
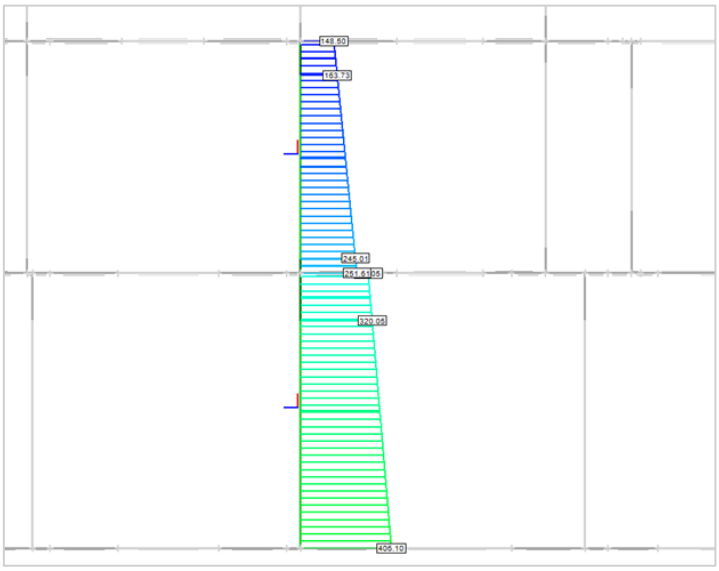

Figure 15. Axial force diagrams. Piers 6 and 205

Focusing on Piers 6 and 205 in Figure 15, we notice a larger value of the axial force with respect to the previous approach (Figure 12). The difference is more evident in Pier 6 at the ground floor, which is affected by the weight of the most recent part of structure. In this case the variation of axial force at the interface of the two piers is:

$$N_6 - N_{205} = 302.05 - 251.61 = 50.44\ kN$$

Shear forces and bending moments in masonry piers are considerably reduced with respect to the standard approach, except for the original elements, which are also influenced by the permanent loads acting on the structure built in a later stage.

Again, the following table reports the stress state in Spandrel 14.

	Joint i	Joint j	
N	0.00	0.00	kN
V_y	0.27	0.27	kN
V_z	0.00	0.00	kN
M_x	0.00	0.00	kNm
M_y	0.00	0.00	kNm
M_z	0.22	-0.20	kNm

Table 4. Stress state in Spandrel 14

The stress is slightly larger than the previous approach since the spandrel belongs to the original structure and is affected by the most recent part of the building. Nevertheless, the stress state remains acceptable and consistent with the physical problem and the hypothesis of the proposed approach.

4.4 Manual Calculation

In order to verify the accuracy of the results let us perform a manual calculation of the axial force diagram. The model considered here includes Piers 6 and 205 as well as the pier above them and all the adjacent spandrels. The piers are considered as cantilever, while the spandrels are considered hinged at the two ends in their plane with arch-behavior. Therefore, under the action of vertical loads, the spandrel are unstressed and the piers are simply in compression.

As shown in Figure 16, each pier is subjected to the self-weight and to additional forces, which account for the vertical loads acting on the spandrels and the slab loads at roof level. The values of these forces are:

$$N_3 = 20.00\ kN$$

$$N_2 = 24.16\ kN$$

$$N_1 = 25.10\ kN$$

The following Table provides the dimension of each pier together with the specific weight and allows the calculation of the self-weight.

	Pier 363 Second floor	Pier 205 First floor	Pier 6 Ground floor	
Thickness	0.50	0.50	0.50	m
Width	2.70	2.70	2.30	m
Height	3.10	3.25	3.85	m
Specific weight	23.50	23.50	23.50	kN/m^3
Self-weight	98.35	103.10	104.05	kN

Table 5. Calculation of self-weight

Given these data, the axial force acting on each pier can be calculated and the results may be represented in a diagram. The following Figure is a comparison of the axial force diagram obtained through analysis of the construction stages and the one calculated manually. We notice that the maximum deviation between the two diagrams, at the base of the wall, is equal to 11.49 kN, about 3% of the axial force in the corresponding section. Therefore, the analysis of the construction stages is very accurate especially if compared with the results of the standard approach, which show a much larger discrepancy with the manual calculation.

