify them directly by individual coordinates and displacements. Primitive shapes can be combined in a Boolean fashion and allow to limit the action of the morpher itself. Two shape modifications used in this study are represented in fig. 1. It is worth noticing that the shape information coming from an individual RBF set-up are generated interactively with the help of the GUI and are used subsequently in batch commands that allows to combine many shape modifications in a non linear fashion (non linearity occurs when rotation axes are present in the RBF set-up).



(a) cooling system diffuser (b) wing-fuselage junction

Figure 1: Example of RBF points arrangement for the definition of two shape parameters, (a) the lower wall of the cooling system diffuser is parameterized using a cluster of RBF control points forming a cylinder. A Box Encapsulation is used to limit the effect of the movement in the vicinity of the diffuser, also making sure that the edge forming the diffuser inlet will not be deformed, since it is defined by the fuselage shape which needs to remain intact, (b) a similar setup is used to define the deformation of the wing-fuselage junction close to the leading edge.

3.3 Coupling of RBF mesh morphing with adjoint sensitivities

Once the adjoint-based sensitivities are available, it is possible to easily compute the sensitivities w.r.t. shape parameters exploiting the parametric mesh available using the mesh morphing tool. In order to take into account the non-linear fashion of the morphing field, the mesh deformation velocities are generated by numerical differentiation of the morphing field around the current design point in the parametric space. For a given set of shape parameters, the morpher is capable to update the baseline mesh into the current one. A perturbed mesh, w.r.t. the current one, can then be obtained for each shape parameter, computing the mesh resulting from its perturbation while keeping all the other constant. The sensitivity w.r.t. each given parameter is then obtained by multiplying the surface perturbation field by the surface sensitivities, eq. 10. It is worth noting that the aforementioned coupling works not just at the origin of the parametric space (baseline model) but at any given design point; adjoint data need to be recomputed for

each design point for which local sensitivities are required.

4 OPTIMIZATION ALGORITHM

The gradient-based algorithm used to minimize the objective function is described in brief below:

1. Define the shape modification parameters, section 3.
2. Solve the flow equations, eqs. 1.
3. Compute F.
4. Solve the adjoint equations, eqs. 8.
5. Compute the deformation velocities and through them, the sensitivity derivatives, eq. 10.
6. Update the design variables by using a descent method.
7. Morph the parameterized surface and displace the interior mesh nodes.
8. Unless the stopping criterion is met, go to step 2.

5 APPLICATIONS

5.1 Cooling losses minimization for an electric aircraft

The first application of the automated optimization loop presented in section 4 deals with the minimization of the fluid power dissipation within the cooling system of the electric engine mounted on a lightweight aircraft. The RANS equations are solved around a simplified fuselage geometry which includes the cooling system configuration, fig. 2; a hex-dominated mesh consisting of about 2.1 million cells is utilized. The flow Reynolds number is $Re = 1.22 \times 10^5$ based on the hydraulic diameter of the cooling system inlet and the k-ω SST turbulence model is used. To avoid simulating the flow within the heat exchanger, its impact on the flow is modeled through the addition of a non-isotropic porosity term, eqs. 1b and 2. The objective function to be minimized reads

$$F = \frac{F_1}{F_2}, \quad F_1 = \int_{\Omega_c} \left[\frac{(\nu + \nu_t)}{2} \left(\frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i} \right)^2 + r_{ij} v_i v_j \right] d\Omega, \quad F_2 = \int_{S_{I_C}} v_i n_i dS \tag{17}$$

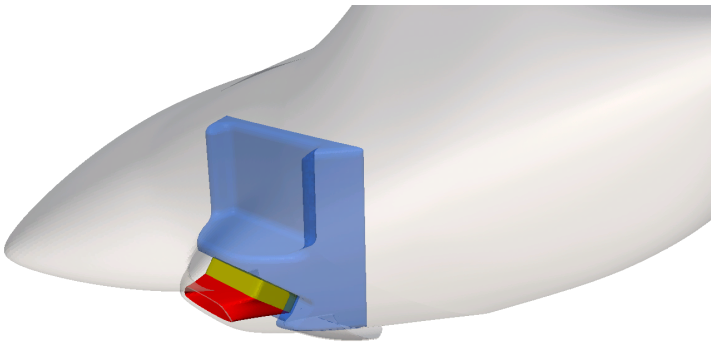
In eq. 17, F_1 expresses the fluid power dissipation within the cooling system domain Ω_c, fig. 2, in the presence of an anisotropic porous medium. Since the flow rate through the cooling system is not fixed, the denominator F_2, quantifying the volume flow rate through the cooling system inlet S_{I_C}, is included in F in order to prevent the optimization algorithm from reducing the power dissipation by dramatically reducing the flow through the radiator. The latter is important since the cooling capacity directly depends on the flow mass passing through the cooling configuration.

Since S_{I_C} is not a mesh boundary, computing the appropriate contributions from the differentiation of F_2 to the adjoint flow is not a trivial task. In order to facilitate the imposition of the adjoint boundary conditions, a couple of coinciding boundaries are defined at S_{I_C}, abbreviated as $S_{I_C}^L$ and $S_{I_C}^R$; flow variables are equated in the corresponding faces of $S_{I_C}^L$ and $S_{I_C}^R$. Due to the

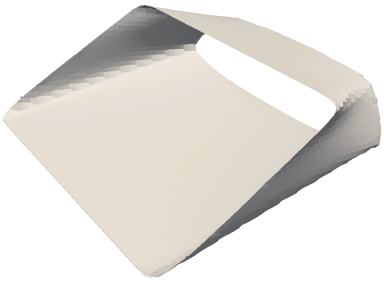
applied boundary conditions, $S_{I_C}^L$ and $S_{I_C}^R$ practically act as internal mesh faces during the solution of the flow equations. Then, for the solution of the adjoint equations, F_2 is defined along only one of these boundaries, say $S_{I_C}^L$. Developing the adjoint to the aforementioned objective function and taking into consideration the primal boundary conditions, the following adjoint boundary conditions are derived along $S_{I_C}^L$ and $S_{I_C}^R$

$$u_i^L = u_i^R \quad , \quad q^L = q^R + \frac{F_1}{F_2^2} \tag{18}$$

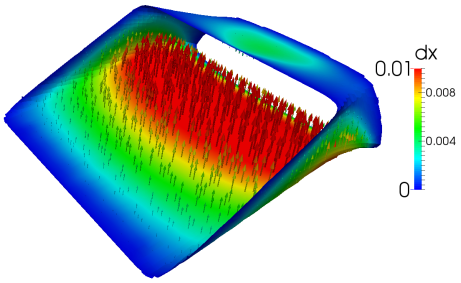
Only the shape of the diffuser of the cooling system, located directly downstream of its inlet, fig. 2(a) is allowed to vary in this optimization study. Eight RBF-based design variables are defined, controlling the upper, lower and side walls of the diffuser, fig. 3. The CG method is used to update the design variables and a 5% reduction in F is obtained within 4 optimization cycles, caused by an 8% reduction in fluid power dissipation and a slight reduction of the volume flow rate by 3%. The optimized diffuser geometry along with the cumulative surface displacement is depicted in fig. 2(c). In fig. 4, the flow streamlines inside the initial and optimized cooling system geometries are presented. The reduction in the objective value can be attributed to the fact that the flow recirculation present close to the upper diffuser wall has practically vanished in the optimized geometry.



(a)



(b)



(c)

Figure 2: Cooling system optimization: (a) the cooling system and its position in the airplane geometry. The diffuser is coloured in red and is the only part of the geometry that is allowed to vary during the optimization. The yellow area is where the actual cooling takes place and is modeled by adding an anisotropic porosity term in the momentum equations. The combination of the red, yellow and blue parts comprises Ω_c, (b) the initial diffuser geometry (flow from right to left) and (c) the optimized diffuser geometry, colored based on the cumulative (after four optimization cycles) surface displacement; the maximum displacement is located at the lower diffuser wall.

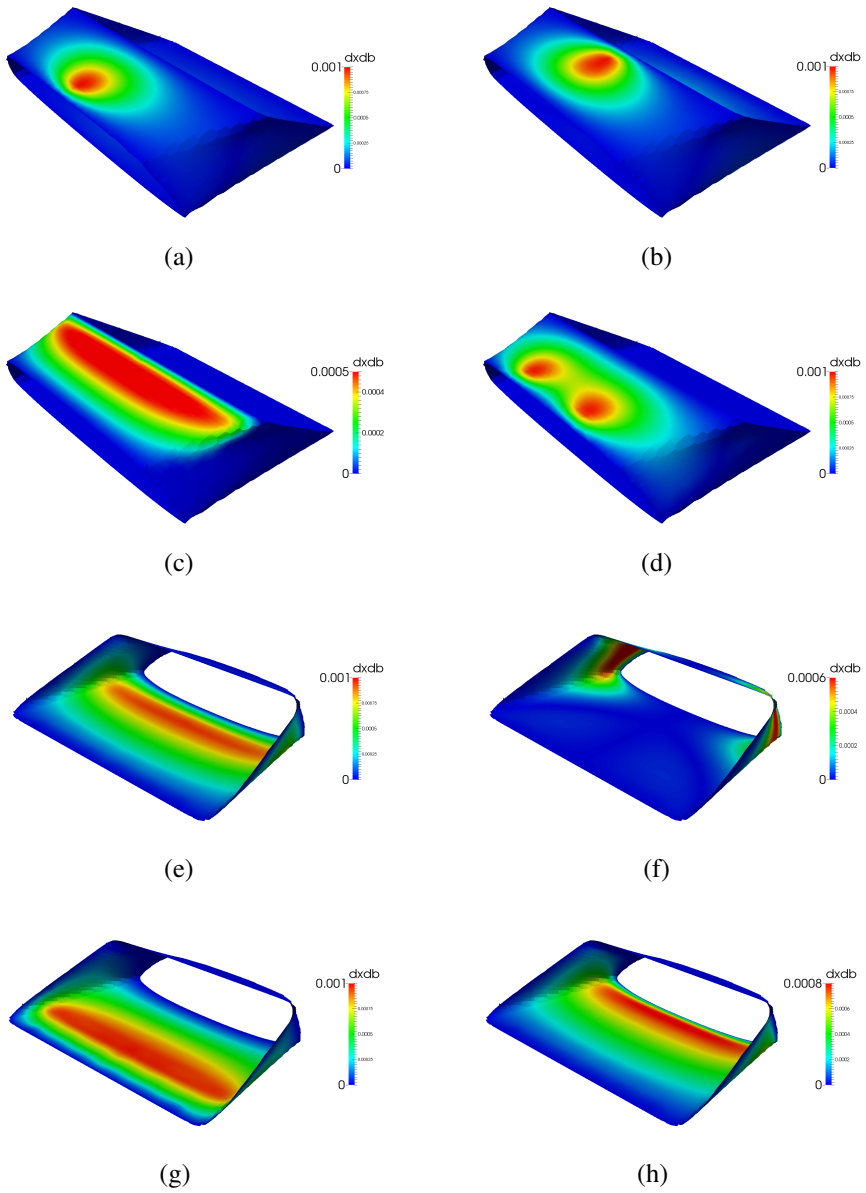


Figure 3: Cooling system optimization: deformation velocity ($\delta x_k/\delta b_m$) for the eight design variables parameterizing the diffuser shape. Design variables (a)-(d) parameterize the upper diffuser wall while those shown in (e)-(h) the side and lower walls.

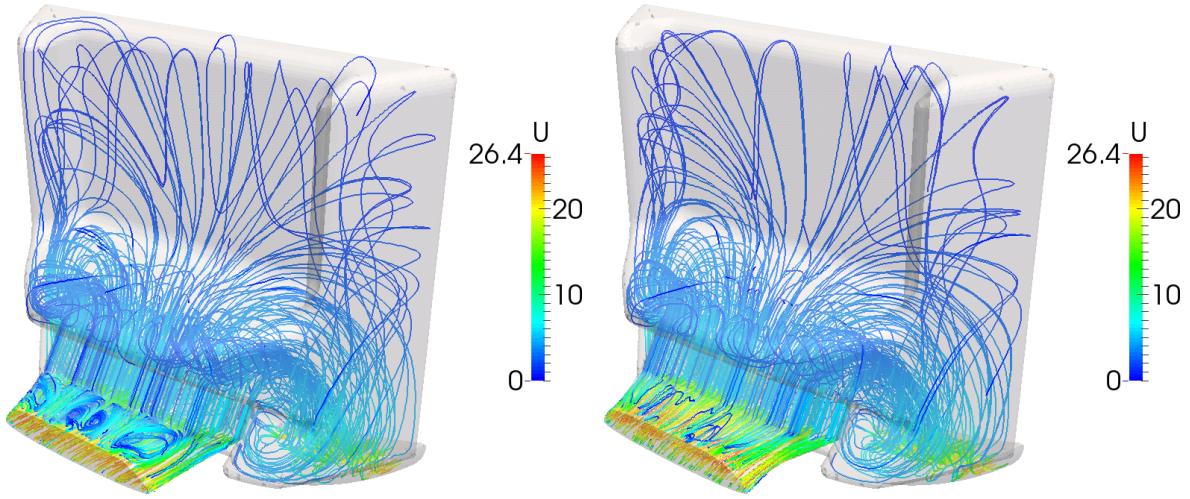
5.2 Lift-to-drag ratio maximization for a glider plane

This section is concerned with the shape optimization of a glider plane targeting the maximization of the lift-to-drag ratio or, equivalently, the minimization of

$$F = -\frac{\int_{S_W} \left(-\tau_{ij} n_j + p n_i\right) r_i^L dS}{\int_{S_W} \left(-\tau_{ij} n_j + p n_i\right) r_i^D dS} \tag{19}$$

where $\mathbf{r^L}$ and $\mathbf{r^D}$ are the lift and drag force projection (unit) directions, respectively. The flow Reynolds number is $Re = 1.55 \times 10^6$ based on the wing chord, the Spalart–Allmaras turbulence model is used, the mesh consists of about 4.7 million cells and the far-field flow angle is 10^o. The geometry is parameterized using four RBF-based design variables depicted in fig. 5, controlling the wing-fuselage junction close to the leading and trailing edges as well as parts of the



(a) initial, $\|v\|$ (b) optimized, $\|v\|$

Figure 4: Cooling system optimization: streamlines plotted through the initial (left) and optimized (right) geometries, coloured based on the flow velocity. The intense flow recirculation present close to the upper diffuser wall has practically disappeared.

upper fuselage surface. The convergence of the steepest descent-driven algorithm presented in section 4 is showcased in fig. 6(a). It can be observed that the lift-to-drag ratio has increased by 15%, caused by 10% drag reduction and a 4% lift increase. The optimized geometry is illustrated in fig. 6(b). In fig. 7, the near-wall velocity isolines are plotted on the glider surface for the initial and optimized geometries. It can be observed that the flow recirculation formed close to the trailing edge-fuselage junction has been significantly reduced.

6 CONCLUSIONS

The continuous adjoint method and an RBF-based morpher, combined into an automated optimization software were used to build a gradient-based optimization algorithm, applied to two low-speed aeronautical applications; the first targeted the losses minimization within the cooling system of a small electric airplane while the second one the increase of the lift-to-drag ratio for a glider plane. The first application required the differentiation of a non-linear, anisotropic porosity model, used to simulate the flow resistance within the radiator of the cooling system. In both cases, the optimized solution was achieved within very few optimization cycles, leading to a small optimization turnaround time. The coupling of the adjoint-based optimization software and the RBF-based morpher is part of the RBF4AERO platform. In a companion paper, [7], the part of RBFAERO platform which combines the RBF-based morpher with an Evolutionary Algorithm-based optimization strategy is also presented.

ACKNOWLEDGMENT

This work was funded by the RBF4AERO ”Innovative benchmark technology for aircraft engineering design and efficient design phase optimisation” project funded in the Aeronautics and Air Transport (AAT) research thematic area of the EUs 7th Framework Programme (FP7-AAT, 2007-2013) under Grant Agreement no. 605396.

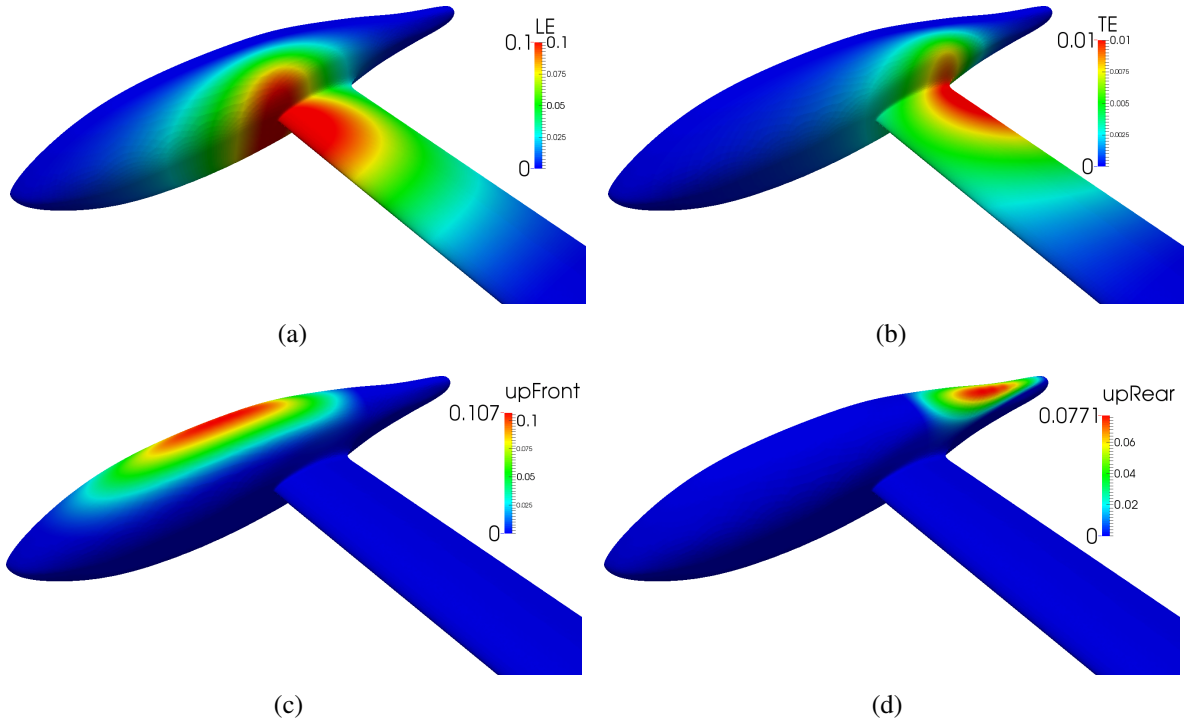


Figure 5: Glider shape optimization: the magnitude of the parametric velocity ($\delta x_k / \delta b_m$) for the four design variables parameterizing the glider shape. The first two parameterize the wing-fuselage junction close to the leading and trailing edges, while the second two affect parts of the upper glider surface. All design variables are allowed to vary within certain limits in order to prevent the generation of non-manufacturable solutions.

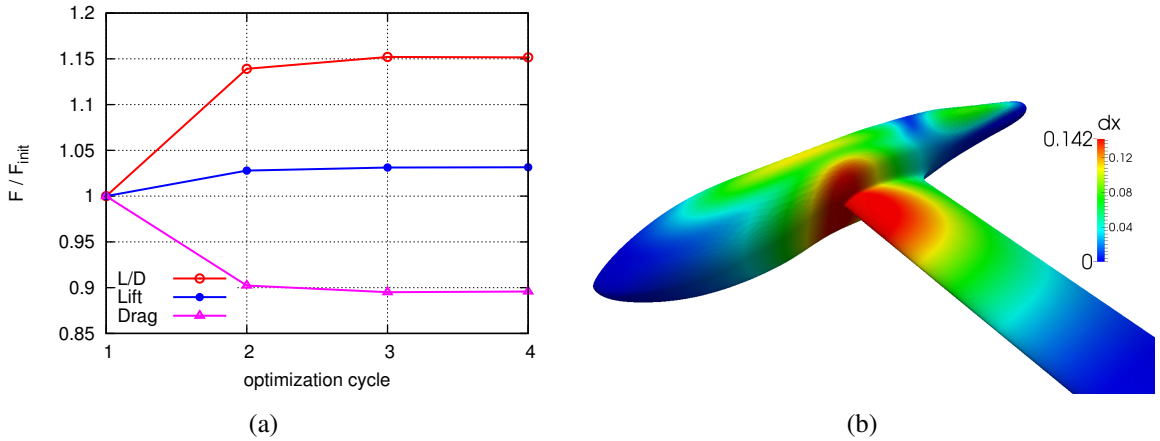

Figure 6: Glider shape optimization: (a) convergence of the lift-to-drag ratio (L/D), along with the lift and drag values. All values plotted w.r.t. the ones obtained using the initial geometry. A 15% lift-to-drag increase is observed in 4 optimization cycles by mainly reducing the drag value and slightly increasing lift, (b) the optimized glider geometry, coloured based on the cumulative surface displacement. A maximum displacement of 14.2 *cm* is observed close to the leading-edge and fuselage junction.

Abstract. *The concept of Smart Micro Vanes (SMV) has been developed and investigated through computational simulations. The concept may significantly extend the applicability of natural-laminar-flow-and-high-aspect-ratio wing for modern, low-cost transport aircraft. The proposed device is an array of deployable micro-vanes (turbulators) located at a front part of the suction side of the wing. In nominal, cruise flight conditions the SMV are hidden in order not to trip the laminar boundary layer. In transonic flow, in extraordinary conditions of sudden gust the SMV are deployed to force laminar-turbulent transition of boundary layer on the suction side of the wing. This causes sudden drop of lift force acting on the wing and significant reduction of a danger of buffet onset. Both these phenomena are beneficial and desirable in the context of active control of aerodynamic loads acting on the wing structure. The paper presents results of computational simulations of transonic flight of simplified model of natural-laminar-flow wing in conditions of sudden-gust appearance. The simulations have been conducted for the case of clean model wing as well as for the same wing equipped with Smart Micro Vanes, deployed automatically (simulation of simple close-loop control) to protect the wing structure against excessive aerodynamic loads.*

1 INTRODUCTION

Reduction of operational costs of modern transport airplanes is one of key goals of contemporary Aeronautical Engineering. The goal is trying to be achieved by reduction of both the aerodynamic drag and weight of aircraft [1]. For transport airplanes operating at transonic air speeds, the main drag components are: induced drag, friction drag and wave drag. Reduction of each of the drag components is achieved by different means. Reduction of induced drag can be achieved by application of higher-aspect ratio wing, but this leads to increased aircraft weight. For this reason a design solution based on active flow control that make it possible to build lighter high-aspect-ratio wings are in demand. On the other hand the known solution for reduction of friction and wave drag is transonic, natural-laminar-flow wing. This solution has, however, significant drawbacks in unsteady flow. In cases of rapid changes of flight conditions, as in sudden gusts the loads on laminar wing grow more rapidly than on turbulent wing and buffet oscillations leading to structural damage of wing may appear earlier than for turbulent wing.

Taking into account all above pros and cons concerning application of Natural Laminar Flow (NLF) technology for wings of low-cost transport airplanes operating at transonic speeds, one may conclude, that such approach needs application of smart devices controlling the flow on the wing and loads acting on the wing in extraordinary flight conditions. In contrast to classic wing-load-control systems protecting the wing structure against excessive loads, such a system for the NLF wing should also protect the transonic flow on the wing against the buffet onset.

The interaction between boundary layer and transonic effects on the NLF wing has been investigated within the FP7 project TFAST (Transition Location Effect on Shock Wave Boundary Layer Interaction). Based on results of computational investigations conducted within the project [2], the authors of the paper have developed concept of Smart Micro Vanes (SMV). This concept may significantly extend the applicability of natural-laminar-flow-and-high-aspect-ratio wing for modern, low-cost transport aircraft. The proposed smart device is an array of deployable micro-vanes (small, thin plates) located at a front part of the suction side of the wing. In nominal, cruise flight conditions the SMV are hidden inside the wing in order not to trip the laminar boundary layer. It is assumed that the SMV are deployed to force laminar-turbulent transition of boundary layer generally in two situations:

1. In extraordinary conditions of sudden gust in transonic flow:
    - to alleviate growing aerodynamic load acting on the wing
    - to reduce a danger of buffet onset (as well as wing buffeting)
2. Optionally, in takeoff-and-landing conditions (low speed, high lift) to avoid a danger of laminar-stall appearance at high angles of attack (which is well known drawback of laminar airfoils and wings).

The paper presents results of computational simulations of transonic flight of simplified model of NLF wing in conditions of sudden-gust appearance. The simulations have been conducted for the case of clean NLF wing as well as for the same wing equipped with Smart Micro Vanes, activated (deployed) to protect the wing structure against excessive aerodynamic loads.

2 RESEARCH SUBJECT AND METHODOLOGY

The computational investigations of SMV applied for wing-load control via boundary-layer control were conducted for the case of simplified model of wing segment presented in Figure 1. The segment was built based on V2C laminar airfoil designed by Dassault Aviations especially for investigations of SWBLI in the TFAST project. Two configurations of the wing

have been investigated: the clean wing (with fully retracted micro vanes) shown on the left side of Figure 1 and the wing equipped with SMV, which were retracted or deployed depending on current flight conditions. The latter configuration in nominal cruise flight conditions looked exactly the same as clean-wing configuration. In sudden-gust conditions, when aerodynamic loads exceeded given threshold, the SMV were deployed and investigated configuration looked as it is shown on the right side of Figure 1.

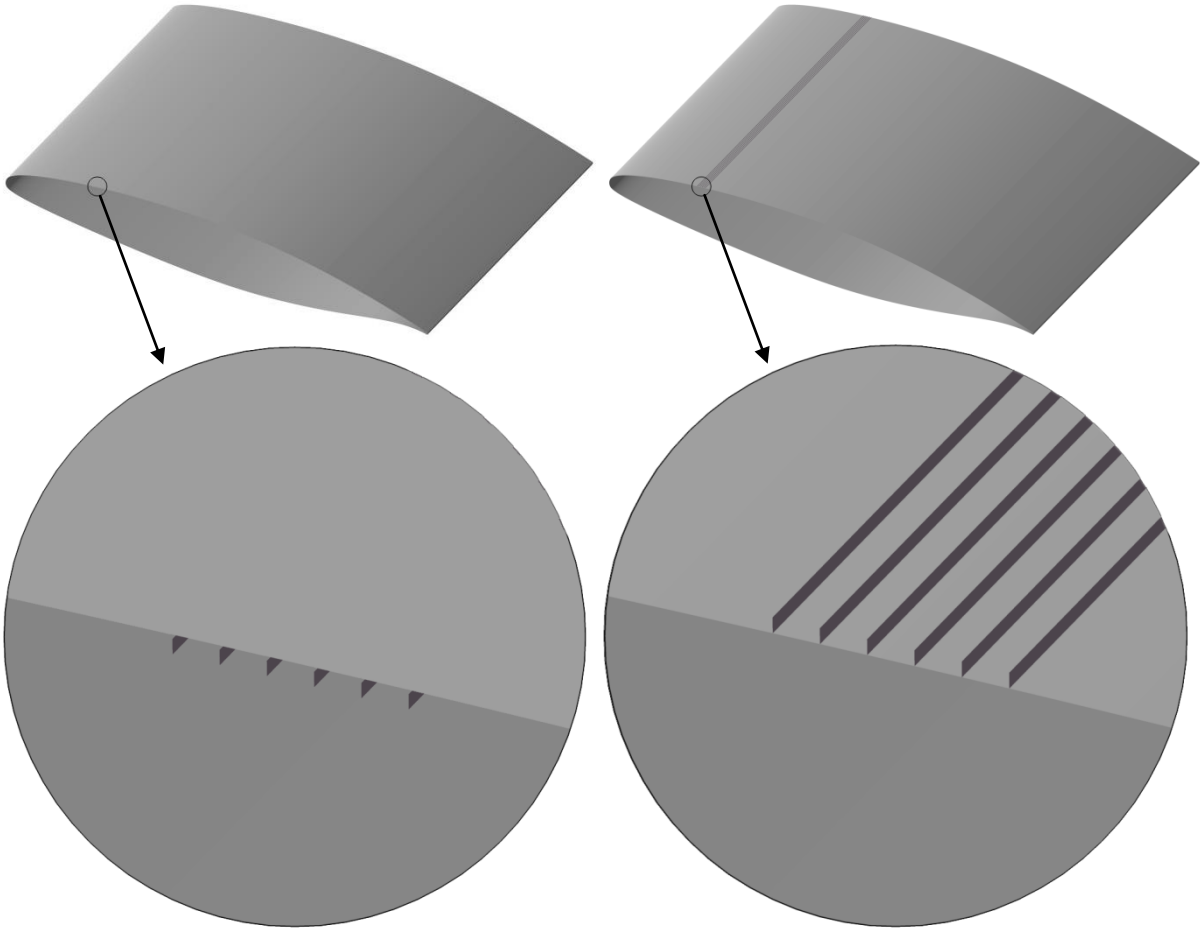

Figure 1: Investigated model of NLF-Transonic Wing equipped with Smart Micro Vanes.
Left side: Clean NLF Wing with retracted SMV. Right side: Wing with fully deployed SMV.

The wing-flight simulations were conducted through solution of Unsteady Reynolds-Averaged Navier-Stokes Equations (URANS) using ANSYS FLUENT solver [3]. For the modelling of investigated phenomena the four-equation Transition SST turbulence model was applied. This model solves additional four equations on four unknown variables: k – turbulent kinetic energy, ω - specific dissipation rate of k, γ - intermittency (probability of boundary layer being turbulent) and Re_θ - Reynolds number based on boundary layer momentum thickness. Second-order spatial and temporal discretisation of URANS equations was applied.

In conducted simulations, instead of finite-span wing segment, the infinite-span wing was investigated, utilising periodicity conditions at the ends of wing segment. The chord of the wing was C=0.2m.

During the wing-flight simulations, the effect of sudden gust was modelled by sudden growth of angle of attack, which was achieved by physical rotation of computational mesh.

The effect of deployment of SMV was realised through a change of status of cell walls modelling physical surfaces of deployed vanes. In case when the vanes were retracted, the surfaces had status "interior" while for fully deployed vanes they had status "wall".

In conducted CFD simulations, a simple Closed-Loop Control (CLC) of wing loads was introduced. It was assumed that during the flight, the control system is monitoring current values of load factor (n), defined as the ratio:

$$n = L / W \tag{1}$$

where L is a current lift force acting on the wing and W is a weight of aircraft. According to assumed CLC algorithm: the load/flow control system was activated (SMV were deployed) when for increasing load factor it exceeded the assumed activation threshold n=1.3.

Similar approach using time-accurate solution of URANS equations was already applied for analysis of reduction of aerodynamic loads in gust as an effect of fluidic wing-load-control devices [4],[5].

3 SIMULATION OF TRANSONIC FLIGHT OF NLF WING IN SUDDEN-GUST CONDITIONS

3.1 Flight Conditions

In conducted computational simulations, the nominal, cruise flight conditions were assumed as follows:

- Mach number: M=0.7
- Reynolds number: $Re=2.67 \cdot 10^6$
- Lift coefficient: $C_L = 0.76$

The assumed sudden-gust model was realised through change of current angle of attack - physical rotation of computational mesh with angular speed 5deg/s. As a result, the gust velocity profile presented in Figure 2 was applied in the conducted simulations. In presented results, only the gust-velocity-growth phase was taken into consideration.

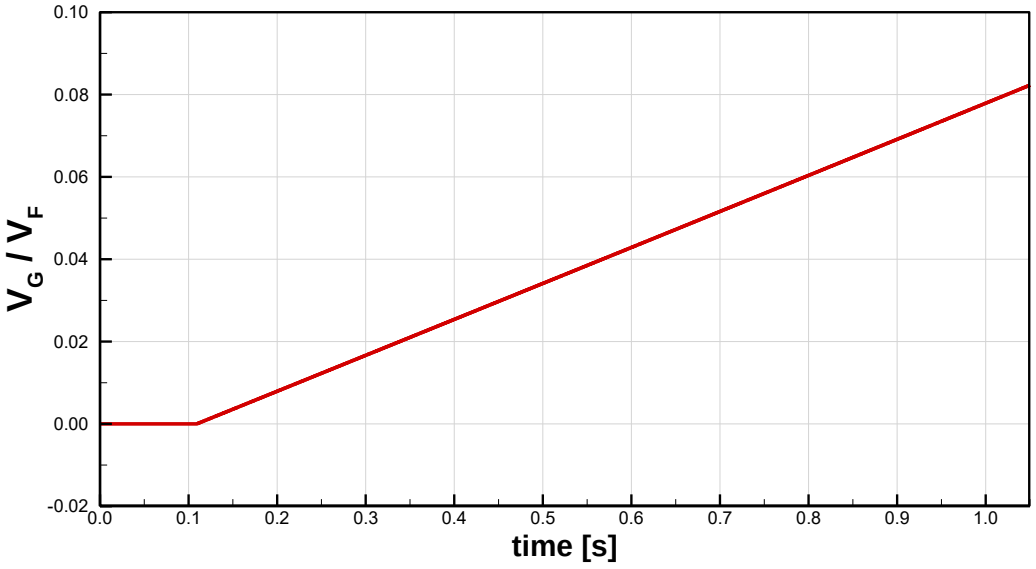

Figure 2: Assumed model of sudden-gust conditions. Time-variable gust velocity (V_G) related to flight velocity (V_F) during the gust-velocity-growth phase.

Within the TFAST project, several different positions and heights of SMV were investigated from point of view of their effectiveness and suitability for wing-load-control purposes. In the presented simulations only the configuration of six rows of SMV of height of 0.125% of wing chord, located at 20% of wing chord (see Figure 1) was investigated, because such configuration seemed to be optimal based on previously conducted research [2].

3.2 Results of Simulations

Time history of flight in sudden gust conditions of two compared configurations: clean wing and wing equipped with SMV, in synthetic form is presented in Figure 3.

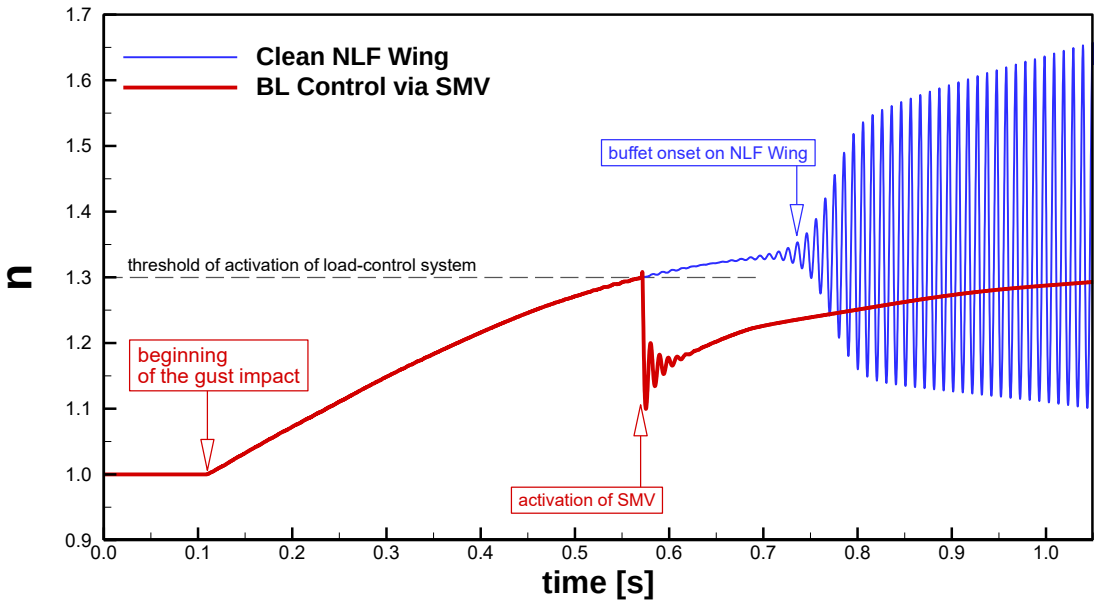

Figure 3: Comparison of time histories of load factor (n) during the sudden, growing gust, for two configurations: 1) Clean NLF Wing and 2) the Laminar Wing equipped with SMV controlling the flow inside the boundary layer.

According to assumed gust profile (Figure 2) the gust started influencing the wing loads at the moment t≈0.11s of simulation. The load factor started growing from this moment, and it exceeded the threshold 1.3 at the moment t≈0.57s. For the clean-wing configuration, the load factor continued growing smoothly until the moment t≈0.70s. Starting from this moment, the load factor for the clean-wing configuration indicated oscillations of quickly growing amplitude. These oscillations were effect of buffet onset on the suction side of the wing, due to a strong, unsteady flow separation behind the shock wave. Frequency of the observed buffet was approximately 98 Hz.

For the configuration of wing equipped with SMV, the simulation of unsteady gust load was the same as for the clean wing until the moment t≈0.57s when the load factor exceeded assumed threshold 1.3. At the moment, the SMV were fully deployed. Figure 3 shows that activation of SMV caused sudden drop of load factor of nearly 0.2. Next, for a moment, the load factor indicated some diminishing oscillations and after it continued smooth, mild increase. For the conditions, where the flow around clean wing indicated strong buffet, the flow around the wing with deployed SMV was free of any instabilities.

The same qualitative differences in the transonic flow around two compared configurations are visible in Figure 4, where the time histories of wing pitching-moment coefficient are compared.

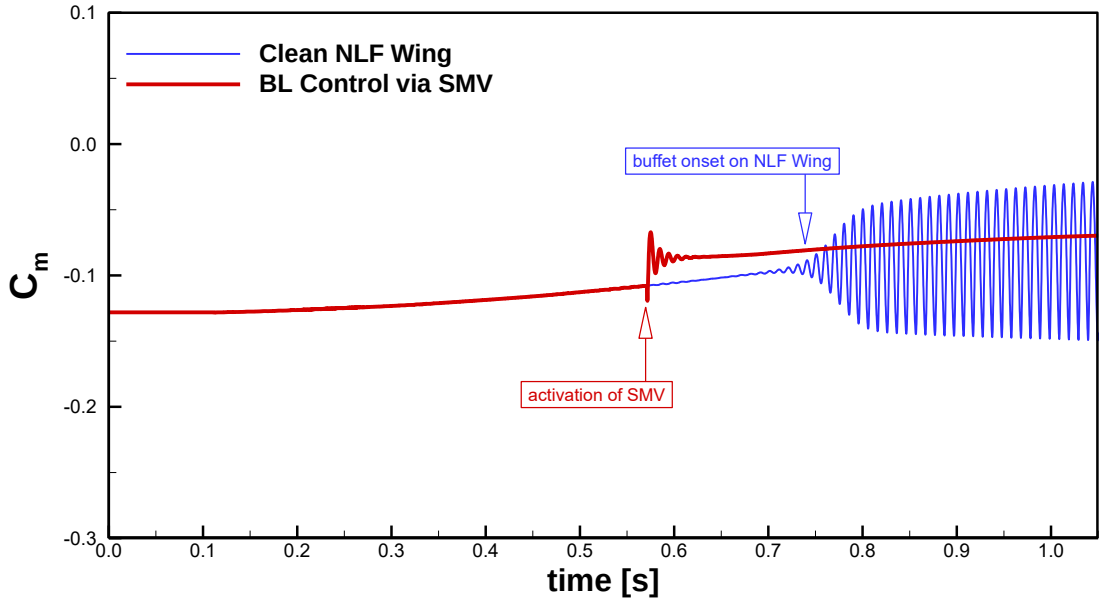

Figure 4: Comparison of time histories of pitching-moment coefficient (C_m) during the sudden, growing gust, for two configurations: 1) Clean NLF Wing and 2) the Laminar Wing equipped with SMV controlling the flow inside the boundary layer.

Figure 5, Figure 6 and Figure 7 present numerical Schlieren visualisations (contours of gradient of air density projected on appropriate direction) of shock waves in the flow around two compared configuration captured in selected moments of wing-flight computational simulations. For the moments t=0.6172 (Figure 5) and t=0.7072 (Figure 6) the visualisations show that in turbulent flow forced by the deployed SMV the shock waves are slightly weaker and located nearer the leading edge of the wing than in purely laminar flow.

Figure 7 presents Schlieren visualisations of shock waves in the flow around two compared configuration captured at the moment, when for the clean wing the strong buffet is observed. In this case the shock wave is extremely unsteady and it quickly changes its position causing quick changes of flow parameters. Extreme-front and extreme-back positions of the shock wave during the buffet observed for the clean wing are shown in upper and middle part of Figure 7. For the configuration of wing with deployed SMV, the shock wave does not indicate any instabilities.

Figure 8, Figure 9 and Figure 10 present distribution of pressure coefficient (C_P) in selected cross-section of the wing, captured for two compared configuration in selected moments of simulations. The C_P distributions presented in Figure 8 are captured at a moment shortly after achieving by the load factor (n) the threshold 1.3 and after deployment of SMV. The differences in C_P distribution clearly explain significant drop of aerodynamic load concerning the configuration with deployed SMV. For this configuration, the observed decrease in pressure difference between upper and lower surfaces of the wing is a result of deceleration of the flow on the upper surface caused by both the deployed SMV and induced by them turbulent boundary layer which is much thicker than laminar boundary layer.

In Figure 10 the unsteady C_P distributions on the clean wing captured during the strong buffet are compared with C_P distribution on the wing with deployed SMV, which does not indicate any instabilities.

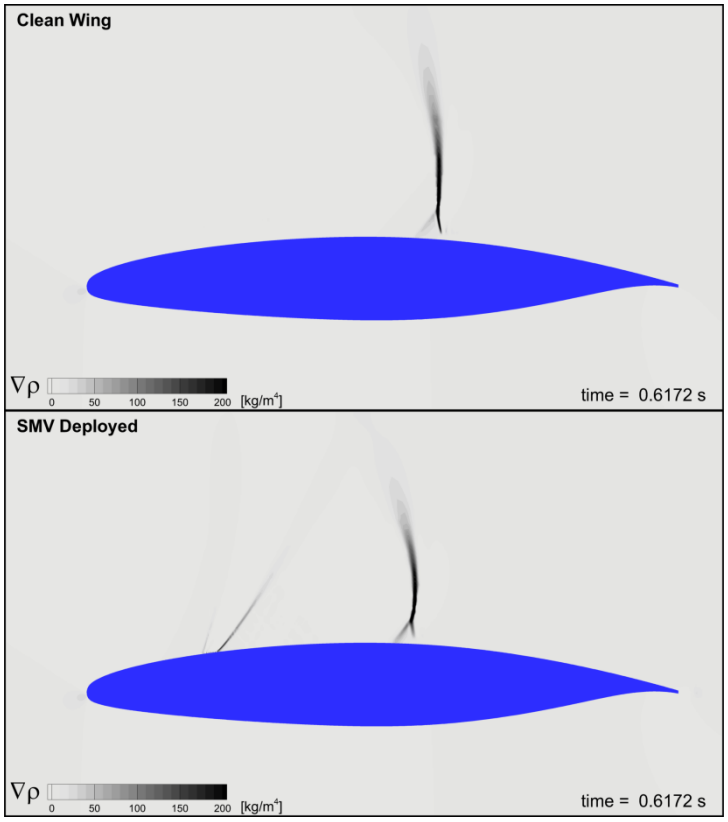

Figure 5: Schlieren visualisation of shock waves at a moment shortly after deployment of SMV. Upper graph: clean-wing configuration. Lower graph: configuration with fully deployed SMV.