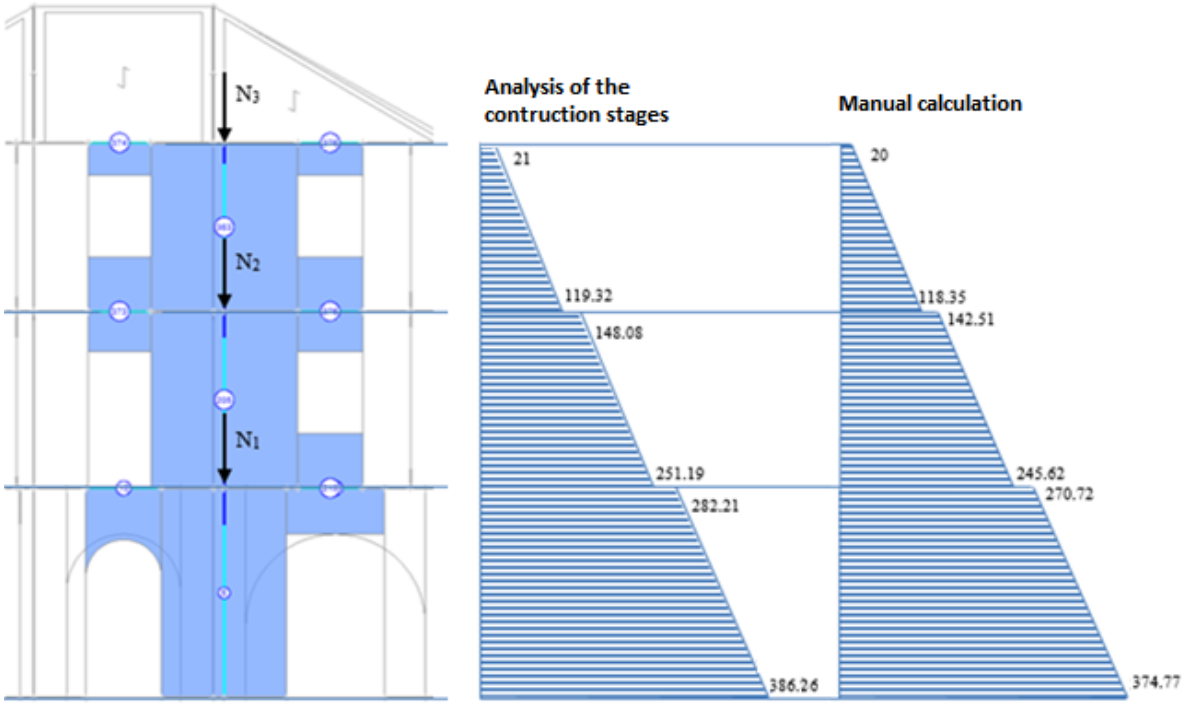

Figure 16. Comparison of axial force diagrams from analysis of the construction stages and manual calculation

5 CONCLUSION

In this paper, a methodology aimed to improve the application of the equivalent frame model, through a more realistic stress distribution, was introduced. The approach, based on the construction phases analysis, consists in the use of different structural models for the analysis of the different load actions. The models vary in terms of mechanical characteristics of the materials, internal releases of the frames, joint restraints and load distribution. This allows to obtain a more accurate stress state of the elements and to overcome the typical issues related to the equivalent frame method when applied according to the standard approach.

Three phases have been defined. Phase 0, where the sole permanent loads are applied, aims to catch the ability of the structure to settle under its own weight during the construction. Therefore, in this phase the equivalent frame is not completely established and the stress is distributed consistently with the influence areas of each element. Moreover, the spandrels are modelled with arch-behavior and remain unstressed under the action of vertical loads.