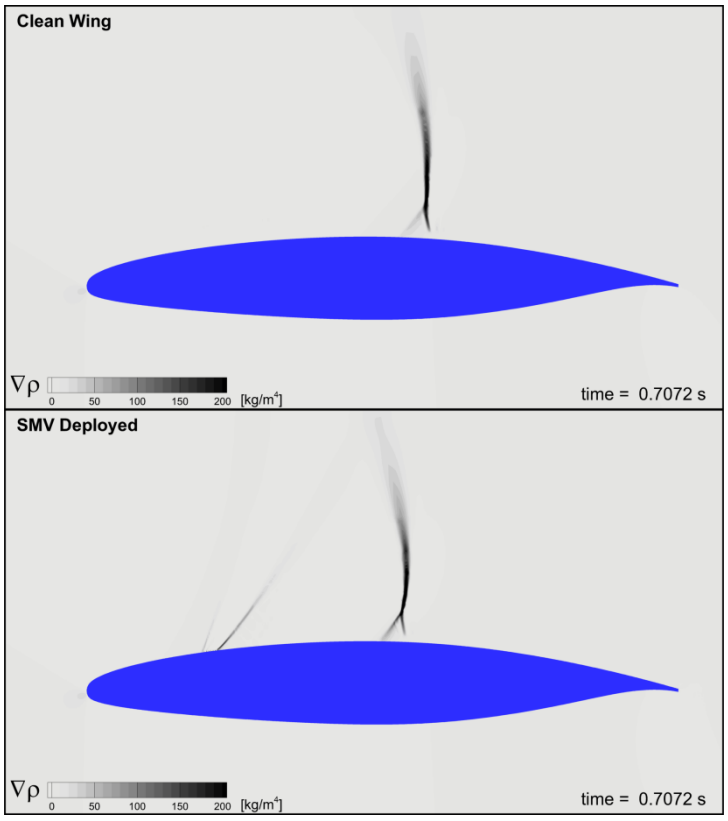

Figure 6: Schlieren visualisation of shock waves at a moment shortly before the buffet onset on the clean wing. Upper graph: clean-wing configuration. Lower graph: configuration with fully deployed SMV.

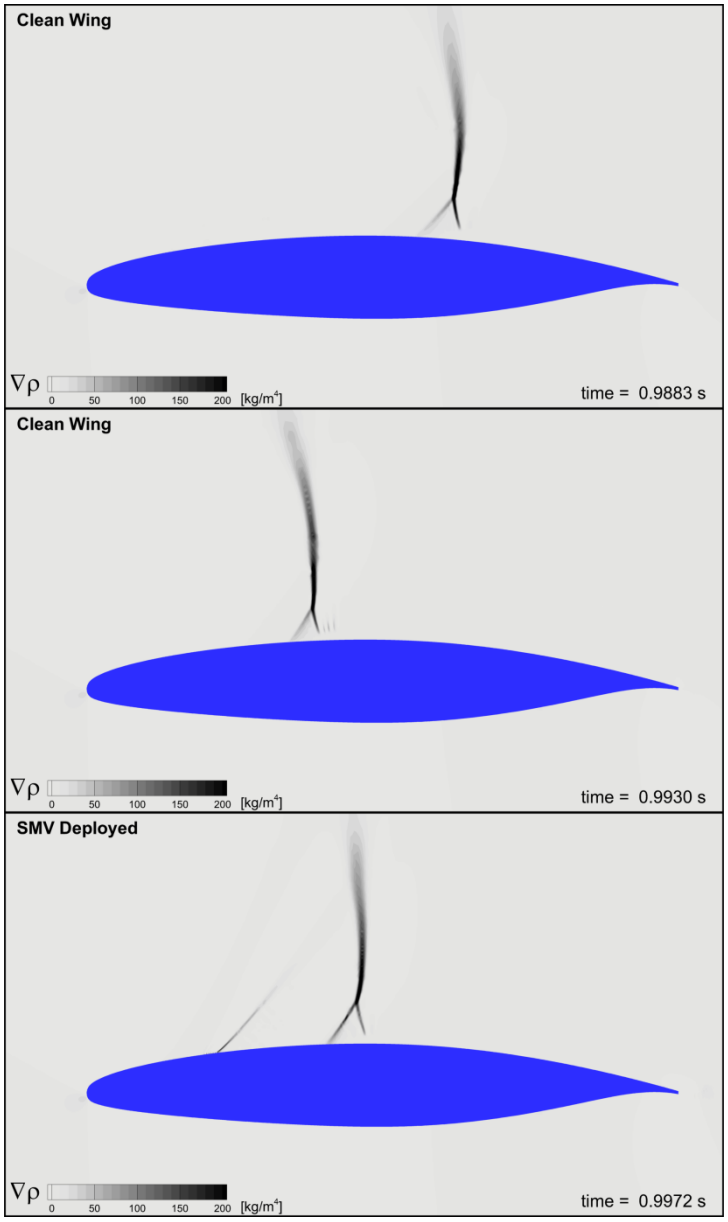

Figure 7: Schlieren visualisation of shock waves during a strong buffet on the clean wing. Upper and middle graphs: clean-wing configuration for extreme-back and extreme-front positions of the shock waves. Lower graph: configuration with fully deployed SMV and steady position of the shock wave.

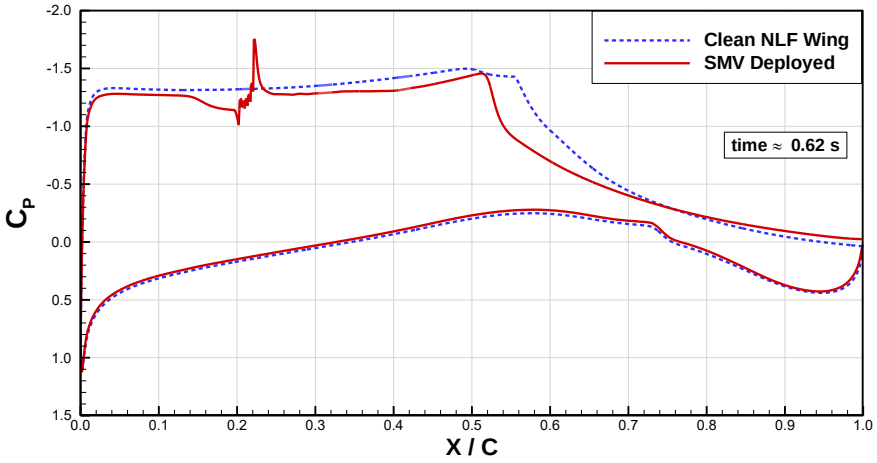

Figure 8: Comparison of pressure-coefficient (C_P) distribution on the wing at a moment shortly after deployment of SMV, for two configurations: 1) Clean NLF Wing and 2) the Laminar Wing with fully deployed SMV.

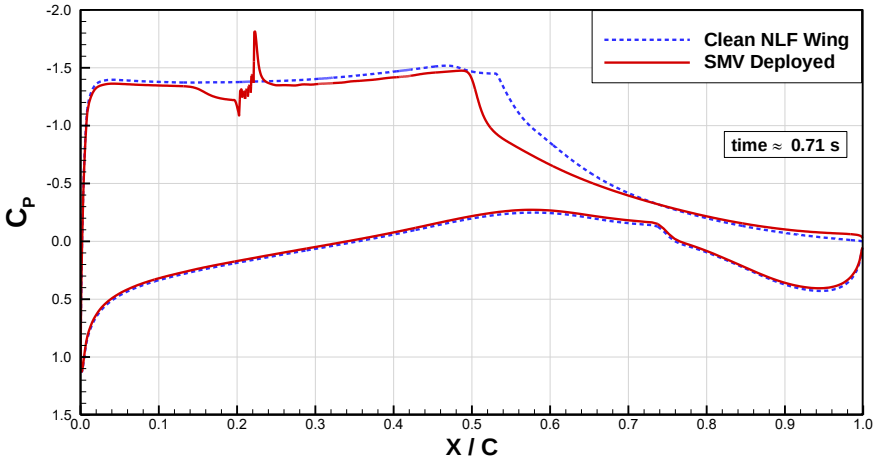

Figure 9: Comparison of pressure-coefficient (C_P) distribution on the wing at a moment shortly before the buffet onset on the clean NLF wing, for two configurations: 1) Clean NLF Wing and 2) the Laminar Wing with fully deployed SMV.

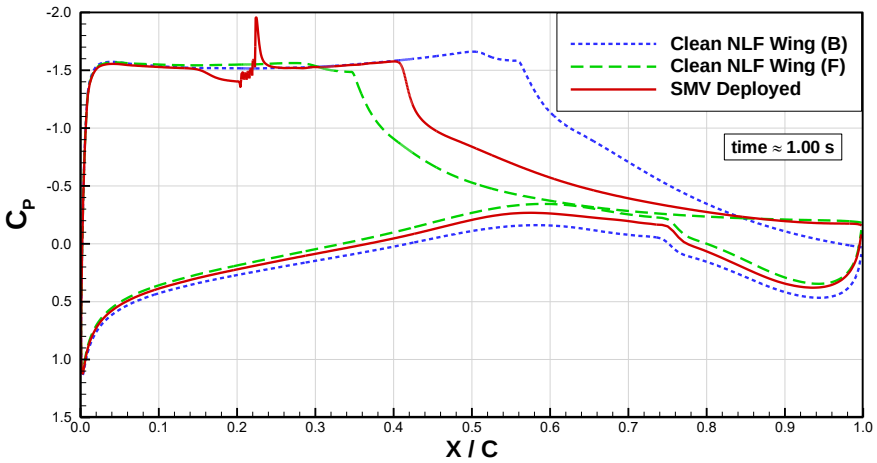

Figure 10: Comparison of pressure-coefficient (C_P) distribution on the wing during a strong buffet on the clean NLF wing, for two configurations: 1) Clean NLF Wing, two cases of extreme-front (F) and extreme-back (B) positions of shock waves and 2) the Laminar Wing with fully deployed SMV and steady position of the shock wave.

4 CONCLUSIONS

- The concept of Smart Micro Vanes has been developed and investigated through computational simulations so as to prove its potential advantages which may significantly extend the applicability of natural-laminar-flow-and-high-aspect-ratio wings for modern, low-cost transport aircraft operating at transonic air speeds.
- The proposed device is an array of micro-vanes which in extraordinary, high-aerodynamic-load flight conditions are deployed to force laminar-turbulent transition which leads to immediate drop of excessive wing load as well as to reduction of danger of transonic buffet onset.
- Conducted simulations showed that effective flow control and wing-load control may be ensured by Smart Micro Vanes of height at least 0.125% of wing chord, preferably located at 20% of wing chord.
- For the investigated configuration of wing equipped with Smart Micro Vanes, in sudden-gust conditions, observed reduction of load factor, being the effect of activation of the device, was approximately 0.2 shortly after activation and 0.1 in a further phase of the gust.
- For the investigated configuration of wing equipped with Smart Micro Vanes, in sudden-gust conditions, in contrast to the clean-wing configuration, the transonic-buffet phenomenon was not observed.

5 ACKNOWLEDGEMENTS

The research leading to these results has received funding from the European Union's Seventh Framework Programme **(FP7/2007-2013)** within the project TFAST (Transition Location Effect on Shock Wave Boundary Layer Interaction), under Grant Agreement No. 265455.
The project was also co-financed by the ministry of science of Poland from the funds dedicated to scientific research in 2012-2015, agreement no. **2641/7.PR/12/2013/2** and by Institute of Aviation.
Computational support was obtained from university of Warsaw Interdisciplinary Centre for Mathematical and Computational Modelling, in the computational grant no. G57-2.

NOMENCLUATURE

C	- wing chord
C_L	- lift coefficient
C_m	- pitching moment coefficient
C_P	- pressure coefficient
L	- lift force
M	- Mach number
n	- load factor – def. (1)
t	- time
V_G	- gust velocity (normal to flight direction)
V_F	- flight velocity
W	- weight of aircraft
Re	- Reynolds number
ρ	- density

BL - Boundary Layer
NLF - Natural Laminar Flow
SMV - Smart Micro Vanes
SST - Shear Stress Transport
URANS - Unsteady Reynolds-Averaged Navier-Stokes Equations

Keywords: Morphing, Adaptive Trailing Edge Device, Actuation system, Flutter Analysis

Abstract. *This paper deals with the design of an adaptive trailing edge aimed at increasing the range capacity of a large commercial aircraft. Moving from the requisites, a brief discussion about the expected performance will be introduced together with a suitable layout. Then, the design of the structural system able to guarantee both the deformability and the structural resistance will be presented. The next step is devote to the actuation system design, able to be integrate din the structural body and bear the external aerodynamic load. The external skin contributes to load bearing but also to the actuation effort required. Details refer to other publications while here it is considered though its effect only. An aeroelastic study, ensuring the stability of the proposed device over the whole wing system will be finally dealt with. A discussion on the real applicability in the aeronautics will conclude the work, pointing out at the necessary improvement required. Other work on the same subject, but referring to other design and implementation aspect will be fully referred to.*

1 INTRODUCTION

Conventional high lift systems, such as flaps or slats, are the common way to modify aircraft wing geometry during take-off and landing in order to provide additional lift at low speed. However, they have limited efficiency due to the geometric discontinuities, require high installation efforts and offer no functional flexibility in cruise, as, for instance, differential surface deflection. For some last-generation aircraft as B787 and A350, additional functions, such as differential flap settings are ensured by innovative flap actuation system concepts.

In the framework of SARISTU project, research was conducted to develop an adaptive trailing edge device aiming at maximizing wing aerodynamic performance in cruise. Wing shape is controlled during flight in order to compensate the weight reduction following the fuel burning, by allowing the trimmed configuration to remain optimal in terms of efficiency (Lift to Drag ratio) or minimal drag. Trailing edge adaptations were investigated to achieve significant benefits in aircraft fuel consumption whose reduction ranges from 3% to 5% depending on flight mission. Target morphed shapes - to be reproduced in flight - were determined through CFD-based optimization analyses; the same applies to the overall dimensions of the morph-able trailing edge (chord/span, see Figure 1). In order to assure the necessary figures for the aerodynamic efficiency of the reference A/C wing, it was found that the morphable trailing edge portion should have spanned 3.0 meters along the inner wing (kink) and 9.6 meters along the outer wing region; the required chordwise extensions should have been equal to the 20% and to the 10% of the wing MAC (nearly 3.5 meters) respectively for the inner and the outer segments.

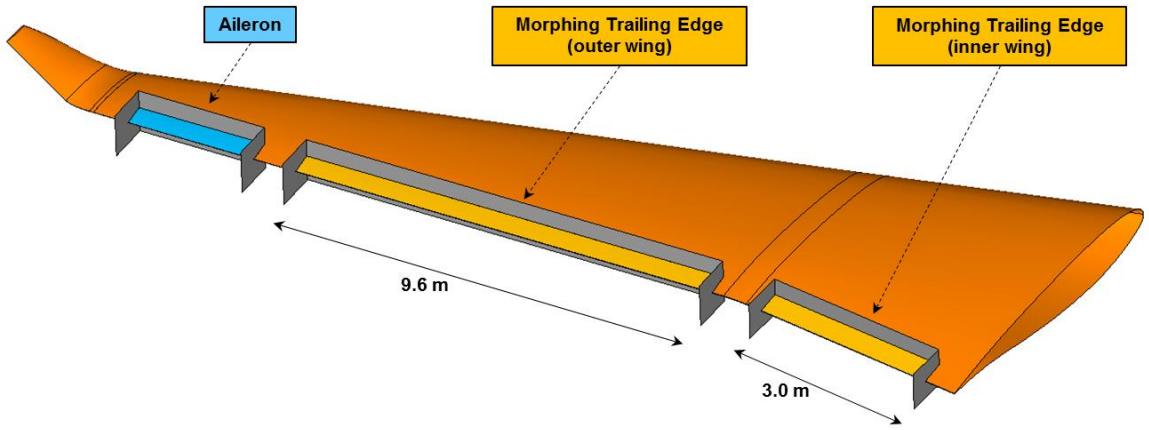

Figure 1: Morphing trailing edge regions [1].

Morphing is enabled by a multi-finger architecture driven by load-bearing actuators systems (hidden in Figure 2), designed to work synchronously to provide camber variation. After information gained from a widely distributed strain sensor network, the control system drives actuators movement. An adaptive, highly deformable skin, (shown in Figure 3), consisting of hard and soft segments, absorbs part of the external loads and insures a smooth profile. While the soft skin segments release a smooth, gapless transition between movable and fixed parts of the underlying kinematic structure, the hard skin segments compensate deformations due to air pressure gradients. The soft segments are based on elastomer foam while the hard segments consist of aluminum profiles. Both segments are covered by a thin layer to ensure a smooth surface. The system keeps its structural properties while actuated, then allowing the

preservation of a specific target shape regardless the action of the operational loads. The soft segments are located above and under the rib hinges while the hard segments are connected to the rib structure.

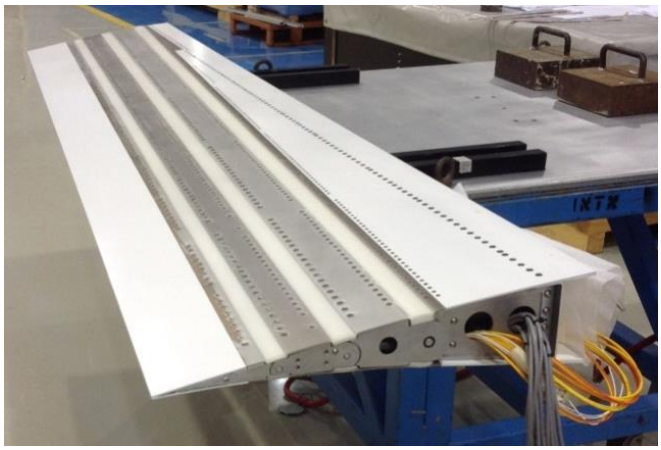

Figure 2: The Adaptive Trailing Edge (ATED) device [5].

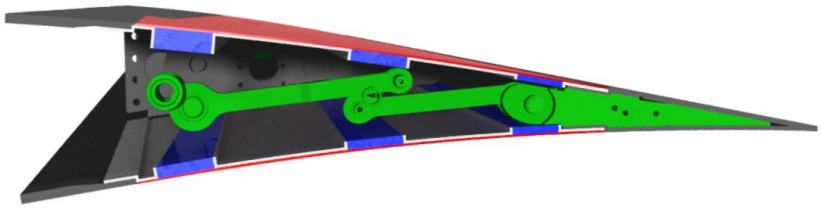

Figure 3: The morphing skin consists of hard and soft segments. Elastomer foam is used for soft segments which are located above and under the rib hinges. Hard segments are alumium profiles (grey). Hard and soft segments are covered with a thin elastomer layer [5].

These geometrical parameters were used as input for the definition of the structural concept enabling the transition from the baseline trailing edge configuration to the morphed one. The structural sizing of the concept was addressed while considering the effective operative loads expected in service and the applicable airworthiness requirements; nevertheless, for the economy of the project, detailed design activities were carried out with reference to the installation on wind tunnel demonstrator only. On the other side, the wind tunnel demonstrator replicated the last eight bays of the wing in full-scale size; the morphing trailing edge layout pertinent to the outer wing segment of the reference aircraft was then simply relocated along the wing span and supposed to be installed in the region usually occupied by the aileron (Figure 4). Its overall dimensions remained therefore unchanged with respect to real aircraft installation.

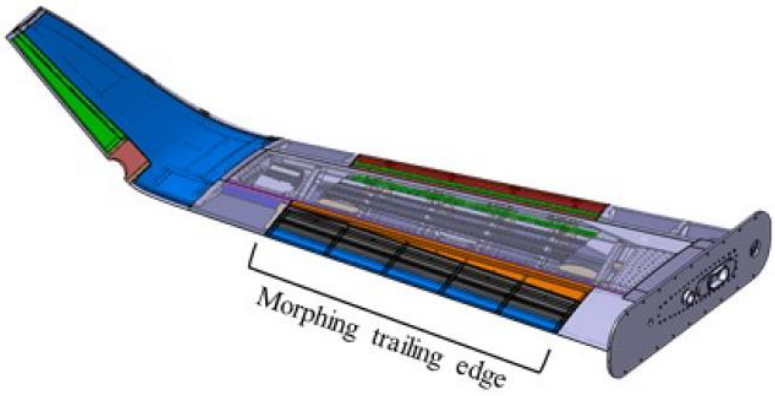

Figure 4: Wind Tunnel Demonstrator.

2 MORPHING TRAILING EDGE CONCEPT

In order to enable the transition of the trailing edge sections from the reference (baseline) shape to the target ones, a morphing structural concept was developed for ribs. Each rib (Figure 5) was assumed to be segmented into four consecutive blocks (B0, B1, B2, B3) connected to each other by means of hinges located on the airfoil camber line (A, B, C). Block B0 is rigidly connected to the rest of the wing structure, while all the other blocks are free to rotate around the hinges on the camber line, thus physically turning the camber line into an articulated chain of consecutive segments. Linking rod elements (L1, L2) - hinged on not adjacent blocks - force the camber line segments to rotate according to specific gear ratios compliant with the shapes to be achieved

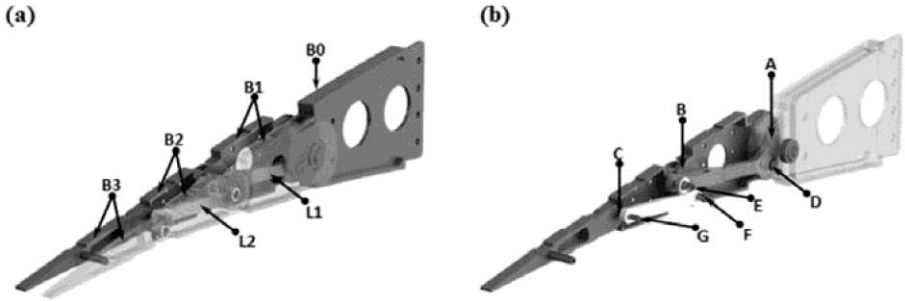

Figure 5: Morphing rib layout: (a) blocks and links, (b) hinges

These elements make each rib equivalent to a single-DOF mechanism: if the rotation of any of the blocks is prevented, no change in shape can be obtained; on the other hand, if an actuator moves any of the blocks, all the other blocks follow the movement accordingly. The rib mechanism uses a three segment polygonal line to approximate the camber of the ATED airfoil and to morph it into the desired configuration while keeping approximately unchanged the airfoil thickness distribution.

The ribs' kinematic was transferred to the overall trailing edge structure by means of a multi-box arrangement (Figure 6(a)). Each box of the structural arrangement was assumed to be characterized by a single-cell configuration delimited along the span by homologue blocks of consecutive ribs, and along the chord by longitudinal stiffening elements (spars and/or stringers).

Servo rotary load-bearing actuators coupled to quick-return mechanisms were adopted for the independent control of each rib of the device. An FBG-based system based on sensing

elastic beams located at the middle of each bay was used to detect shape configurations and to generate the information for appropriate open- and closed-loop control actions.

The structural concept herein described resulted from an iterative design process consisting of three main loops; the executive layout was obtained by progressively updating a preliminary assessed configuration on the base of feasibility considerations and stress analyses outcomes. The updating process followed the design progress of the ATED main equipment (basically actuation/sensing system) and structural interfaces with the rest of the wing (dead box). Finally, in order to assure the safety of the wind tunnel test, aeroelastic investigations on wind tunnel demonstrator were carried out in order to show the clearance of the device installation from any flutter up to three times the maximum airspeed to be tested (80 m/s).

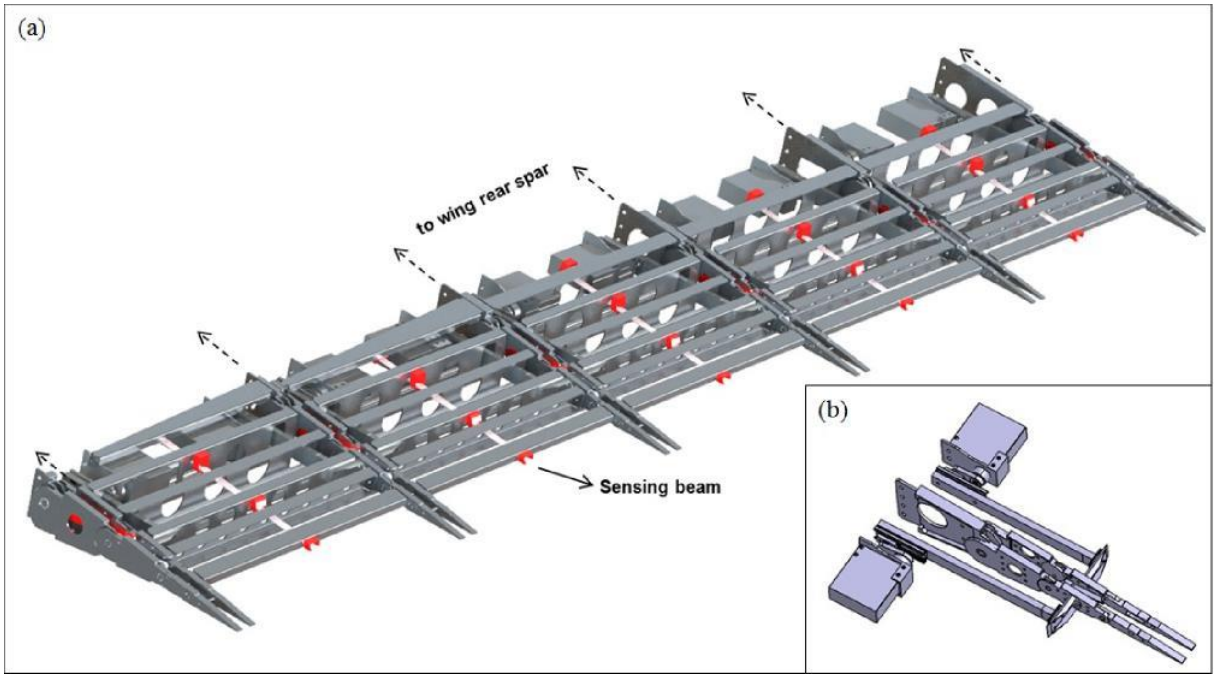

Figure 6: Morphing box architecture (a) and actuation system (b).

3 ACTUATION SYSTEM

Contrary to flexural joints-based compliant morphing mechanisms, the morphing trailing edge device combines a rigid-body mechanical system with a compliant adaptive skin. The actuation kinematics is based on a "direct-drive" actuation consisting of an arm (actuation beam) that is rigidly connected to the B2 block shown in Figure 6 (b). This arm rotates the resulting 1-DOF-based mechanical system and transmits the actuation torque from the actuator to the adaptive rib.

In order to minimize the actuation torque necessary to hold and move the ATE device, different actuation kinematics were assessed during the design phase. The size and shape of a suitable actuator were in turn estimated taking into account weight and safety constraints. The torque needed to activate the device is generated by an actuation force acting perpendicularly to this arm (if the friction can be considered equal to zero) resulting from the contact between a carriage and a linear guide. This force is generated by a rotational actuator via a crank rotating with the actuator shaft. A simplified sketch of the mechanism is shown in Figure 7. The actuation arm rotates around the "virtual hinge" (the point around which the second rib block rotates during the movement of the ATE device) and transmits the actuation load (torque) from the actuator to the second rib block. As shown in Figure 8, the mechanical advantage

increases with the morphing angle and this is much more evident as higher is the ratio between the arm length L (distance between the second rib block virtual hinge) and the actuation crank radius R. However, the higher the L/R ratio is, the higher the actuator rotation angle has to be. This limits the palette of Commercial Off-The-Shelf (COTS) servo actuators suitable for the actual application.

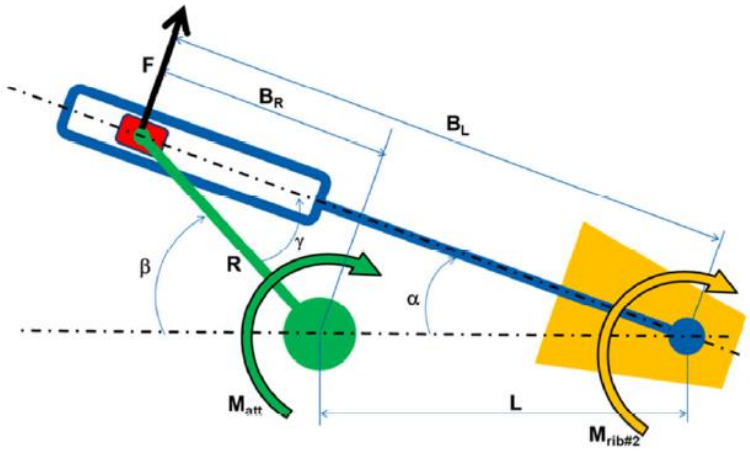

Figure 7: The actuation system layout [6].

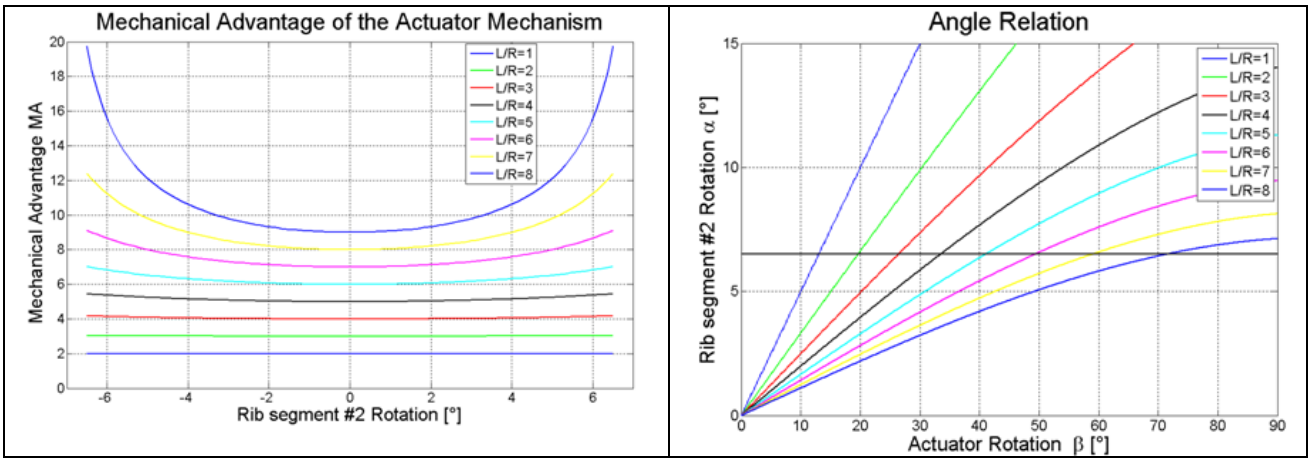

Figure 8: Mechanical advantage and actuator shaft angles of the actuation system.

4 FLUTTER ANALYSIS

In order to assure the safety of wind tunnel tests, flutter analyses were carried by considering the morphing trailing edge device integrated into the full-scale SARISTU wind tunnel demonstrator. The finite element used for static analyses was condensed into a dynamically equivalent one characterized by a reduced number of degrees of freedom. Dynamic condensation was based on the generation of direct input matrices at grids [7] to capture both inertial and stiffness properties of the device.

Reduction grids were rationally selected to get optimal modes shape resolution. The condensed dynamic model was then assembled to the FEM of the test article (Figure 9) and the overall system modes were evaluated.

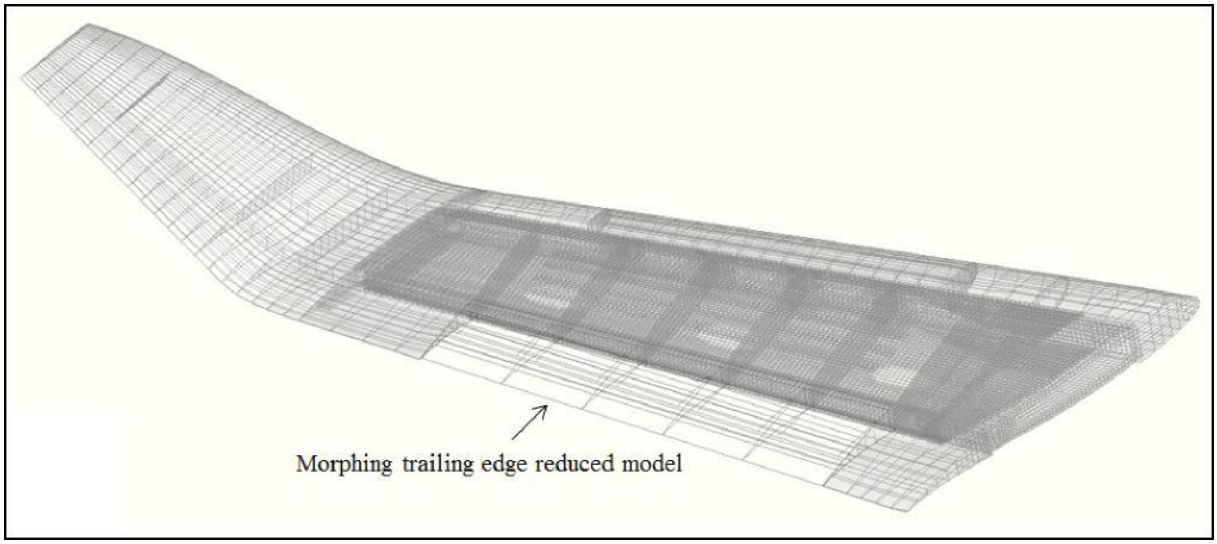

Figure 9: Structural model used for aeroelastic computations.

Doublet lattice method was adopted for the evaluation of the unsteady aerodynamic coefficients; a suitable 3D paneling was implemented for such a purpose (Figure 10). Surface splines were used to interpolate modal displacements along the centers of the aerodynamic panels and generalized aerodynamic forces were evaluated with reference to the airflow conditions expected during tests.

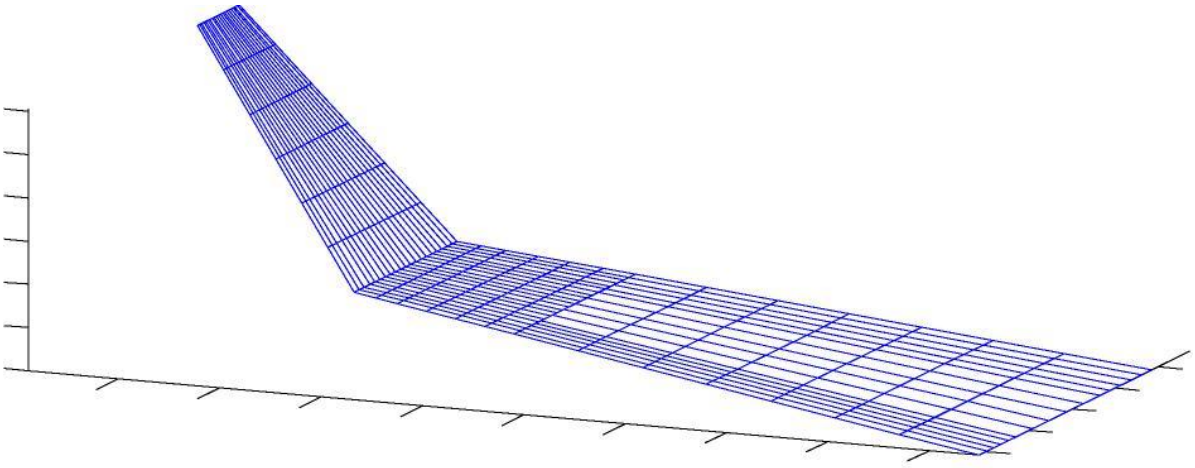

Figure 10: Test article aerodynamic model.

PK method [9] was adopted to investigate the occurrence of flutter in the speed range 0-3*Vmax, being Vmax the maximum speed expected during tests (=80 m/s). 1% critical damping was conservatively assumed for all elastic modes. No flutter was detected up to 240 m/s (Figure 11); a first instability was found at 250 m/s and essentially due to the coupling of test article bending and trailing edge elastic deflection (Figure 12).

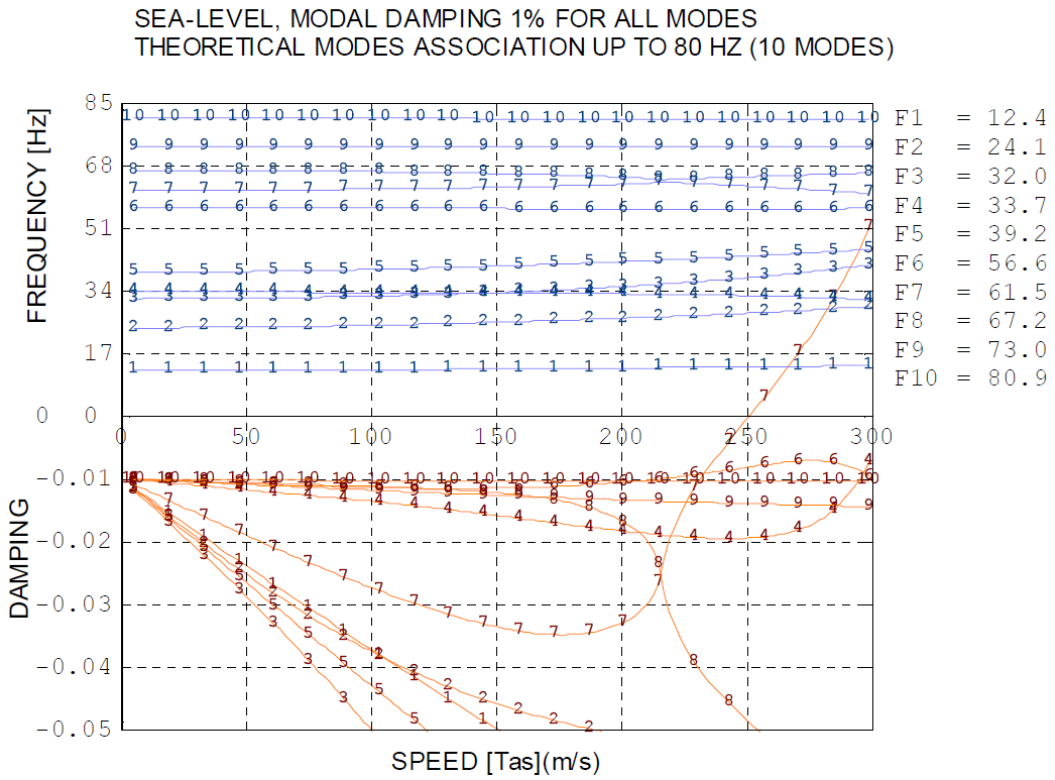

Figure 11: Flutter Vg plot.

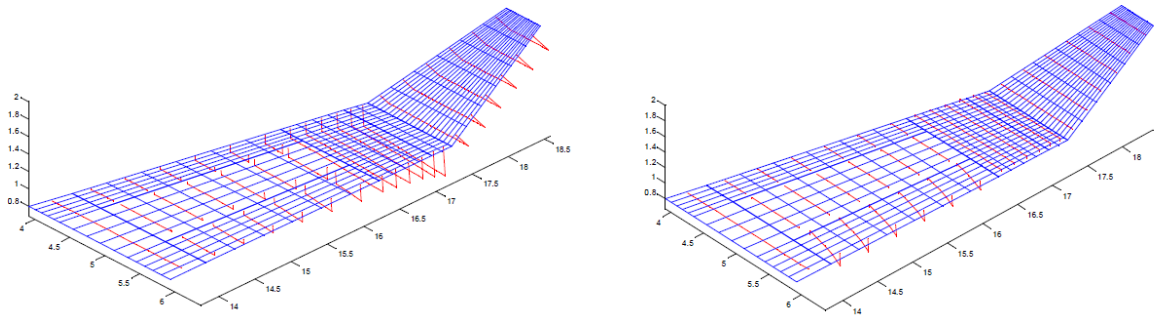

Figure 12: Modes highly participating into flutter dynamic : test article bending (left), trailing edge elastic deflection (right).

5 CONCLUSIONS

A novel architecture enabling wing trailing edge camber morphing was addressed with reference to large aircraft end-applications (EASA CS-25 category). The conventional monolithic box arrangement was replaced by a multi-box solution characterized by conventional spars and segmented adaptive ribs. Single-degree-of-freedom mechanisms, driven by load-bearing electro-mechanical actuators, were implemented to change the wing trailing edge shape by controlling the adaptive ribs individually. A compliant multi-material skin was used to accommodate the large deformation induced by ribs kinematics while providing enough stiffness to properly withstand external aerodynamic loads.

A brief and general description of the approaches and methodologies followed for the structural assessment of the overall device was presented; design strategies and consequent

results were outlined. Some open issues still remain on the developed architecture, installation aspects and implementation strategy. The specifications should be improved by considering a complete aircraft, so to compute the overall effect of the trailing edge device on the overall aircraft aerodynamic polar. The layout of the device shall also derive from the global reference geometry, so to find the best arrangement along the wing span and its chord. Further complications are also expected, following the implementation of a complex kinematic system on a movable surface such as a flap. On the other hand, the available room should be far more adequate to host the innovative components with respect to the wing tip zone. Indeed, studies to verify the possibility of inserting such systems in the aileron are currently performed by this same team and other researchers.
The actuator system design shall be integrated within the structural design, so to come to a unique active structural, load-bearing system, instead of merging to components, separately developed. Finally, control system capability, not addressed in this paper, should move from adaptive feedforward architectures, based on pre-built strain maps, to real-time feedback systems, sensible to the selected objective parameter; therefore included into the overall aircraft avionics.

Keywords: high-lift, Synthetic Jet Actuator, Computational Methods.

Abstract. *Synthetic jets actuators that produce a zero net mass flow rate have been locally applied at the pylon-wing junction to suppress the high-lift penalties caused by the closely coupled engine integration. The high fidelity numerical simulations utilizing unsteady Reynolds-averaged Navier-Stokes have been performed to simulate this problem. A wind tunnel model representing a 2,5D wing with pylon, nacelle and deployed high-lift devices is used for this study. Active flow control applied at the wing-pylon junction area can prevent the larger flow separation on the wing behind the nacelle caused by the slat cutback, increase the lift and to postpone the stall angle by interaction of the vortices from the SJA with vortices dominating this region. The performed unsteady CFD simulations demonstrate the possibility locally affect the flow by utilization of AFC. The geometrical setup of the actuators and the flow variables (blowing coefficient, actuation frequency) have been varied, as well. Two different shapes and positions of the nacelle's strike have also been considered during the simulations. The positive effect of the application of the SJA on maximum lift and stall angle has been observed.*

1 INTRODUCTION

Utilization of the Ultra-High Bypass Ration (UHBR) engine in air transport is driven by ecological and economical aspects. These new engines have lower emissions of CO2 and NOx, higher efficiency and smaller fuel consumption. On the other hand the integration of UHBR engine is very challenging part from two aspects, at least. The first one is the high-lift conditions at high angles of attack and low-speeds and the second one is connected with the clearance between the runway surface and the nacelle. To avoid longer landing gear struts suffering from weight and space penalties, the nacelle should closely-coupled to the wing. This closely-coupled integration causes the high-lift penalties due to the high-lift devices cut-back to prevent clashes with the nacelle or thrust reverser [1]. Among other techniques the Active Flow Control (AFC) can be successfully applied to remedy this lift lost due to the high-lift devices cut-back.