In Phase 1, only vertical variable loads are applied to the equivalent frame model. Besides axial force, piers may now be subjected to shear force and bending moments, while the spandrels still behave as arches.

In the third and last phase, Phase 2, horizontal variable loads (wind, seismic action) are applied. The hypothesis are the one of the standard equivalent frame model with no modifications.

Once the analyses are performed for each load action through the corresponding phase and model, the results are combined according to the relevant load combinations.

Furthermore, a procedure for the analysis of structures built in two different periods has been described. The analysis of the construction stages is based on the construction phases analysis but this time the original part of the structure and the one built in a later construction stage are treated differently. The application of the construction phases analysis in this case requires to split Phase 0 into two more Phases (0-A and 0-B). This allow to properly assess the influence of the most recent structure on the original one.

The case study of a building rather regular in plan and in elevation was presented. The structure, built in two different periods, was analyzed according to three approaches: standard approach, construction phases analysis and analysis of the construction stages. The typical issues related to the standard application of the equivalent frame model were highlighted; especially with respect to the stress distribution, which in many case is affected by unrealistic stress migration. A comparison of the results obtained with the proposed approaches confirmed that they are more realistic and consistent with the real physical problem. The accuracy of the results has been proven through comparison with the stress state obtained through a simple manual calculation.

The building was analyzed though static linear analysis since the proposed methodologies mainly influence the structural behavior under the action of vertical loads. In a later work, the results of seismic analyses performed through the construction phases approach will be presented. The advantages of the proposed methodologies are evident in pushover analysis where the capacity curve of the structure is more realistic than the one obtained with the standard approach.

Finally, the proposed procedures represent an improvement of the equivalent frame method, leading to more accurate results with a slightly higher computational effort. This is particularly important, considering that the equivalent frame method is widely used in the engineering practice. However, the concepts of construction phases analysis could be applied even to more refined finite element models, since they are based on the differentiation of the structural model depending on the nature of the load actions.

Keywords: monuments, marble, pullout phenomenon, restoration, contact interfaces.

Abstract. *The present study describes the first stage of an ongoing research project aiming to investigate the failure mechanisms activated when reinforcing bars are pulled-out from the body of the reinforced element. Attention is given to the progressive failure of the interfaces between the constituent elements of the marble-cement paste-titanium (MCT) complex, which appears in case marble structural members of classic stone monuments are restored according to the pioneering technique used on the Acropolis of Athens worksite. Experience from already implemented projects indicates that, when restored structural members are subjected to tension or bending, the failure of these interfaces leads to debonding and finally to catastrophic pull-out of the reinforcing bar from the body of the marble volume.*

In this direction, a series of pull-out experiments were implemented, with specimens made of Dionysos marble, in the form of prisms of various dimensions with threaded titanium bars inserted into predrilled holes which were then filled with suitable cement paste. The results obtained from these experiments, by employing both conventional and innovative sensing techniques, were used for the calibration of a Finite Element model, which will be used for the thorough investigation of the parameters affecting the overall response of the restored element.

The commercial package ABAQUS was used for the implementation of the numerical analysis. The surface contact features of the package were properly exploited in the direction of comparatively exploring and evaluating of possible modeling approaches for simulating the actual interfaces of the marble-cement-titanium complex. A reliable performance law, allowing for the incorporation of damage initiation and evolution criteria, was determined permitting satisfactory modeling of the pull-out behavior at the interface between marble and cement paste. Critical parameters, material properties and modeling choices that have a significant impact on the final outcome were considered. The numerical model finally designed approaches in a very satisfactory manner the experimentally obtained load-displacement curve, providing an easy-to-use, flexible and reliable tool for further study of the pull-out phenomenon.

1 INTRODUCTION

The pioneering technique that is nowadays adopted for the restoration of fractured structural members of classic marble monuments of Greek architecture is based on the insertion of threaded titanium bars into pre-drilled holes, while filling the intermediate gap with a suitable cementitious paste (Fig. 1) [1]. The number and the diameter of the bars are chosen in such a way that the restored epistyle sustains its self-weight and the weight of the structural elements that are planned to be superimposed on the structure in the future. Furthermore, attention is paid for the extent of interventions to the authentic marble to be the minimum possible. The basic principle that governs this kind of restorations is the reversibility of the interventions. This means that if needed, the monument can be restored to its condition prior to the intervention.

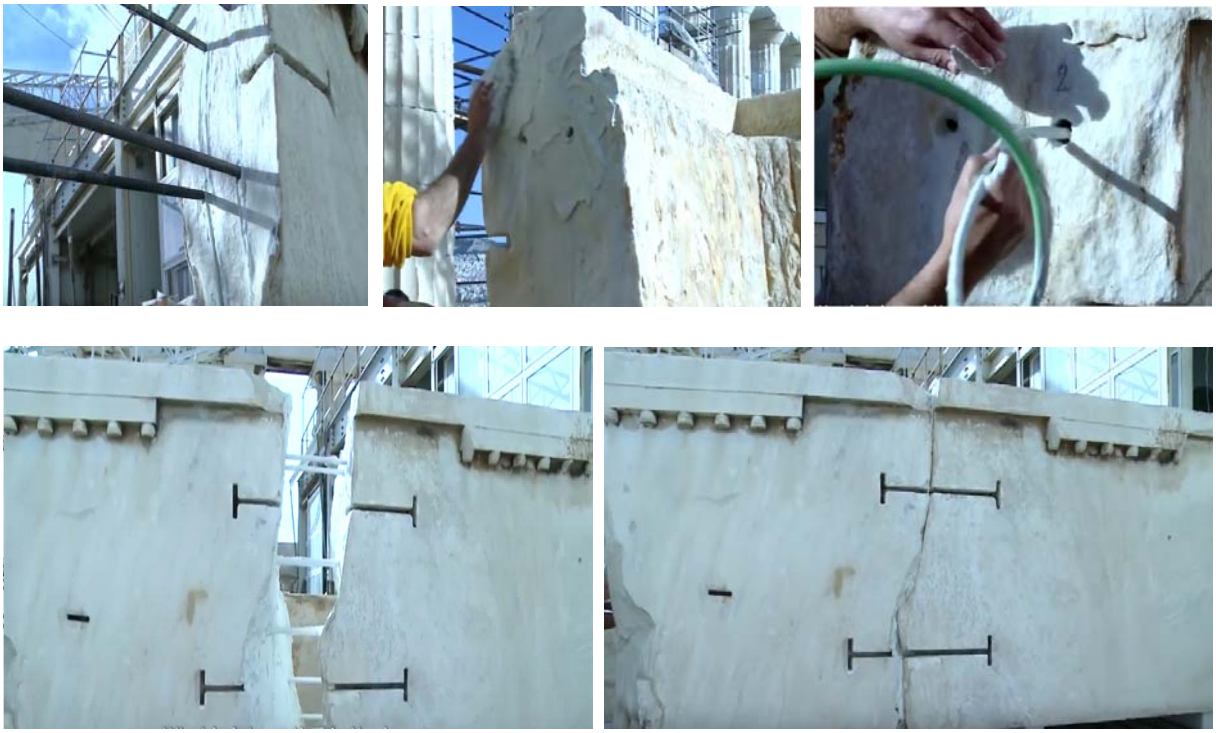

Figure 1: The main steps for the restoration of a marble epistyle [2].

Experience gathered by the scientists working for the restoration project of the Acropolis monuments has shown that the integrity of the structure after restoration strongly depends on quite a few details of the aforementioned technique. Several experimental and numerical studies have been conducted, investigating the parameters that influence the mechanical response of the specific joint [3]. It has been definitely proven that the weakest link of the three materials (MCT) chain lies within the layer of the cementitious material [3, 4]. The failure mode most commonly observed, is the relative slip of the bar-mortar block with respect to the marble volume (without fracture of neither the marble nor the bar) which is known as pull-out.