Within the European project AFLoNext [2] one of the main goals is the application of Active Flow Control (AFC) techniques, like pulsed jet blowing and Synthetic Jet Actuators (SJA), on wing/pylon junction to remedy the lift losses caused by in closely-coupled engine integration. A significant effort of experimental and numerical investigation of the application of the passive and AFC techniques to locally suppress the flow separation or improve the high-lift performances at the wing-pylon area, outer-wing or applied to high-lift devices has been done [3-7]. This paper summarized the results of the SJA of the high-lift configuration using the CFD simulation by means of URANS approach. The effect of the momentum coefficient $C\mu$ and actuation frequency f is discussed.

2 GEOMETRICAL SET-UP

2.1 Wind tunnel model

Model used for CFD studies is based on a wing section of a generic high-lift wing, the DLR-F15 [8], which is representative for today's transport aircraft high-lift system layout. It is equipped with a slat and a single-slotted Fowler flap. Because of the AFLoNext project this model was modified to integrate pylon and nacelle. It represents 2,5D wing with sweep angle 28deg equipped with the side plates.

2.2 Strake configurations

Two different strake's configurations were used during this study. They differ in the shape and location on the nacelle. Both strakes are depicted in Figure 1. The new strake is located closer to the wing to be more effective and creates stronger strake's vortex. The effect of the original and new strake on baseline flowfield is described in subsequent section.

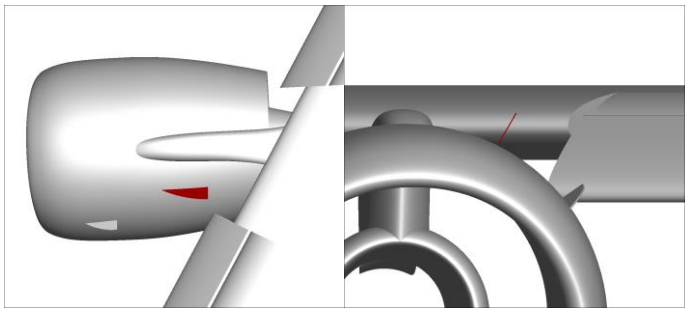

Figure 1 Position of old (grey) and new strake (red) on nacelle

2.3 Actuator's geometry and position

The circular actuator with area $5mm^2$ was used for simulation of the synthetic jet. Two configurations of the actuators were used during this study. They differ in the location and number of actuators. The first configuration is characterized by two rows of actuators located at 0.01% and 0.021% of the chord of the wing. The spanwise position of this configuration with two rows of actuators is limited by the inner slat-end on one side and the pylon's axis on the other side. The actuators in the second row are placed in cascade regarding the actuators in the first row. The second configuration was created from the first one by omitting the second row of actuator. One halve of actuators is considered in comparison with the first configuration. The spanwise location remained the same. The spanwise spacing between the actuators is 0.01m.

Actuators of both configurations were placed parallel with the leading edge and inclined 30deg towards the wing's surface. The actuators' cavities were physically modeled to enable the development of boundary layer inside them.

3 NUMERICAL METHODS

3.1 Grid creation

All grids used during this study were created in Pointwise grid generation software. The grids are unstructured with rectangular elements on the model surfaces and with tetrahedral elements in the volume. The boundary layer is simulated by prismatic elements and the condition of y+ bellow 1 was fulfilled. The region of interest was refined to capture all flow phenomena (interaction of the vortices, flow separation,…). In case that the modification of the strake or actuator's positions was considered, the same grid topology was used. Only the blocking of the surface grid on the nacelle and in the region of actuators was modified due to new strake and different actuators locations, the number of nodes remained the same. The grid in the region of interest was not changed.

3.2 Boundary conditions and CFD solver

Mass flow inlet/outlet boundary conditions (BC) were used to simulate the flow from SJA. The mass flow, total temperature and flow direction are defined at these BC. The adjusted mass flow corresponds to the required blowing velocity at the cavity's outlet. The simulation of the synthetic jet is done by switching between the mass flow inlet and mass flow outlet boundary condition controlled by harmonic (or step) function. It is possible to define the desired peak velocity and frequency of the synthetic jet using the harmonic function. In case that the step function is used, the duty cycle can be also controlled. The typical course of the mass flow in time for synthetic jet actuator is depicted in Figure 2. The cavities of the actuators were physically modeled during the mesh generation process to enable the development of boundary layer velocity profile inside them. The boundary conditions were applied at the bottom part of these cavities. The fully modeled cavities have some drawback in terms of the grid creation, number of cells etc., but the flow at the cavities' outlets is more realistic. On the other hand same effort has been devoted to applying the surface boundary conditions simulating the flow from actuators and actuation models in the past [7, 9-11].

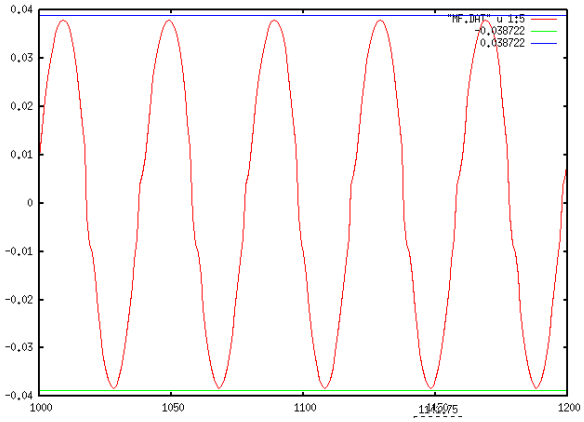

Figure 2 Typical course of the mass flow during the simulation of synthetic jet

3.3 Flow conditions

All of the computations were performed at a chord-based Reynolds number of $Re=4.65 \cdot 10^6$, the freestream Mach number 0.2 and freestream pressure corresponded to the 0m International Standard Atmosphere. These flow conditions correspond to the landing conditions of the characteristic airliner.

3.4 Baseline configuration – strake effect

The effect of the strake on the local flowfield has been experimentally and numerically investigated in the past [12]. It is usually used to remedy the lift losses due to the slat cut-back. During this study it was found that the original strake did not affect the flow as it was expected. The strake's vortex was too high above the wing and applying the AFC it transported low momentum flow towards the wing. It was the main reason to use a new strake design by DLR during the AFLoNext project. The new strake has been moved towards the wing's leading edge and it is slightly larger than the original one. The position of this strake was verified by numerical simulations performed also by DLR.

The comparison of the lift curves of the original and new strake configurations is depicted in Figure 3. It can be seen that the new strake has a significant effect on the local flowfied behind the nacelle at stall condition and it is able to improve the lift more effectively than the original one. The new strake creates stronger vortex which is closer to the wing and more interacts with the vortices dominating this region.

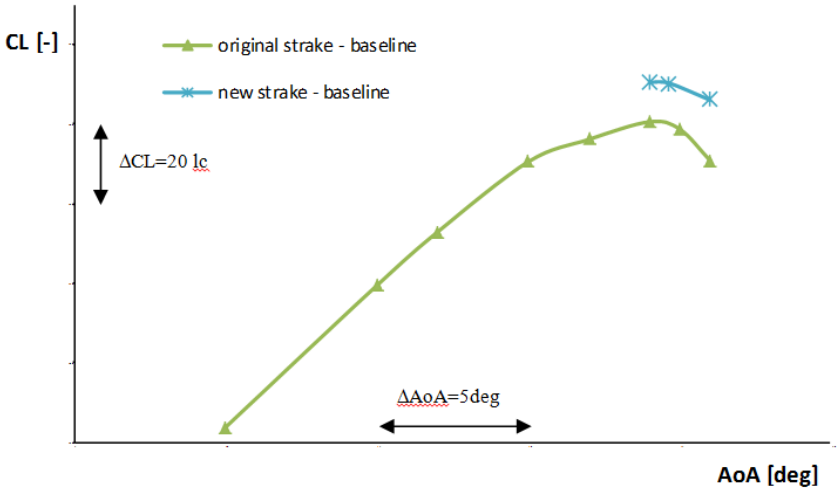

Figure 3 Effect of strakes on baseline flow

The surface streamlines together with the area of separated flow (visualized by negative x component of the skin friction coefficient) of the baseline flow with original strake are depicted in Figure 4. It is possible to see the development of the separated area with increasing AoA (depicted by the arrow). The surface streamlines and flow separation areas of the baseline flow corresponding to the configuration with the new strake is depicted in Figure 5. It is possible to see that for the same AoAs, the flow separation area is smaller in comparison with the configuration with original strake. No flow separation has been observed in the outer part of the wing (behind the pylon's axis in spanwise direction) for the simulated AoAs.

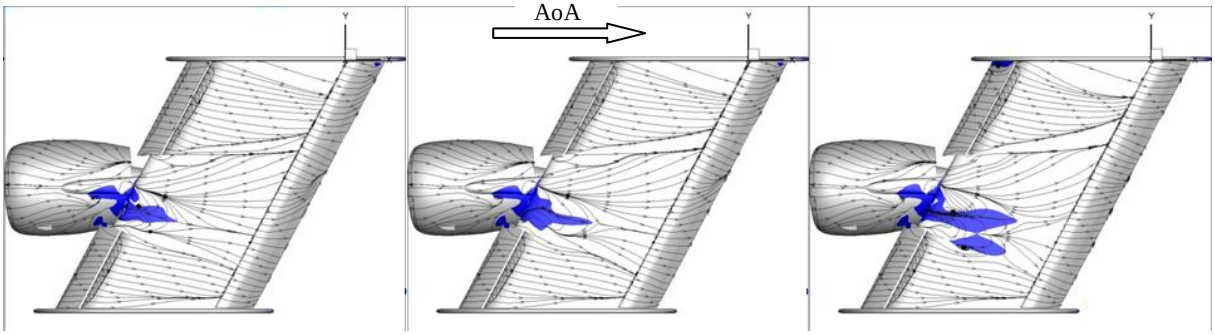

Figure 4 Surface streamlines and flow separation area (visualized by negative Cfx in blue) for baseline configuration – original strake

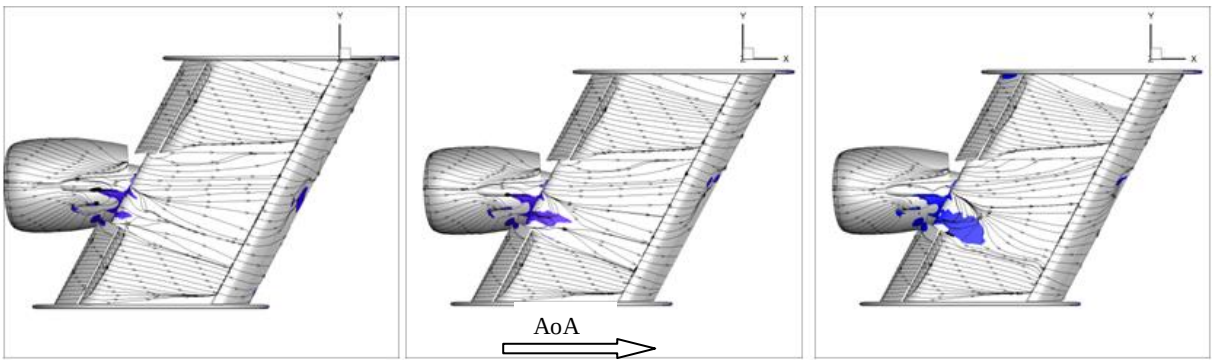

Figure 5 Surface streamlines and flow separation area for baseline configuration with new strake

The location of the flow separated area between the inner slat-end and pylon's axis was the main reason for creation of the configuration of the circular actuators with limited span wise position between the inner slat-end and pylon's axis. The configuration with the new strake was used during the CFD simulations of the SJA.

3.5 Synthetic Jet simulations

The boundary condition described in 3.2 was used for simulating of the Synthetic Jet (SJ) by means of URANS approach. A harmonic function with defined frequency and amplitude, representing the desired mass flow, was used for SJA. The frequency was limited by the limit of 100 Hz at first. A more realistic actuation frequency 1kHz has been simulated consequently. Due to extremely high time consuming simulation of the higher actuation frequency, only one post stall AoA was simulated for the configuration of the actuators in one row. The adjusted mass flow corresponded to the peak velocity 150m/s.

The configurations with one and two rows of actuators have been used to evaluate the effect of Cμ on aerodynamic performances. The frequency effect was evaluated on the configuration with one row of actuators using different actuation frequency.

From lift curves depicted in Figure 6 it is possible to see the effect of SJA with actuation frequency 100Hz (red curve) and the effect of different Cμ and f, as well. The stall angle was delayed by about 2deg in comparison with the baseline configuration. The C_{LMAX} was improved by about 8 lc according to the baseline C_{LMAX} and by about 14 lc at the same post stall AoA of the baseline configuration.

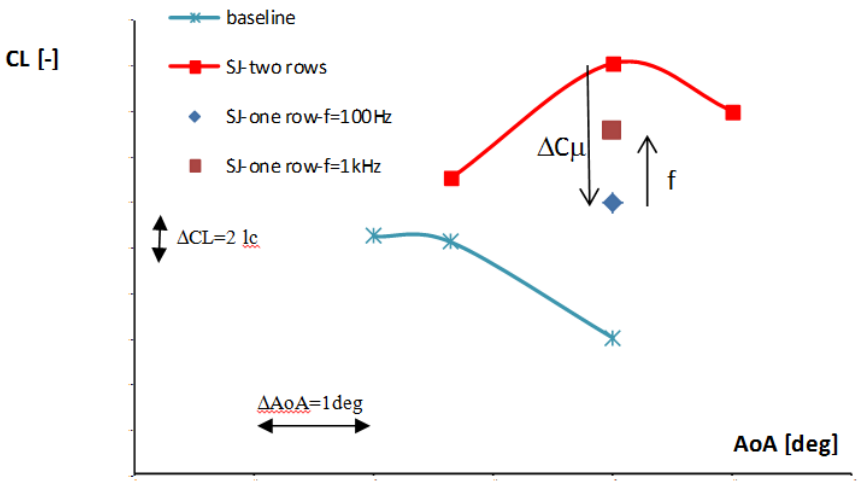

Figure 6 Lift curves and CL values of bsl and SJA of both configurations of actuators

The surface streamlines and separated areas of the configuration of two rows of SJA working with frequency 100Hz at simulated AoAs are depicted in Figure 7. It is possible to see that the separated area at stall angle is almost the same as at lower AoA due to the interaction of the synthetic jet with the inboard LE-step and slat-end vortices (see Figure 8). With increasing AoA the SJA is not able to effectively control the vortices and inboard LE-step vortex bursts and it causes the large flow separation area (see Figure 7 and Figure 8, right). The vortices for simulated AoAs are depicted in Figure 8. It is possible to see the interaction of the flow from SJA with the inboard LE-step and slat-end vortices and the discontinuity of the slat-end vortex and slightly reduced inboard LE-step vortex at post stall AoA. These vortices cannot af-

fect the flow in close vicinity of the wing and the flow separates. It has to be emphasized that these surface streamlines and vortices correspond to the last iteration of the simulations.

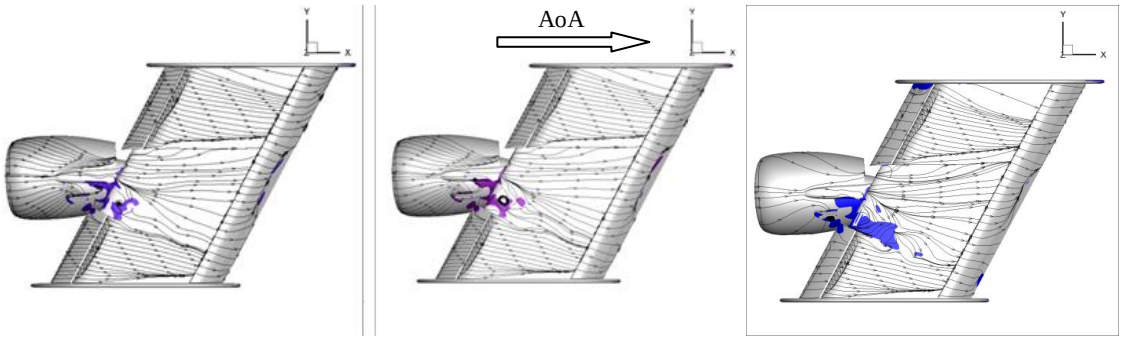

Figure 7 - Surface streamlines and flow separation area for two rows of SJA

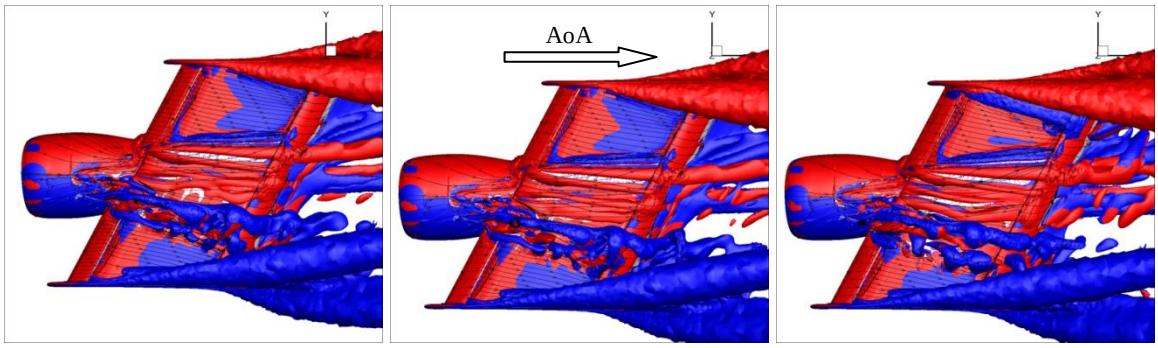

Figure 8 Vortex structures for two rows of SJA, pre-stall AoA (left), stall AoA (middle) and post stall AoA (right)

The effects of Cμ and actuation frequency on C_L at stall AoA are also depicted in Figure 6. The Cμ is decreased from 0.0252% to 0.0127% by using one row of actuators instead of two rows. The effect of reduced Cμ on the C_L is depicted in Figure 6 by the left arrow. The value of C_L is decreased by about 6 lc. The vortex structures for both values of Cμ are depicted in Figure 9 (left and middle figures). It is possible to see the positive effect of higher Cμ on the structure of the inboard LE-step and slat-end vortices. These vortices are more continuous in comparison with the vortices corresponding to the lower Cμ (one row of actuators). For the smaller Cμ the slat-end vortex is more discontinuous and the inboard LE-step vortex is slightly weaker and not so much affects the local flow close to the wing's surface.

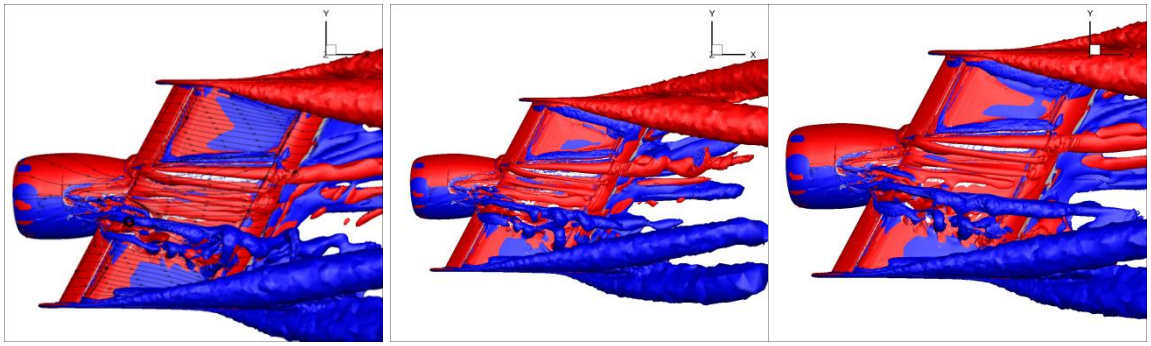

Figure 9 Effects of Cμ and actuation frequency on vortex structures, two rows of actuators (left), one row (middle) and one row of actuators with f=1000Hz (right)

In case that the one row of actuators is used (smaller Cμ) and the actuation frequency is increased from 100Hz to 1000Hz, the CL is increased by about 3 lc (see Figure 6). The right black arrow indicates the change of C_L with the change of actuation frequency. The dimensionless frequencies F^+ corresponding to the 100Hz and 1000Hz are increased from 4.79 to 47.9, respectively. The effect of actuation frequency on forming the vortex structure is depicted in Figure 9 (middle and right figures). In comparison with the lower Cμ and lower frequency (vortices in the middle), the slat-end and also the strake's vortex are more affected by SJA with higher actuation frequency. Especially the LE-step vortex is stronger.
Comparison of the flow separation areas for particular cases with SJA are depicted in Figure 10. It is possible to see that the flow separation area is increased by using smaller Cμ and on the contrary the higher actuation frequency slightly reduce it.

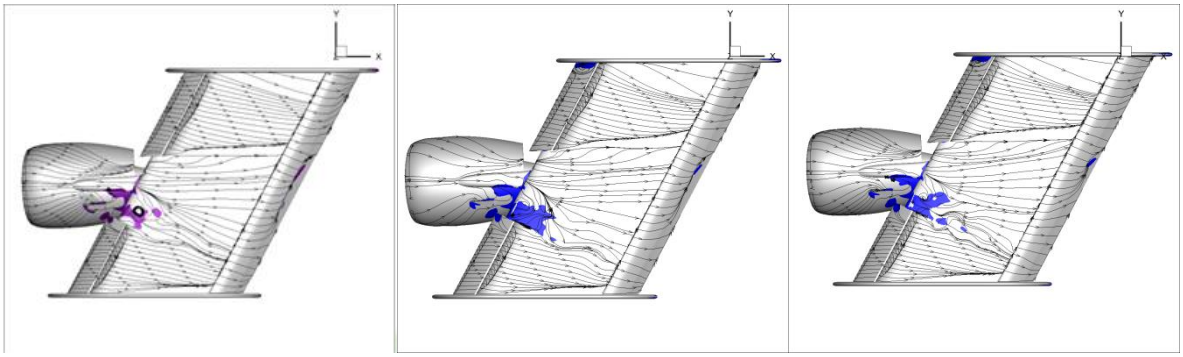

Figure 10 Surface streamlines and flow separation area of two rows of actuator (left), one row of actuator (middle) and one row of actuator with actuation frequency 1000Hz (right)

4 CONCLUSIONS

No flow separation was observed in the outboard part of the wing for the baseline and controlled flows for both strakes configurations. It was the main reason for the location of the actuators between the inner slat-end and pylon's axis.

The strake's shape and its position have a significant effect on the C_L and local flowfield without AFC. The new strake increases the C_{LMAX} by about 9 lc in comparison with the original one.

The stability and vertical position of the vortices forming behind the slat-end and inboard LE-step vortex have a significant effect on local flow separation on the wing-pylon area. If these vortices are "continuous" (not bursting or discontinuous) and closer to the wing's surface, the flow separation is usually suppressed. The structures and positions of these vortices can be, to a certain degree, maintained by a local application of AFC like SJA.

The effect of Cμ and the actuation frequency of SJA was considered and evaluated on the configuration with the new strake. The C_{LMAX} can be increased by about 8 lc by means of applying of two rows of SJ actuators with actuation frequency 100Hz. The Cμ has been changed from 0.0252% to 0.0127% by considering two rows or one row of actuators, respectively. In case that the Cμ is reduced to one half, the C_L is decreased by about 6 lc. But utilizing higher actuation frequency, the C_L can be increased again by about 3 lc. The overall drop of C_L by means of smaller value of Cμ and higher actuation frequency is only 3 lc in comparison with the value of C_L obtained using SJA in two rows and actuation frequency 100Hz.

Due to the very high time consuming of the simulations of the SJA especially with the higher actuation frequency (1000Hz), the effect of the Cμ and f was evaluated only for one post stall AoA.

The simulated high actuation frequency 1000Hz is still approximately one half of the working frequency of the real SJA. The simulation of the working frequency of SJ should be done using large eddy simulation (LES) instead of URANS, but for our target large Reynolds number it is not feasible today.

ACKNOWLEDGEMENT

These activities were done under FP7-AAT-2013-RTD-1 in the frame of AFLoNext, which is gratefully acknowledged.

Access to computing and storage facilities owned by parties and projects contributing to the National Grid Infrastructure MetaCentrum, provided under the programme "Projects of Large Infrastructure for Research, Development, and Innovations" (LM2010005), is greatly appreciated.

This work was supported by The Ministry of Education, Youth and Sports from the Large Infrastructures for Research, Experimental Development and Innovations project „IT4Innovations National Supercomputing Center – LM2015070“.

Abstract. *A novel combined method for highly brittle materials, which provides an efficient and accurate insight into multi-scale fracture modeling, is proposed. In particular, physically-motivated molecular dynamics simulations are performed to predict crack propagation, in the nanoscale, and therewith determine material and other parameters required for the macroscale modeling under a phase-field continuum approach. The proposed computational approach, which does not require any empirical parameters, contributes towards an improved understanding of mechanics at all length-scale levels.*

1 INTRODUCTION

Molecular Dynamics (MD) simulations are considered new computational methods, employed to describe the time evolution of a system of interacting particles. They require the numerical solution of Newton's equations for every particle governed by an interatomic potential, i. e., bonded and non-bonded potentials, keeping track of the evolution of the system in space. Due to their real time scales (pico seconds), MD methods are perfectly suited to study the high-speed crack propagation of brittle materials, as demonstrated in the work of Rountree et al. [30]. Additionally, there have also been some applications of the method for a variety of inorganic crystals, such as Si_3N_4 [16], SiO_2 [31], 3C-SiC [17], and GaAs [34]. Although these studies have provided valuable in-sights into crack dynamics, a systematic analysis of mechanical properties at an atomistic scale, as well as a link to the macroscopic continuum mechanical approaches are still not well established.

Nowadays, typical MD simulations can be performed on systems containing hundreds of thousands, or perhaps, a few millions of atoms for simulation times ranging from a few hundred nanoseconds up to a millisecond. These numbers are certainly respectable, but one may run into conditions, where size and/or time limitations become important. The challenges related to the limited dimensions or time scales can be tackled by upscaling MD parameters and frameworks through continuum models. In fact, as it has been shown in numerous other studies, i. e., [5, 26, 27, 28], the mechanical behavior of a given continuous material can be reproduced in a different scale by using mechanical parameters derived directly from atomistic MD simulations.

In what numerical modeling regards, phase-field modeling (PFM) has emerged as a powerful tool to model brittle fracture under a macroscopic continuum approach, offering a good accordance between numerical treatment, accuracy, and computational costs. The pioneering works related to an elastic energy-based approach to describe brittle fracture, namely the works of Griffith [9] and Irwin [15], as well as the variational formulations presented in [4, 8], can be considered as the pillars of a well-established energy-based framework for brittle fracture. In the past decades, many PFMs, which approximate the sharp edges of the crack by a diffusive interface, have been developed. Due to their simple implementation, these models are able to predict quasi-static and dynamic cases of brittle and ductile fracture, considering diferent fracture modes and loadings, under several discretization schemes [4, 8, 3, 11, 22, 35, 19, 21].

Consequently, this research work pursues to establish a link between the understanding of brittle fracture of a material at an atomistic scale and its macroscopic mechanical features. To this end, an aragonite ($CaCO_3$) tablet undergoing fracture is studied using both, MD and PFM. Herein, the key mechanical properties (e. g., Young's modulus, Poisson's ratio), as well as the phase-field transition width (ϵ) and the mechanical energy release rate (G) of an aragonite crystal are obtained *ab initio*. These physical properties are subsequently employed to reproduce a nanoscale model under a continuous PFM approach.

Given that PFM and MD are relatively new topics in the realm of mechanics, the second and third sections of this work will briefly introduce the implementation of both methods. In the fourth section, a thorough description and brief evaluation of the numerical experiments in MD, as well as PFM are presented. The last section is dedicated to the conclusion and outlook of the present work.

2 MATERIALS AND MD SIMULATIONS

In the present work, MD and PFM simulations are employed to describe the behavior under fracture of Aragonite ($CaCO_3$), a highly brittle ceramic and major constituent of nacre (95 % vol.).

Tablets of this material were modeled, as seen in Fig. 1, by using the software Visual Molecular Dynamics (VMD) [14]. One double-notched tablet model was built with length (l), width (w) and height (h) of $15.38 \times 11.12 \times 4.30$ nm^3, respectively. The pulling layer thicknesses (pt) was considered to be three atomic layers wide. For the subsequent MD simulations, the molecular dynamics program GROMACS 5.0.4 package [33] was used. For aragonite interactions, newly-developed $CaCO_3$ forcefield [36], that describes angle, planar, dihedral, electrostatic and van der Waals interactions, was implemented.

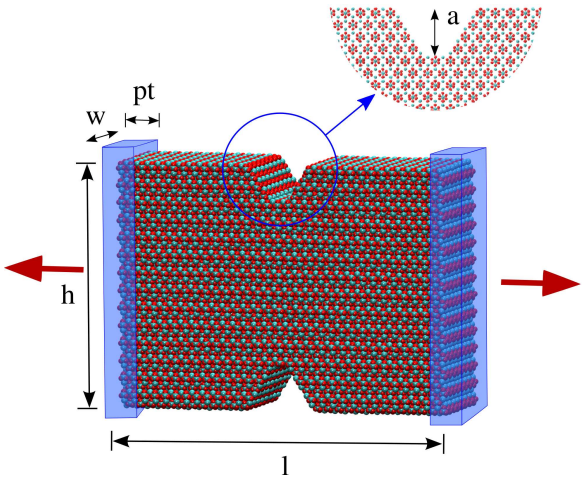

Figure 1: Double-notched all-atom model of an aragonite tablet. Oxygen and carbon atoms of carbonate groups are shown in cyan and red beads, respectively. Calcium atoms are shown with green beads. The dimension a (center) denotes the notch depth, while h, l, w and pt represent the height, length, width and pulling layer thickness, respectively. Pulling directions are perpendicular to the notch depth, which is marked by red arrows. Inset: enlargement of the front view of v-notch region.

The model in question was minimized and equilibrated in the NPT (isothermal-isobaric) ensemble for 10 ns at 300 K and 1.013 bar. The tablet did not show any significant changes neither in structural ordering nor in cell dimensions. The last frames were used to create notched systems as follows: The simulation boxes were extended 12 nm along l and h, leaving as much empty space as required to allow the tablet extension during pulling simulations. The periodic vector through the width w was not extended, resulting in tablets of infinite length along w-direction. Then, the v-shaped notches were introduced by removing atoms. The cut lines followed the (101) and ($\bar{1}$01) lattice planes, which resulted in an opening angle of 84.4 °. Such cut lines impose the removal of one calcium atom per carbonate group, preserving the electroneutrality of the systems.

In the MD calculations, the simulation box, in which the aragonite tablets were pulled, was repeated periodically in all three dimensions using 2 fs time steps. Van der Waals interactions were calculated using a cutoff of 1.0 nm. The Particle Mesh Ewald (PME) method [6] was chosen to account for long-range electrostatic interactions. To increase the simulation time step, a linear constraint solver for molecular simulations (LINCS) [12] was used to constrain all bond vibrations. The Nosé-Hoover [24, 13] temperature coupling was applied with a coupling time constant of 0.1 ps.

Fig. 1 shows an aragonite notched model with loading conditions and representative dimensions. The aragonite tablet model was not constrained at any point (which allows for rigid body motions) to capture a natural behavior in the simulations. The system was further equilibrated in the NVT (canonical ensemble, amount of substance N, volume V and temperature T

are conserved) for 10 ns at 300 K. To avoid tablet drifting, two cuboid volumes parallel to the (100) lattice plane were restrained, each cuboid volume containing the three outermost layers of $CaCO_3$ atoms. This resulted in a system of 66,720 atoms.
Once the equilibration of the system was achieved, a force-probe Molecular Dynamics (FPMD) simulation [10] was employed to enforce an external load. The restrained layers were released and pulled axially outwards with a spring-like force applied to the outer surfaces, with a constant velocity of 10 nm ns^{-1} and a spring constant of 1000 kJ mol^{-1} nm^{-2}. FPMD simulations were performed until tablet rupture, which usually occurred within 13 ns. Altogether, five FPMD simulations were performed. The obtained results were later post-processed to obtain critical material parameters, as well as the phase-field transition width and crack resistance energy.
Postulated in 1920, though still in force, the Griffith's energy-based analysis of cracks [9] states that the fracture strength is always lower than theoretical cohesive strength and attributes this discrepancy to the inherent defects in brittle materials, leading to stress concentration.
One of the underlying principles of fracture mechanics is that crack propagation occurs when the released elastic strain energy is at least equal to the energy required to generate new crack surface. The Griffith's energy criterion for fracture of brittle materials can then be written as

$$\sigma_f = \frac{1}{\alpha}\left[\frac{2E\gamma}{\pi a}\right]^{1/2} \quad , \tag{1}$$

where σ_f is the rupture strength, a is the notch depth, γ is the surface energy, E is the Young's modulus, and α is a geometry correction factor. For double edge notched tension of a semi-infinite tablet with notch depth a and tablet height h, α reads [29]

$$\alpha = 1.12 + 0.43\left[\frac{a}{h}\right] - 4.79\left[\frac{a}{h}\right]^2 + 15.46\left[\frac{a}{h}\right]^3. \tag{2}$$

It is now assumed that the available external and internal energy is transferred into surface energy. In what brittle fracture regards, dissipation and kinetic energy are neglected. This results in the so-called Griffith energy balance where the energy release rate G is equal to 2γ in J/m^2. The mechanical energy release rate in the $CaCO_3$ geometry is the amount of energy per unit area that is supplied by the elastic energy stored in the system.
The energy release rate can alternatively be calculated by integrating the stress-strain curve with respect to strain [20, 17]

$$G = l\int_0^{\varepsilon} \sigma(\varepsilon')d\varepsilon', \tag{3}$$

where l is the model width in the loading direction, see Fig. 1, and σ is the loading direction component of the stress well ahead of the crack tip. At a strain above ε_c, crack propagation at constant velocity is achieved after an initial transient [20].

3 BRITTLE FRACTURE MODELING USING THE PFM APPROACH

The macroscopic modeling of brittle fracture is based on the PFM approach, which has been widely discussed in several research works, see, e.g. [3, 22, 35] for an overview. In this, a phenomenological phase-field variable ϕ is introduced, which approximates the sharp interface of the crack by a diffusive transition zone. Thus, the global potential energy function $\mathscr{F}$ can be written with the help of ϕ and its gradient as an integral over the whole body ([4, 8, 19, 21]) as

$$\mathscr{F}(\phi, \operatorname{grad}\phi, \boldsymbol{\varepsilon}) = \int_V \left[\Psi_{elast}\left(\phi, \boldsymbol{\varepsilon}\right) + \Psi_{crack}(\phi, \operatorname{grad}\phi)\right] \mathrm{d}v \tag{4}$$

with $\boldsymbol{\varepsilon}$ being the linear strain tensor. The phase-field variable $\phi \in [0,1]$, in the sense of an indicator function, represents the crack state, where $\phi = 0$ for a cracked state and $\phi = 1$ for an undamaged state. The fracture energy Ψ_{crack} is defined as

$$\Psi_{crack}\left(\phi, \operatorname{grad}\phi\right) = \frac{G}{4\epsilon}(1-\phi)^2 + G\,\epsilon\,|\operatorname{grad}\phi|^2, \tag{5}$$

where ϵ is an internal length related to the width of the diffusive crack transition zone. As the degradation of the material is assumed to occur only under tension or shear, one applies an additive splitting of the linear elastic energy into a positive part Ψ^{+}_{elast}, that considers the tension and shear responses, and a negative part Ψ^{-}_{elast}, that considers the compression response. Moreover, the degradation function $g(\phi)$ can simply be defined in a quadratic form as $g(\phi) = [(1-\eta)(\phi)^2 + \eta]$ to obtain

$$\Psi_{elast}\left(\phi, \boldsymbol{\varepsilon}\right) = g(\phi)\ \Psi^{+}_{elast} + \Psi^{-}_{elast}\,. \tag{6}$$

Here, η is a residual stiffness added for numerical stability purpose. The linear elastic stress $\boldsymbol{\sigma}$ is obtained through the derivation of the phase-field potential with respect to the strain tensor, see [23].

$$\boldsymbol{\sigma}(\phi, \boldsymbol{\varepsilon}) = \frac{\partial \mathscr{F}}{\partial \boldsymbol{\varepsilon}} = g(\phi)\ \frac{\partial\, \Psi^{+}_{elast}}{\partial \boldsymbol{\varepsilon}} + \frac{\partial\, \Psi^{-}_{elast}}{\partial \boldsymbol{\varepsilon}}\,. \tag{7}$$

Furthermore, the momentum balance equation under the assumptions of a quasi-static state and neglecting the body forces can be expressed as

$$\operatorname{div}\boldsymbol{\sigma} = \mathbf{0}\,, \tag{8}$$

allowing the computation of displacement field $\mathbf{u}$. To this end, the evolution of the phase field is derived using the Allen-Cahn model,which describes the process of crack evolution via a reaction-diffusion equation as

$$\begin{aligned} \dot{\phi} &= \frac{\partial \phi}{\partial t} = -M \frac{\partial \mathscr{F}}{\delta \phi} \\ &= -M \left[2\,(1-\eta)\phi\ \Psi^{+}_{elast} - \frac{G}{2\epsilon}(1-\phi) - 2\,G\,\epsilon \operatorname{div}\operatorname{grad}\phi \right], \end{aligned} \tag{9}$$

where $M \geq 0$ represents a mobility constant.

For the numerical implementation of the PFM problem, an initial boundary-value problem of mode-I fracture, illustrated in Figure 2, is solved using the finite element package FlexPDE.

The numerical solution is computed considering quadratic shape functions for the displacement and the phase-field variable, and the time integration is applied using the 2^{nd}-order backward difference formula (BDF2), where a time-step automatic adaptivity is also employed. Moreover, a fixed mesh, refined in the area between the notches, is implemented. A plane stress, linear elastic model is used to reproduce the MD simulation. Under this setup, the stress is applied until instantaneous rupture of the plate takes place.

The material parameters, E, ϵ and G, for the PFM of the aragonite plate were directly derived from the outcomes of the MD simulations as will be discussed in the next section. Therewith, the obtained values were $E = 126$ GPa for the Young's modulus. The crack resistance (or energy release rate) was found to be $G = 2.091$ J/m^2 and the internal length scale $\epsilon = 0.05$ nm. The values of the mobility and the residual stiffness parameters were set to $M = 10{\times}10^9$nm^2/Ns

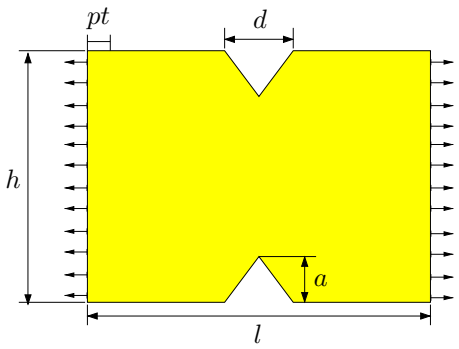

Figure 2: Boundary conditions of the IBVP (load-controlled). For the boundary layers with width pt, $\nu = 0$ and zero-stress in vertical direction. In the middle of the extreme edges (left and right), two points are fixed in the vertical direction to prevent a rigid body motion. The dimensions here are h=11.2 nm, l=15.3 nm, d=3.08 nm, and a=1.84 nm.

and $\eta = 10^{-5}$, respectively, whereas the applied Poisson's ratio is $\nu = 0.44$. The material properties such as Possion's ratio ν and the density ρ were benchmarked with the aragonite-related literature ([1, 2, 7, 25]), whereas the mobility parameter M and the residual stiffness parameter η are in good agreement with the ranges proposed in, e.g., [18, 23].

4 RESULTS AND DISCUSSION

As stated previously, to examine the fracture behavior at atomistic scale of aragonite, monotonic tension tests were performed by means of FPMD. The molecular system was loaded by moving virtual springs applied to the outer surfaces of the tablets with constant velocity. The force is obtained directly from the resultant spring force at the boundaries. Accordingly, the stress is computed by dividing the spring force by the cross sectional area comprehended between two notches. Moreover, the relative displacement of atoms was measured between the center of mass of both pulling layers. Here, the engineering strain is obtained by dividing the total displacement of the center of mass of any pulling layer by the original distance between this layer and the center of specimen. The crystals deformed during the FPMD simulations until the externally applied stress reached the ultimate tensile strength σ_f, resulting in a sudden rupture. Due to the chemical structure of calcium carbonate $[Ca^{2+}][CO_3^{2-}]$, and its arrangement in compact crystal, it is not always possible to have symmetric notches on both edges as well as notches at the exact center of all tablets of $CaCO_3$ models. Therefore, the v-notches in the tablets are not sharp, and the notch tips can have, either, single or double $CaCO_3$ units (enlarged view in Fig. 1). Thus, different crack propagations were observed in the tablet models, e. g., the crack starts at the top edge, bottom edge or at both edges simultaneously (shown in Fig. 3). For all simulations, the cracks propagated with an s-shape along the (101) and ($\bar{1}$01) lattice planes, as expected.

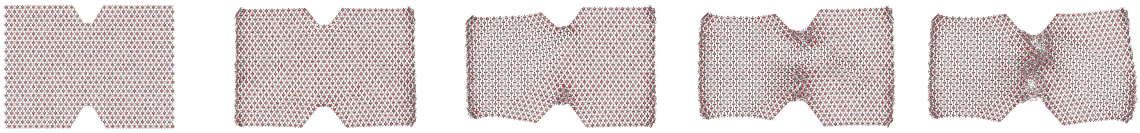

Figure 3: Rupture of the double-notched aragonite tablets. The snapshots show the fracture of the aragonite tablets under constant pulling velocity. As the two atom groups at the ends are pulled, the tablets slightly stretch and break abruptly around the notch. Here, the crack initiates at the bottom, though, is propagated from both sides and with an s-shape.

Fig. 3 shows snapshots of the rupture processes observed in the $CaCO_3$ tablet models. The model was loaded with a constant velocity for 12.88 to 13.056 ns, without observing crack initiation. However, the crack initiation took place during the following 0.012 ns, inducing an instantaneous total failure.

The results describe a good agreement with the expectations. First of, the energy release rate G can be calculated using the MD results together with either Griffith's criterion given in Eq. (1) or by use of Eq. (3). Both equations confirm that the fracture of the $CaCO_3$ tablet occurs at a value $G \approx 2.091$ J/m^2. This value is slightly lower than the theoretical values of G for $CaCO_3$ (2.10 – 3.74 J/m^2), which can be found in the literature [1, 2, 7], though this difference is merely negligible. Therefore, $G = 2.091$ J/m^2 is adopted for the PFM.