This work focuses on the development of a reliable numerical model that, hopefully, could effectively describe the behavior of a thin layer between the cement paste and the marble body while being effective concerning the computational time. Critical parameters influencing the effectiveness of the model in terms of time requirement are considered to be the model's meshing, the analysis of time-increment and the choice regarding two or three-dimensional modeling. The models developed are calibrated taking advantage of the data for the load-displacement curve of a series of pull-out experiments which were implemented at the Laboratory of Testing and Materials of the National Technical University of Athens.

2 EXPERIMENTAL PROCEDURE

2.1 Specimens

The specimens tested were orthogonal prisms cut from Dionysos marble blocks. Their dimensions were equal to 10x10x15 cm^3. A central through hole, of diameter equal to d_{hole}=14 mm, was drilled normally to the upper face of the prisms. The hole was then filled with liquid cementitious material and a threaded titanium bar, of outer diameter equal to d_{bar}=11.0 mm, was driven in the hole and kept normal to the upper face of the cube until setting of the cement paste. All specimens have the same dimensions, anchoring length (7.5 cm) and thread's geometry and were cured for 28 days (Fig. 2). Attention was paid for the prisms to be cut normally to the material layers of the blocks in order to reduce scattering due to marble's anisotropy.

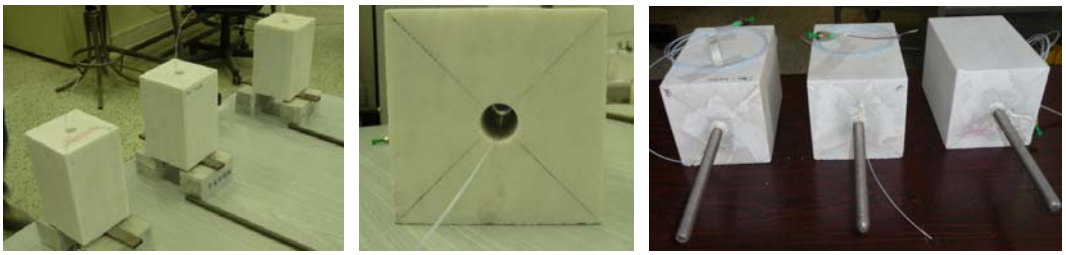

Figure 2: Preparation of the specimens.

2.2 Experimental procedure

For the experimental procedure, a stiff servo-hydraulic INSTRON loading frame of capacity 250 kN (Model 1126) was used. All tests were carried out under quasi-static displacement-control mode at a rate equal to 0.2 mm/min, with the titanium bar gripped by the frame's upper jaw. The marble cube was constrained by a rigid metallic plate with a hole of diameter equal to 50 mm in its center. The plate was supported by four stiff threaded bars (Fig. 3 (a), (b)). For the direct measurement of the axial strain developed along the titanium bar an Instron-Dynamic Extensometer of gauge length equal to 12.5mm was used (Fig. 3 (c)).

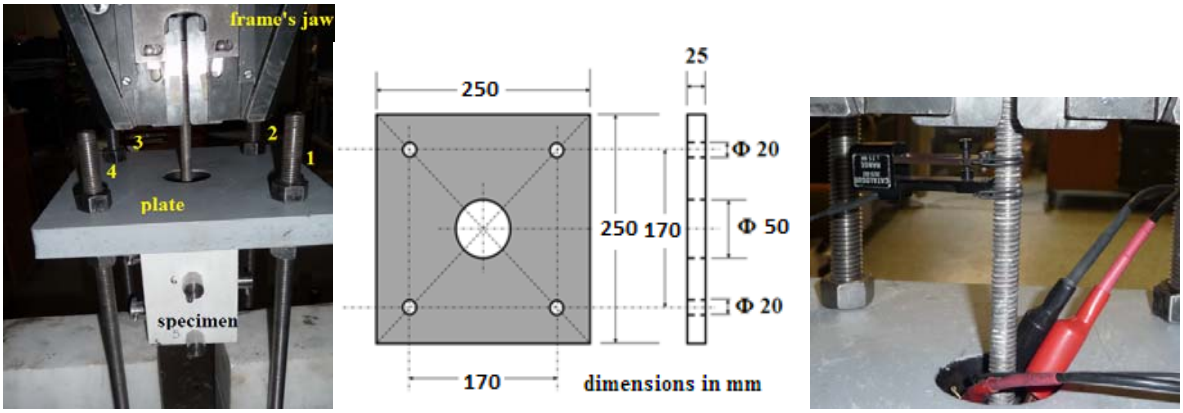

Figure 3: (a) The experiment set up, (b) The configuration of the metallic plate (c) The Dynamic Extensometer used in the experiments

During the tests, the relative displacement of the bar with respect to the marble prism was measured and recorded using a calibrated LVDT (Linear Variable Differential Transformer) touching the bar's lowest end through the cube's bottom face (Fig. 4 (a), (b)). Furthermore, in order to monitor the whole system's deformation and determine the actual movement of the bar, three additional LVDTs were placed at the bottom of the rigid plate (Fig. 4 (c)).

Figure 4: (a) The LVDT's position schematically (b) The lowest end of the cube (c) The LVDTs' positions under the rigid metallic plate.

In the experimental procedure, two innovative sensing techniques were employed, namely the Acoustic Emission (AE) and the Pressure Stimulated Currents (PSC) ones. So far, it is proven that these two techniques, when applied to brittle materials, can successfully detect cracks and damages at the material's interior while providing consistent pre-failure indicators [5, 6].

AE is based on the detection and record of transient elastic waves which are produced when the stress field developed exceeds (either locally or globally) the material's critical limits resulting to damage. The sudden release of energy accompanying damage produces waves which propagate spherically outwards until they are captured by a number of acoustic sensors, properly mounted on the specimen's surface [7]. In the present experimental protocol, eight acoustic sensors were attached on the marble surface, as close as possible to the area where the acoustic signals were expected to be produced, permitting 3D detection (Fig. 5(a)).

On the other hand, the PSC technique is based on the detection of weak electrical signals produced during the formation and growth of micro-cracks inside rock-like materials [5, 6]. For the PSC recordings two electrical contacts were placed in the specimens. The first one was embedded in the cement paste before its curing while the second one was inserted in a short predrilled hole (of depth equal to 1cm) on the marble (Fig. 5(b), (c)). The main goal is the accurate recording of electrical signals produced on the marble-cement paste interface.

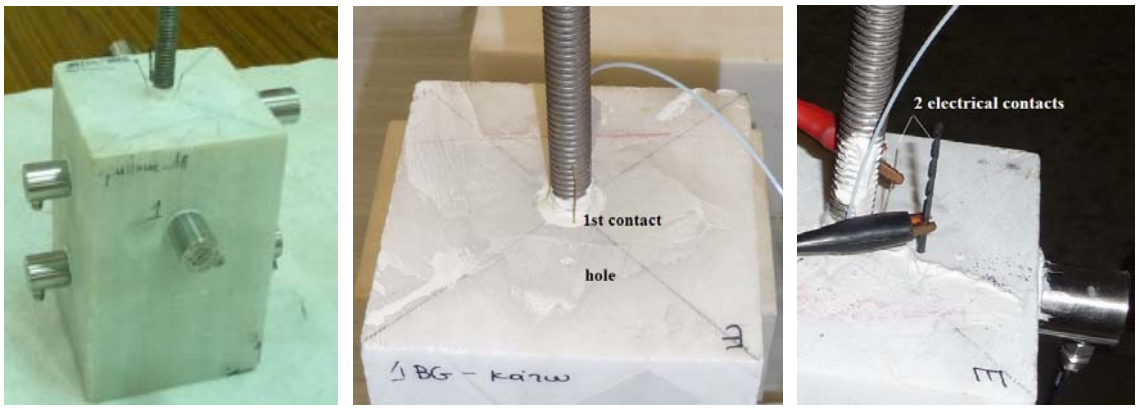

Figure 5: (a) The acoustic sensors on the marble surface (AE) (b), (c) The electrical contacts (PSC).