To avoid model dependency in MD simulations, five different aragonite tablet models were considered, and the stress-strain curves were jointly analyzed. The recovered elasticity modulus E of aragonite ranges between 106 to 148 GPa, which is in the range of experimental and theoretical studies, see [1, 2, 7]. With regard to the ultimate tensile strength, the resulting MD simulations value of the aragonite notched samples is 4.6 GPa. This value is slightly lower than the theoretical strength of flawless minerals, which was estimated to lie in the range of 5 to 10 GPa [32].

Fig. 4 shows the force-displacement curves of the continuous PFM (considering a Young's modulus of $E = 126$ GPa) and all-atom simulations. With regard to the force at failure, the resulting MD simulations value of the aragonite notched samples is 47 μN and the nonlinear behavior, which is due to the potential energy non-linearities, is clearly observed. Although, a linear elastic model was considered for the PFM, an outstanding correlation of the results is observed.

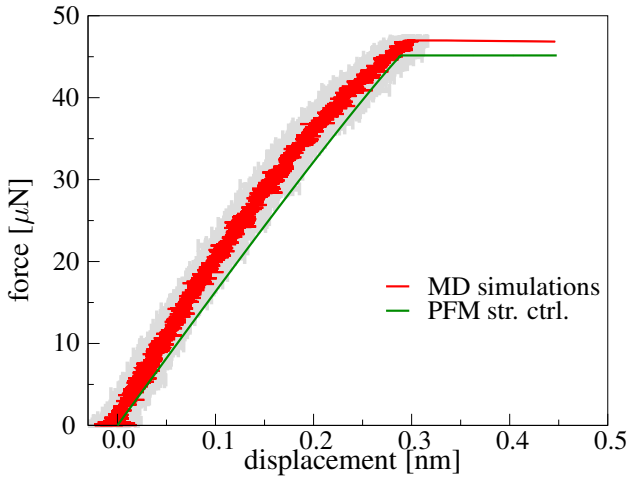

Figure 4: Force-displacement curves for the aragonite tablet models. The red line is the averaged force-displacement curve from the MD simulations, and the gray shaded area indicates the standard error deviation. The green line indicate the force-displacement curves obtained from the PFM stress-controlled simulation.

Phenomenologically, the s-shaped crack propagation (along the (101) and ($\bar{1}$01) lattice planes) is obtained in both MD and PFM approaches. Moreover, the ultimate tensile strength obtained in the PFM simulations falls perfectly into the ranges described in the all-atom simulations. Nevertheless, a discrepancy between the two schemes can be seen which can be traced to two main reasons: On the one side, the boundary conditions in the MD simulation allow for rigid body rotations and translations, which are constrained in the continuum model by fixing the vertical displacement of two points. This fixation causes an artificial symmetry and simultaneously

stiffens the material. On the other side, the PFM considers a linear elastic material response, which is not able to account for the inherent material non-linearities. As seen in Fig. 4, these non-linearities are naturally captured in the atomistic simulations.
An important outcome, particularly for the phase-field parameters, is the theoretical and numerical consistency of the critical energy release rate G, and a potential relationship between the molecular transition (distortion) zone and the phase-field transition width governed by the internal length parameter ϵ. The former can be estimated by means of the Griffith's theory or by integration of the stress-strain curve, yielding a value within the literature range (approximately 2.1 J/m^2). The latter can be obtained by measuring the cracked surfaces in a straightforward post-processing step. The results of the MD and PFM simulations are shown in Fig. 5. Taking into account the density plot of the MD and overlapping it with the resultant intact-to-cracked material transition of the PFM, as seen in Fig. 5, the phenomenological correlation is evident.

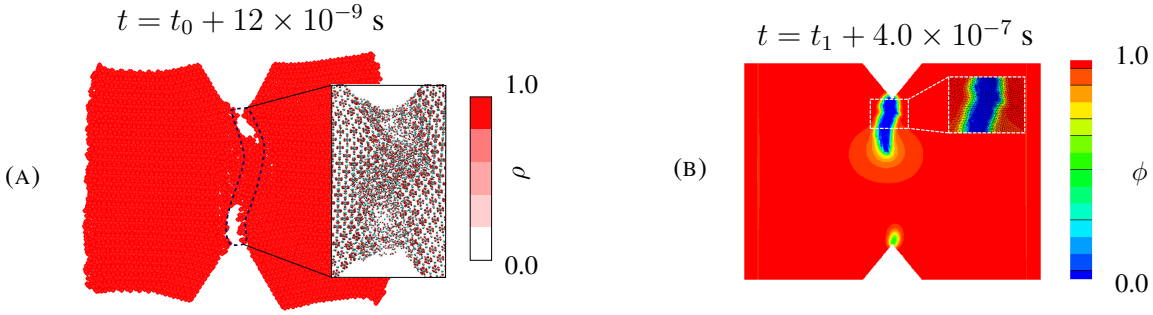

Figure 5: Crack initiation and propagation comparison: (A) Density plots of atoms in MD simulations (ρ stands for density). The s-shaped crack is illustrated with a dotted line, and the inset shows an all-atom simulation snapshot of the crack propagated area. (B) PFM results for stress-controlled simulations (ϕ stands for the damage phase-field, blue corresponds to cracked material, and red refers to undamaged material). The times t0 and t1 are the total loading times before crack initiation in MD (t0 = 13056 ps) and PFM stress-controlled (t1 = 0.0403089 s) respectively.

5 CONCLUSIONS

As shown in this work, the efficiency of continuum mechanics allows to infer mechanical properties from the molecular scale, which is the key to understand a material's interplay of the atomic structure and its overall performance. Through an atomistic obtention of the material parameters, the PFM presented in this work observes a fair convergence, and more important remains qualitatively and quantitatively within the outcomes of MD simulations and the benchmarked literature. Moreover, a correlation between the phase-field parameter ϵ (which is of extreme importance for convergence) and an MD transition zone was captured for the first time. Through further study, this could result in a physical meaning and obtention of the parameter value, which is up to date "fitted́ according to each model. Moreover, the observed molecular dissipative zone between the undamaged and cracked material allows to think that in fact, brittle fracture observe a transition zone, under a purely atomistic standpoint.
As part of a novel approach, this work remains to have improvement areas. The outlook of this research will firstly consist of implementing a non-linear elastic model in order to better capture the material behavior from all-atom simulations. Moreover, further MD as well as PFM simulations under different setups (shear, combined loadings, dynamic case, different

geometries, etc.) are required. Deeper and extensive studies of the molecular dissipative zone observed in the simulations of this work, are also to be carried over.

Abstract. *The direct integration of Computer Aided Geometric Design (CAGD) models into a numerical simulation improves the accuracy of the geometrical representation of the problem as well as the efficiency of the overall analysis process.*

In this work, the complementary features of isogeometric analysis and boundary integral equations are combined to obtain a coalescence of design and analysis which is based on a boundary-only discretization. Following the isogeometric concept, the functions used by CAGD are employed for the simulation. An independent field approximation is applied to obtain a more flexible and efficient formulation. In addition, a procedure is presented which allows a stable analysis of trimmed geometries and a straightforward positioning of collocation points.

Several numerical examples demonstrate the characteristics and benefits of the proposed approach. In particular, the independent field approximation improves the computational efficiency and reduces the storage requirements without any loss of accuracy. The proposed methodology permits a seamless integration of the most common design models into an analysis of linear elasticity problems.

1 INTRODUCTION

Isogeometric analysis aims to close the existing gap between the design process and analysis such that a simulation can be performed without generating a mesh. Consequently, the accuracy and efficiency of the overall simulation process is improved, since meshing is time-consuming [1, 2] and introduces additional (geometrical) approximation errors. In addition, the basis functions used by design models, i.e. NURBS, provide further benefits such as high continuity [3, 4].

However, during the last years, it has become clear that a true integration of design and analysis is far from trivial due to several reasons: first of all, most engineering design models are based on a *boundary representation* (B-Rep) rather than a volume description. Secondly, three dimensional B-Rep models are usually defined by a *non-conforming* partition of NURBS surfaces, i.e. their mathematical parametrizations have no explicit relation to each other. Thirdly, each boundary surface is based on a tensor product structure which is a very efficient representation but has limitations due to its four sided nature. As a result, almost all NURBS based design models use *trimming* procedures to increase the flexibility of tensor product surfaces. This means that only a certain area of a surface is visualized while the underlying mathematical parametrization remains unchanged.

In this work, a coherent framework is presented which allows a seamless integration of trimmed NURBS models into an analysis. In general, the governing equations of the problem are expressed by means of boundary integral equations which are discretized by a numerical approximation method. Here, the *boundary element method* (BEM) is used since it is the most versatile approach. However, it should be pointed out that other schemes like the Nyström method can be applied as well [5, 6]. An *independent field approximation* concept is introduced in order to obtain a flexible BEM formulation. Furthermore, this allows the stabilization of trimmed NURBS geometries by the application of *extended B-splines*. The following sections provide an overview of the proposed methodology. They actually recap and unify the main features presented in [6–8]. Hence, the interested reader is particularly referred to the first one of these references for an in-depth discussion.

2 METHODOLOGY

2.1 Isogeometric Boundary Element Method

A linear elastic body Ω subject to external loading without body forces is considered. The closed boundary of the domain is denoted by Γ and the surface normal $\mathbf{n}$ points outside. Using Betti's or Green's theorem the following integral equation also known as *Somigliana's identity* is obtained

$$\mathbf{u}(\boldsymbol{x}) = \int_\Gamma \mathsf{U}(\boldsymbol{x},\boldsymbol{y})\,\mathbf{t}(\boldsymbol{y})\,\mathrm{ds}_{\boldsymbol{y}} - \int_\Gamma \mathsf{T}(\boldsymbol{x},\boldsymbol{y})\,\mathbf{u}(\boldsymbol{y})\,\mathrm{ds}_{\boldsymbol{y}} \qquad \forall \boldsymbol{x} \in \Omega,\ \forall \boldsymbol{y} \in \Gamma \tag{1}$$

where U and T are fundamental solutions for displacement and traction, respectively [9]. In general, a fundamental solution $\mathsf{U}(\boldsymbol{x},\boldsymbol{y})$ provides the response at a *field point* $\boldsymbol{y}$ due to a unit point source applied at $\boldsymbol{x}$, which is denoted as *source point*. It should be noted that once the Cauchy data, i.e. displacement $\mathbf{u}(\boldsymbol{y})$ and traction $\mathbf{t}(\boldsymbol{y})$, are known on the entire boundary Γ, the representation formula (1) describes the displacement $\mathbf{u}(\boldsymbol{x})$ within the whole domain Ω. In order to solve for unknown boundary values, the source points $\boldsymbol{x}$ are shifted to Γ leading to the

boundary integral equation

$$\mathbf{c}(\boldsymbol{x})\mathbf{u}(\boldsymbol{x}) = \int_\Gamma \mathsf{U}(\boldsymbol{x},\boldsymbol{y})\,\mathbf{t}(\boldsymbol{y})\,\mathrm{ds}_{\boldsymbol{y}} - \int_\Gamma \mathsf{T}(\boldsymbol{x},\boldsymbol{y})\,\mathbf{u}(\boldsymbol{y})\,\mathrm{ds}_{\boldsymbol{y}} \qquad \forall \boldsymbol{x},\boldsymbol{y} \in \Gamma \tag{2}$$

in which the coefficient $\mathbf{c}(\boldsymbol{x})$ depends on the geometrical angle of Γ at $\boldsymbol{x}$ and the Poisson's ratio [10]. Equation (2) represents the governing equations of the problem by means of an integral over the boundary of the computational domain. Hence, corresponding numerical approximation methods like the BEM do not require a domain discretization.

In isogeometric boundary element formulations, the geometry as well as the boundary data are represented by B-spline or NURBS basis functions. The boundary Γ of the computational domain is specified by a disjoint set of patches (curves or surfaces) γ such that

$$\Gamma = \bigcup_{i=1}^{I} \gamma_i \tag{3}$$

which is equivalent to the representation of design models. Since this is the best geometry representation available the computational boundary is described as accurate as possible.

Within each γ, the geometry $\boldsymbol{x}(\xi)$ is defined by a set of basis functions $B_{i,p}$ of degree p with corresponding coefficients in physical space $\boldsymbol{c}_i$ which are denoted as control points. The geometrical mapping χ from parameter space ξ to physical space is given by

$$\chi(\xi) \coloneqq \boldsymbol{x}(\xi) = \sum_{i=0}^{I-1} B_{i,p}(\xi)\,\boldsymbol{c}_i \tag{4}$$

with I representing the total number of basis functions. The main advantages of these patches are that their continuity is directly controlled by the applied basis functions. The parameter space ξ as well as the properties of this basis functions are determined by a knot vector Ξ which is a non-decreasing sequence of parametric coordinates ξ_i. For more detailed information on B-splines and NURBS the interested reader is referred to [2, 11]. Similar to the geometric mapping (4), displacements and tractions of each γ are discretized by

$$\mathcal{Y}_u(\xi) := \mathbf{u}(\xi) = \sum_{i=0}^{I-1} B_i(\xi)\,\tilde{\mathbf{u}}_i \qquad \text{and} \qquad \mathcal{Y}_t(\xi) := \mathbf{t}(\xi) = \sum_{j=0}^{J-1} B_j(\xi)\,\tilde{\mathbf{t}}_j. \tag{5}$$

The coefficients $\tilde{\mathbf{u}}_i$ and $\tilde{\mathbf{t}}_j$ are control parameters of the corresponding field and the related basis functions are denoted by B_i and B_j.

The system of equations is set up using a collocation approach where the boundary integral equation is enforced in a set of *collocation points* $\boldsymbol{x}^c$. In particular, each basis function B_i of the unknown field is related to a certain $\boldsymbol{x}_i^c$. It has been demonstrated by several authors [7, 12, 13] that the Greville abscissae

$$\bar{\xi}_i = \frac{\xi_{i+1} + \xi_{i+2} + \cdots + \xi_{i+p}}{p} \tag{6}$$

are a robust and accurate choice for the location of the collocation points, i.e. $\boldsymbol{x}_i^c = \chi(\bar{\xi}_i)$. For each $\boldsymbol{x}_i^c$, the integrals of the boundary integral equation (2) with $\boldsymbol{x} = \boldsymbol{x}_i^c$ are evaluated using numerical integration. Since each γ may contain non-smooth regions, it has to be subdivided

into integration elements. Within those integration elements, the integrand is smooth and hence numerical integration can be performed properly.

Usually, equation (6) leads to some collocation points located on the boundary of each γ. Hence, they should be considered during the integration of adjacent γ as well. For two dimensional problems, i.e. boundary curves, this is not challenging. However, in case of boundary surfaces, detection of adjacent surfaces and determination of the collocation points' intrinsic coordinates within them may be very involved. Especially, if non-conforming partitions of trimmed surfaces are considered. The application of discontinuous collocation is an elegant remedy to this issue [6, 7]. Using such schemes, collocation points along the boundary of γ are slightly shifted inside, thereby abolishing the link to adjacent surfaces. In general, this is possible since interelement continuity is not necessarily required in BEM [14].

2.2 Independent Field Approximation

In the context of isogeometric BEM, the Cauchy data are discretized by means of B-splines or NURBS. The related mappings (5) are denoted by $\mathcal{Y}_u(\xi)$ and $\mathcal{Y}_t(\xi)$ for displacements $\mathbf{u}$ and traction $\mathbf{t}$, respectively. In the following, the distinction between *isoparametric* and *subparametric* patches is introduced. The former employs the isoparametric paradigm, i.e. all fields are represented by the same basis functions, as it is generally the case in isogeometric analysis. The latter utilizes the proposed independent field approximation. The term subparametric indicates that less parameters are used for the description of the geometry than for the Cauchy data.

2.2.1 Isoparametric Patches

In an isoparametric discretization, the mappings $\mathcal{Y}_u(\xi)$ and $\mathcal{Y}_t(\xi)$ are equal to the geometrical one $\chi(\xi)$. This implies some compromises. First of all, the same refinement is applied to all fields. On the one hand, refinement of the unknown field is mandatory to improve the solution. But as a consequence, the geometry and the known field are refined even though they may be exactly represented by the initial basis functions. In addition to refinement aspects, the fields have different continuity requirements along corners and edges. In particular, discontinuous basis functions are required to describe traction jumps. However, they are not optimal for representing the displacement field, which should be continuous according to the physical constraint. Furthermore, the number of basis functions would be increasing unnecessarily.

Thus, a preliminary conclusion is that an isoparametric discretization introduces superfluous control variables. This increases the numerical effort and storage requirements for setting up the system of equations, particularly for its right hand side. Moreover, refinement of CAGD models affects the efficiency of all geometry evaluations performed during the analysis. These points motivate the application of the proposed subparametric approach presented next.

2.2.2 Subparametric Patches

In this section, subparametric patches are introduced. The key idea is to treat each field separately in order to fulfill their individual needs. In particular, the concept of a subparametric element is adopted, i.e. more basis functions will be used to represent the field variables than for the geometry representation. The basis functions of the geometry, the displacements, and the tractions are defined by the knot vector Ξ_g, Ξ_u, and Ξ_t, respectively. Without loss of generality, basis functions of the Cauchy data are defined as an extended version of Ξ_g, so that $\Xi_g \subset \Xi_u$ and $\Xi_g \subset \Xi_t$. This definition guarantees a proper partition of integration elements. It should,

however, be noted that it allows the variation of basis functions types. For instance, the Cauchy data over a NURBS patch may be approximated by B-splines. The resulting benefits are that the evaluation of Cauchy data becomes more efficient and the refinement procedure is simplified. Moreover, it has been demonstrated that the approximation quality is hardly effected by such a combination [7, 13].

In the present implementation the geometry knot vector Ξ_g provides the initial basis for all fields. Subsequently, basis functions are refined only if it is necessary. Discontinuous basis functions are introduced only for the traction field at non-smooth boundaries. The known Cauchy data are classified as *simple* or *complex* boundary conditions as indicated in Figure 1. The former can be exactly represented by Ξ_g, hence the corresponding discretization does not need to be refined. Homogeneous boundary conditions or constant loading are examples for such boundary conditions. The latter can only be approximated and the corresponding basis functions have to be refined to improve the representation of the known Cauchy data. In such a case, refinement is performed equally to the one for the approximation of the unknown field.

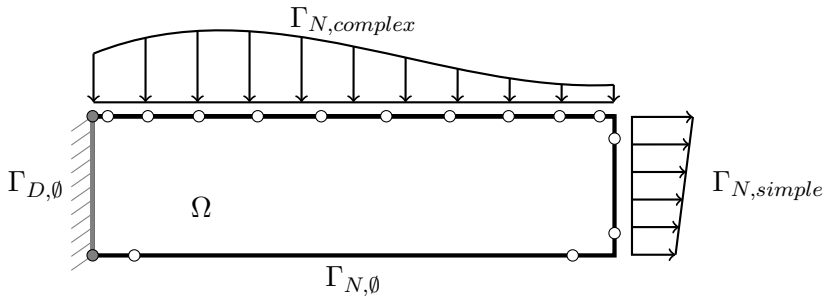

Figure 1: Examples of simple and complex boundary conditions applied to a cantilever beam. Homogeneous boundary condition are denoted by the subscript $\emptyset$. Circles indicate the related Greville abscissae of the basis functions which represent the known data.

To sum up, the main aim of independent field approximation is to avoid redundancies in the discretization, leading to an enhanced isogeometric BEM formulation. At the same time, no discretization errors are introduced and the initial design model remains unchanged during the simulation which simplifies the interaction with CAGD software.

2.3 Stable Basis for Trimmed Geometries

In general, a trimmed parameter space has only a certain area which represents the part of an object that is visualized. This part is denoted as valid domain Ω^{v} for the remainder of this paper. Usually, trimming is used for surfaces and in this case Ω^{v} is determined by so-called trimming curves which are defined within the parameter space of the surface.

There are two main aspects that have to be considered if trimmed geometries are integrated into a numerical simulation: firstly, only the visualized part has to be considered for the analysis. Secondly, the trimmed parameter space has to be stabilized, because basis functions with small support occur which may lead to ill-conditioned system matrices. Several different approaches [15–20] have been proposed to address the former issue. However, the latter has hardly been considered in the literature so far. Hence, the current section focuses on this aspect. In particular, it is proposed to stabilize trimmed parameter spaces by using so-called *extended B-splines* which have been originally introduced in the context of fictitious domain – finite element methods [21–24].

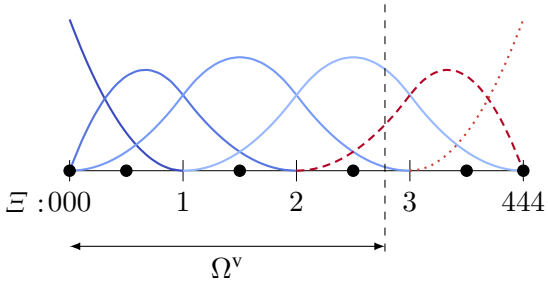

Figure 2: Classification of basis function types in case of a trimmed parameter space: stable (continuous), degenerated (dashed), and exterior (dotted). The related Greville abscissae are illustrated by circles.