Observing macroscopically the fractured specimens, three main failure modes were distinguished, depending on the composition of the cementitious paste: pull-out of the titanium bar, fracture of the marble prism and failure (fracture or yield) of the titanium bar (Fig. 6 (a), (b), (c)). Taking into account the aim of the present study, attention is restricted from this point on to the tests for which the marble cube and titanium bar remained intact while the bar was pulled out.

Figure 6: (a) Pullout of the bar (b) Marble's fracture (c) Bar's failure.

2.3 Results

Typical results from experiments in which pure pull-out was observed are presented in Fig. 7(a), where the variation of the load is plotted versus the bar's axial strain. The differences observed, concerning the maximum load attained are significant and could be well attributed to uncontrollable parameters related to the inhomogeneity and anisotropy of Dionysos marble [8, 9], which dictate marble's response. On the contrary, the differences observed for the overall stiffness of the system (namely the slope of the load - axial strain curve) are rather negligible.

The pull-out phenomenon is typically described by the load-bar's displacement curve. Such a typical curve is shown in Fig.7b. It consists of an almost linear initial portion (until slightly before the maximum load) followed by a well distinguishable non-linear portion till the maximum load. A decreasing branch follows the peak force, the slope of which decreases gradually.

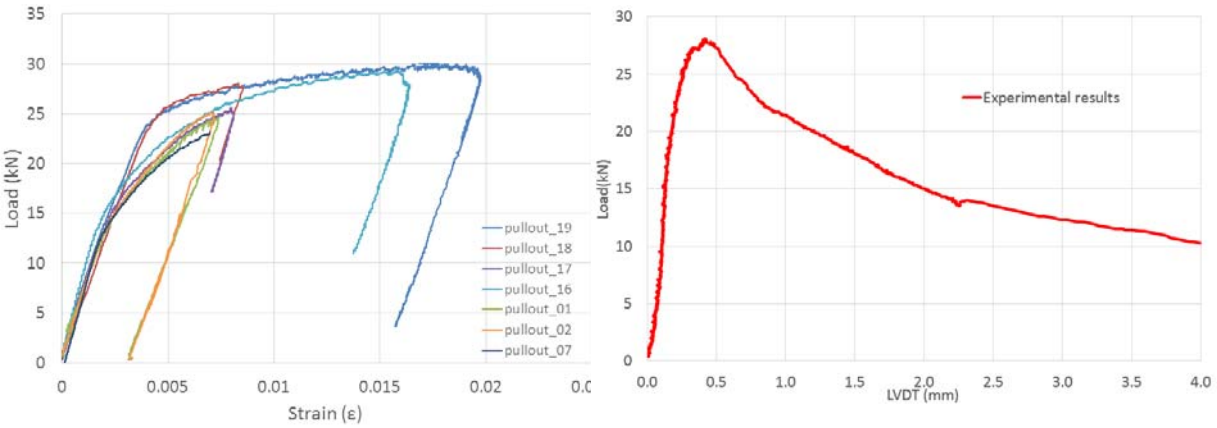

Figure 7: (a) Load vs bar's strain (b) load vs bar's displacement.

3 NUMERICAL ANALYSIS

The numerical model designed to simulate the pullout experiments was developed using the commercially available finite element software ABAQUS [14]. The specimens and the experimental procedure were simulated in every detail, to achieve optimum reproduction of the tests.

3.1 Model's geometry and materials' properties

The models consist of three bodies, i.e. the threaded titanium bar, the cement paste and the marble prism. The dimensions of the prism are the same as those of the tested specimens (Fig. 8 (a)). The geometrical characteristics of the threaded titanium bar are shown in Fig. 8 (b).