The basic idea of extended B-splines is to replace basis functions which may cause instabilities by extrapolations of neighboring ones which have a sufficient large support. In order to classify the B-splines of a trimmed parameter space, three types are introduced: stable, degenerated, and exterior. We propose to label B-splines $B_{i,p}$ as stable if their corresponding Greville abscissae is within the valid domain, i.e. $\bar{\xi}_i \in \Omega^{\mathrm{v}}$. The support of exterior B-splines, on the other hand, is entirely outside of Ω^{v}. The remaining degenerated basis functions are partially inside of Ω^{v} but their Greville abscissae is outside, i.e. $\bar{\xi}_i \notin \Omega^{\mathrm{v}}$. These various types are shown for an univariate parameter space in Figure 2. Once the degenerated B-splines are detected, the functions within their support are substituted by extensions of the closest stable segments as illustrated in Figure 3. The resulting extended B-splines $B^e_{i,p}$ are defined by a linear combination of the original ones

$$B^e_{i,p} = B_{i,p} + \sum_{j \in \mathbb{J}_i} e_{i,j} B_{j,p} \tag{7}$$

where $\mathbb{J}_i$ is an index-set of all degenerated B-splines $B_{j,p}$ related to the current $B^e_{i,p}$. For univariate basis functions, the corresponding extrapolation weights $e_{i,j}$ are generally defined by the so-called *de Boor–Fix* or dual functional (see e.g. [6, 23, 25]). In addition, a simplified formula can be derived for uniform parameter spaces [22, 24]. In the bivariate case, the extrapolation weights are simply determined by the tensor product of univariate values.

Extended B-splines inherit most properties of conventional B-splines and provide a stable basis for the analysis of trimmed geometries. The proposed strategy for detecting degenerated basis functions is particularly beneficial for collocation schemes, because the definition of the collocation point locations within Ω^{v} is straightforward, i.e. equal to the non-trimmed situation.

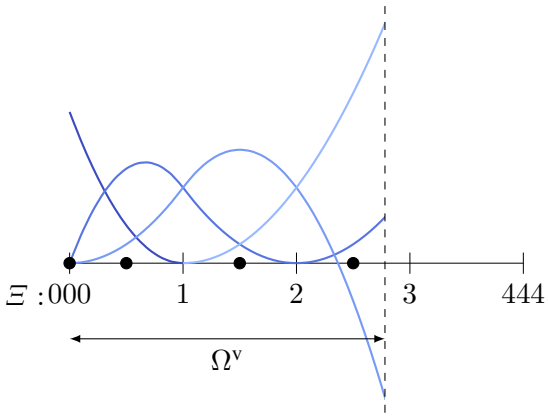

Figure 3: Extended B-splines

The presented concept focuses on B-spline basis functions. However, if the geometry is defined by trimmed NURBS, we take advantage of the independent field approximation and simply approximate the Cauchy data by B-splines without modifying the geometrical representation.

3 NUMERICAL RESULTS

The following examples emphasize the benefits of the proposed methodology. Firstly, the advantage of accurate geometry models is investigated. Secondly, the performance of isogeometric and subparametric patches is compared. Finally, the approximation quality of extended B-splines is studied.

3.1 Sphere

The excavation of a spherical cavity with radius $r_s = 5.0\,\mathrm{m}$ is investigated. An isotropic elastic material is considered with Poisson's ratio $\nu = 0.3$ and Young's modulus $E = 1000\,\mathrm{MPa}$. Hydrostatic stress $\sigma_0 = 1.0\,\mathrm{MPa}$ is applied as loading which leads to a uniform internal pressure along the excavation surface. The resulting radial displacement u_r can be determined analytically by

$$u_r = \sigma_0 \frac{1+\nu}{2\,E} \frac{r_s^3}{r^2} \tag{8}$$

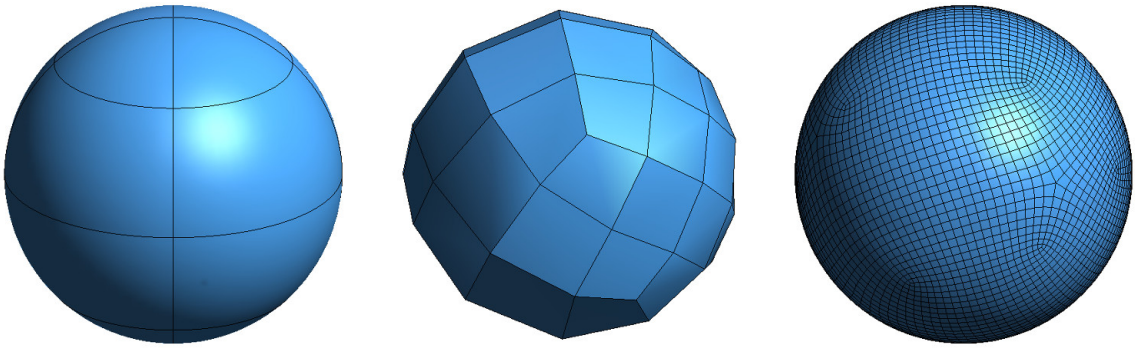
where r denotes the distance of the point observed to the center of the sphere. Hence, the reference solution for u_r along the boundary, i.e. $r = r_s$, is $3.25 \times 10^{-3}\,\mathrm{m}$.

The problem is solved by conventional and isogeometric BEM simulations. Both approaches employ quadratic basis functions. The conventional BEM meshes approximate the boundary of the computation domain with quadratic Serendipity elements. In the isogeometric case, NURBS basis function of degree $p = 2$ are used. In fact, the geometry can be represented exactly by a single NURBS patch which has degenerated edges at each pole of the sphere. This model has been exported from the CAGD software Rhinoceros, where the precision of the exported data was set to $\epsilon_e = 10^{-8}$. Discontinuous collocation is applied in order to deal with the degenerated edges of the model.

The relative error of the radial displacement ϵ_{u_r} as well as the relative deviation of the geometry representation to an analytical sphere ϵ_{geo} are summarized for various degrees of freedom n in Table 1. Further, three numerical results and their corresponding discretizations are illustrated in Figure 5 and Figure 4, respectively.

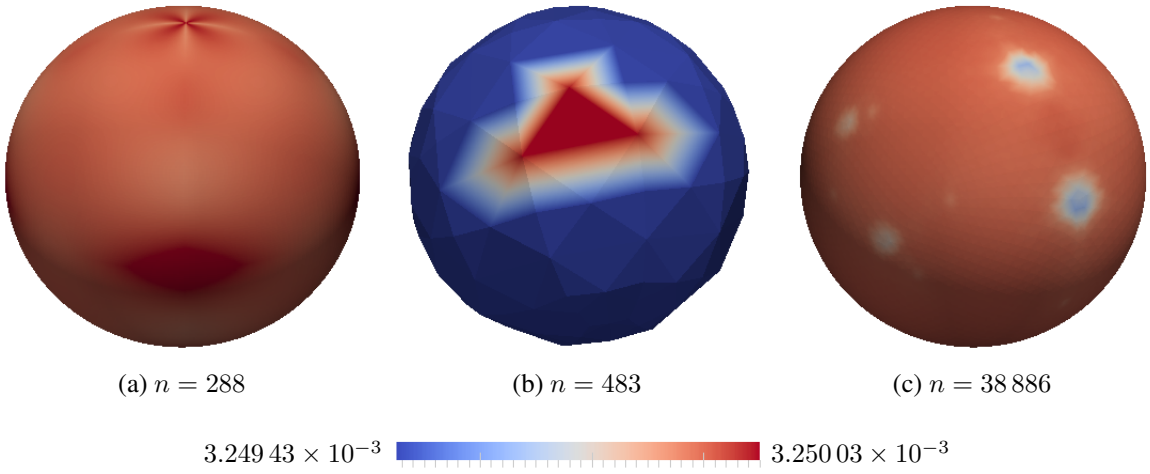
Isogeometric BEM			Conventional BEM		
n	ϵ_{u_r}	ϵ_{geo}	n	ϵ_{u_r}	ϵ_{geo}
216	1.74×10^{-5}	3.42×10^{-8}	483	1.61×10^{-2}	4.76×10^{-1}
288	2.65×10^{-6}	3.42×10^{-8}	2436	1.27×10^{-3}	1.53×10^{-2}
			9312	5.58×10^{-4}	1.81×10^{-3}
			12 120	4.42×10^{-4}	1.10×10^{-3}
			21 858	1.49×10^{-4}	3.21×10^{-4}
			38 886	7.52×10^{-5}	1.08×10^{-4}

Table 1: Relative error of solution ϵ_{u_r} and geometry representation ϵ_{geo} of the spherical excavation measured in L_2-norm due to an isogeometric and conventional BEM analysis with quadratic basis functions.



(a) $n = 288$ (b) $n = 483$ (c) $n = 38\,886$

Figure 4: Various unknown field discretizations of the spherical cavity with different degrees of freedom n: (a) finest isogeometric BEM, (b) coarsest, and (c) finest conventional BEM analysis.



(a) $n = 288$ (b) $n = 483$ (c) $n = 38\,886$

Figure 5: Radial displacement u_r of various spherical excavation discretizations: (a) finest isogeometric BEM, (b) coarsest, and (c) finest conventional BEM analysis.

The error ϵ_{geo} demonstrates clearly the superiority of the isogeometric concept concerning accurate geometry representations. The unrefined NURBS patch provides already a precise geometric model, while a large number of Serendipity elements is required for an adequate approximation. Note that ϵ_{geo} correlates to the accuracy of the input data ϵ_e in the isogeometric case, hence it can be controlled by the user. Moreover, the isogeometric solution provides excellent results for u_r despite of the low number of degrees of freedom n. It should, however, be noted that the example suits NURBS basis functions ideally. Such remarkable differences between isogeometric and conventional BEM solutions can not be expected in general. Nevertheless, conic sections and their three dimensional counterparts, e.g. spheres and cylinders, are very common design elements for which NURBS surpass the approximation quality of conventional basis functions.

3.2 Crankshaft

The concept of independent field approximation is applied to a crankshaft example. The geometry is defined by several regular NURBS patches and illustrated in Figure 6. Displacements are fixed at the axle and flywheel, while the crank pins are subjected to vertical loading. These boundary conditions are exactly represented by the initial discretization and do not require re-

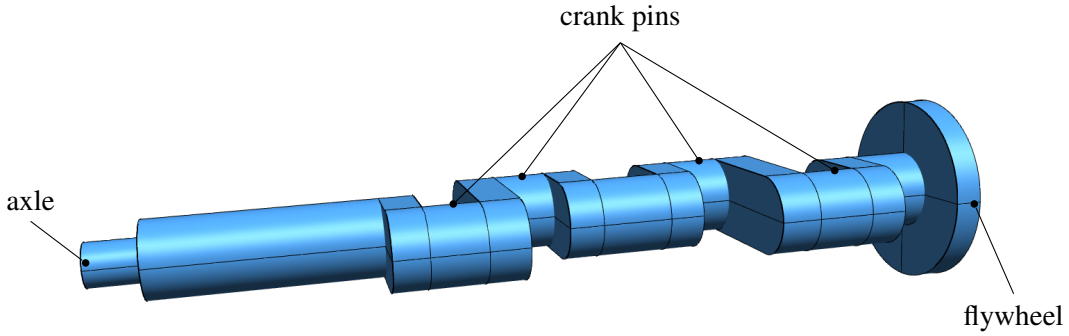


Figure 6: Geometry model of the crankshaft.

finement. The material property is specified by $E = 210\,\mathrm{GPa}$ and $\nu = 0.25$.

Subparametric and isoparametric discretizations are applied to the problem. They differ not only in the refinement procedure, but the type of basis function used for representing the Cauchy data. In particular, B-splines are employed in the subparametric case. The degree of the basis functions related to Cauchy data p_c is either equal to the one of the geometry representation p_g or increased by means of degree elevation, i.e. $p_c = p_g + 1$. Subsequently, knot insertion is used to improve the results, which is the equivalent to h-refinement in conventional analysis. For each simulation, the analysis time t_i and t_s of the isoparametric and subparametric discretization are compared. To be precise, the runtime for setting up the left hand side matrix $\mathbf{L}$ and the right hand side matrix $\mathbf{R}$ of the system of equations is measured. Each analysis has been performed single-threaded, concurrently for each t_i and t_s, and repeated several times.

The resulting speedup factors t_i/t_s are summarized in Figure 7. In addition, the displacements corresponding to the third h-refinement step of the case where $p_c = p_g$ are exemplarily shown in Figure 8.

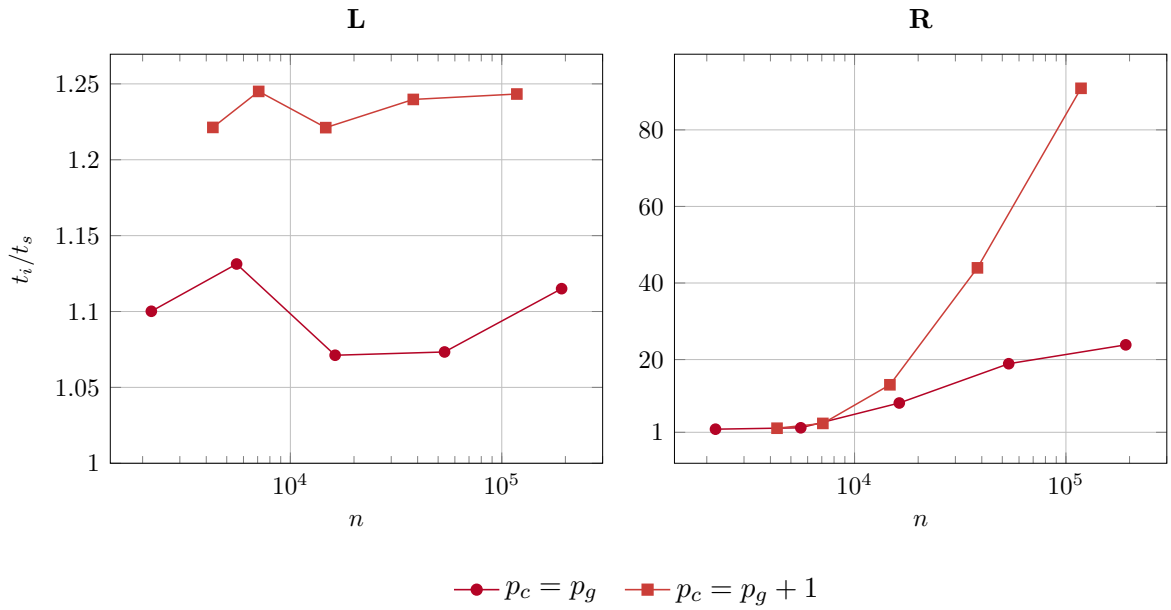

Figure 7: Computational time for the set up of $\mathbf{L}$ and $\mathbf{R}$ related to various discretization of the crankshaft example as a function of the degrees of freedom n. The runtime of the isoparametric discretization t_i is related to the subparametric one t_s.

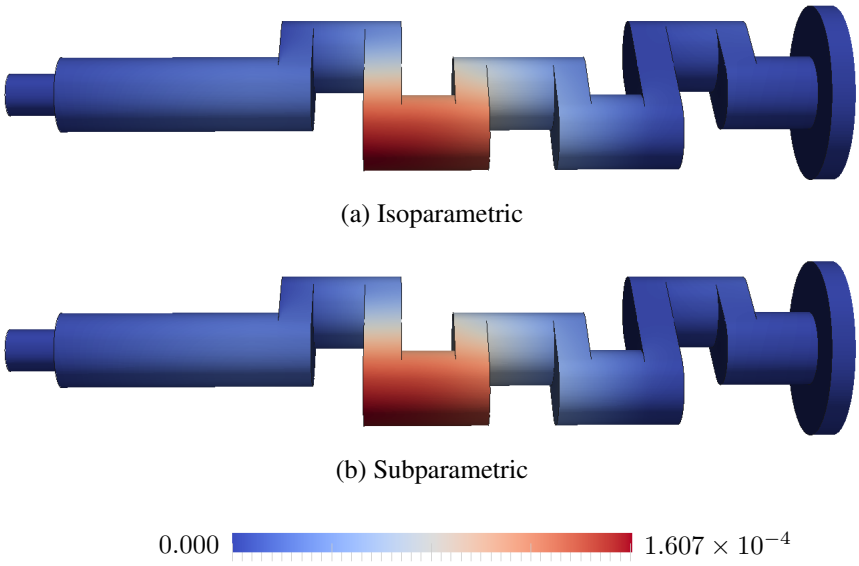


(a) Isoparametric

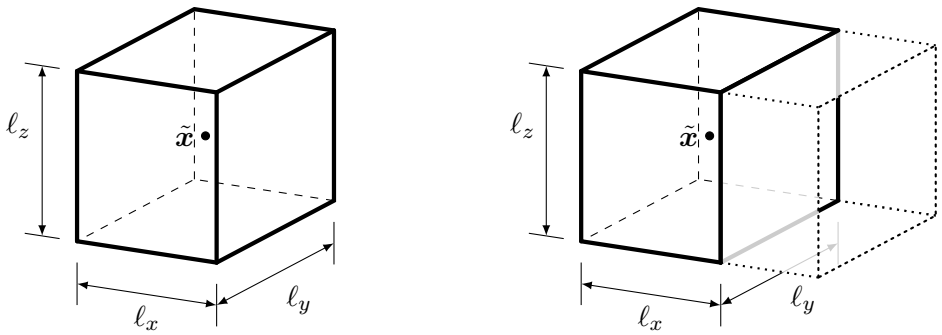
(b) Subparametric

Figure 8: The absolute displacement $|\mathbf{u}|$ of the crankshaft example without degree elevation and three h-refinement steps due to an (a) isoparametric BEM and (b) subparametric BEM discretization.

The shown results indicate that independent field approximation reduces the computational effort, especially for the right hand side of the system of equations. The number of columns of $\mathbf{R}$ is constant for all subparametric discretizations, because known Cauchy data do not need to be refined. Hence, its storage requirement is linear with respect to the degrees of freedom n which is the driving force for the enormous speedup with respect to $\mathbf{R}$. The efficient geometry evaluation as well as the substitution of NURBS by B-splines are the key factor regarding the faster computation of $\mathbf{L}$ in the subparametric case. The former impact is clearly indicated by the additional offset between the graphs related to $p_c = p_g$ and $p_c = p_g + 1$ on the left hand side of Figure 7.

3.3 Trimmed Cube

In order to investigate the approximation quality of extended B-splines in the context of an isogeometric BEM analysis a unit cube is analyzed. The geometry is discretized by two different models as illustrated in Figure 9. One is described by 6 regular patches, whereas 4 trimmed patches are included in the other. Both represent the same geometry, i.e. $\ell_x = \ell_y = \ell_z = 1.0$,



(a) Untrimmed

(b) Trimmed

Figure 9: Discretization of a unit cube by (a) regular patches and (b) trimmed patches.

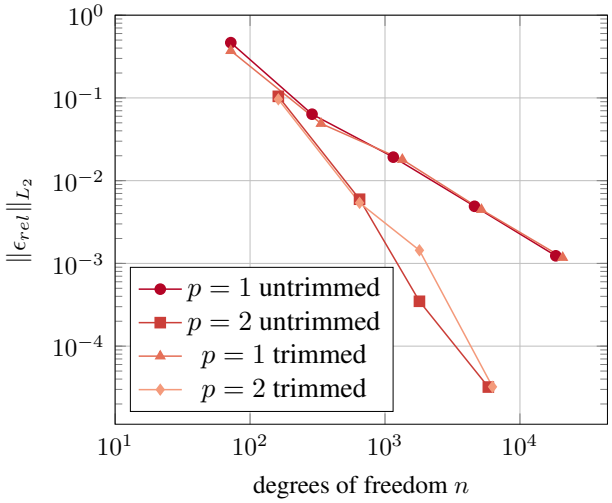


Figure 10: Relative L_2-error of an exterior Neumann problem on the (trimmed) cube example with respect to the number of degrees of freedom n.

which defines the boundary Γ of an infinite domain Ω. The boundary condition is given by

$$\mathbf{t}(\boldsymbol{y}) = \mathsf{T}(\tilde{\boldsymbol{x}}, \boldsymbol{y}) \qquad \boldsymbol{y} \in \Gamma,\ \tilde{\boldsymbol{x}} \in \Omega^- \tag{9}$$

with Ω^- denoting the void, i.e. $\tilde{\boldsymbol{x}} \notin \Omega$. In particular, a source point $\tilde{\boldsymbol{x}}$ in the center of the cube defines the boundary conditions for the exterior Neumann problem. The discretizations are set up for different degrees $p = \{1, 2\}$ and knot insertion is applied to improve the solutions. The relative approximation error is determined by

$$\epsilon_{rel} = \frac{\mathbf{u}(\boldsymbol{y}) - \mathsf{U}(\tilde{\boldsymbol{x}}, \boldsymbol{y})}{\mathsf{U}(\tilde{\boldsymbol{x}}, \boldsymbol{y})} \qquad \forall \boldsymbol{y} \in \Gamma,\ \tilde{\boldsymbol{x}} \in \Omega^- \tag{10}$$

where $\mathbf{u}(\boldsymbol{y})$ is the obtained solution along the boundary. In Figure 10, the results measured with respect to the L_2-norm, i.e. $\|\epsilon_{rel}\|_{L_2}$, are shown. It can be observed that the trimmed model shows very good agreement with the untrimmed case.

4 CONCLUSIONS

A comprehensive concept for integrating design models into a numerical simulation has been presented. The essential ingredient is that the isogeometric method applied is based on boundary integral equations. This allows to overcome the challenge of deriving a volume discretization from a design model, in a simple and elegant manner. In addition, no connectivity information is required between adjacent patches. The proposed concept is completed by an independent field approximation paradigm allowing a more flexible interaction with the design model and a technique which stabilizes trimmed parameter space. These enhancements are by no means restricted to the boundary element method used in this work.

The presented results demonstrate the superiority of isogeometric schemes regarding accurate geometry description, the computational advantage of independent field approximation related to conventional isoparametric formulations, and the suitability of the proposed stabilization. The latter results are indeed very promising and deserves to be investigated in more detail. For instance, the behavior for higher degree approximations has been neglected in the present work and is of particular interest for further research.