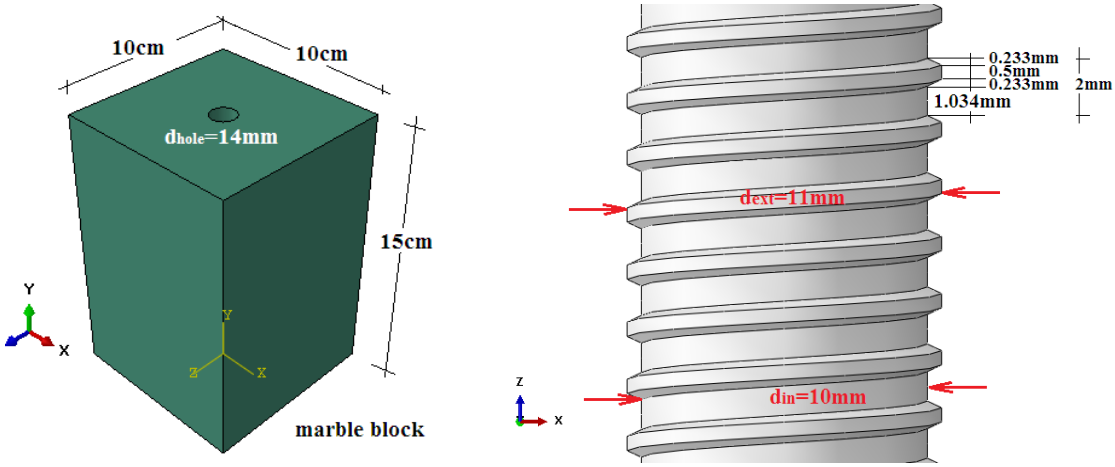

Figure 8: (a) Dimensions of the Marble block (b) Thread characteristics.

The second step of the numerical analysis is the identification of the mechanical properties of the three materials. For the Acropolis monuments, Dionysos marble is almost exclusively used since it is considered the material most compatible to the authentic building stone (i.e. Pentelic marble). It is characterized by two principal anisotropy directions (parallel to the material layers and normal to them) thus appearing to be transversely isotropic. Moreover, it is slightly non-linear and bimodular, i.e. its elastic modulus in compression exceeds slightly that in tension [8-10]. For the sake of simplicity, these features were here ignored and Dionysos marble was simulated as linearly elastic and isotropic. Its modulus of elasticity was set equal to E_m=84.5 GPa, its Poisson's ratio equal to v_m=0.26 and its density equal to 2.78 gr/cm^3.

Titanium was modeled also as linearly elastic (given that the loads to be imposed produce stresses well below its linearity limit) and isotropic material. Its modulus of elasticity was set equal to E_t=105 GPa, its Poisson's ratio equal to v_t= 0.32 and its density equal to 4.51 gr/cm^3.

Finally, with regard to the cementitious paste interposed between marble and titanium, it was considered, also, as linearly elastic and isotropic material with modulus of elasticity equal to E_p=15.4 GPa, Poisson's ratio equal to v_p=0.26 and density equal to 1.70 gr/cm^3 [11-13].

3.2 Contact properties

As already mentioned, previously reported experimental data, have definitely indicated that the most common failure mode in pullout tests was the debonding at the paste-marble interface [9, 10]. For this reason, the metallic bar in the model was considered perfectly bonded to the cementitious paste (obviously the threaded geometry of the bar is considered to play a significant role in this direction). Consequently, the overall behavior of the MTC complex is here dictated by the failure of the intermediate interface, i.e. that between marble and paste.

In ABAQUS practice, in case of bonded interfaces the thickness of which is negligibly small, the response of the cohesive layer is defined directly in terms of traction versus separation [10]. The available traction-separation model assumes an initially linear elastic behavior, which is followed by the initiation and evolution of damage. When the damage initiation criterion is met, the resultant behavior of the interface follows a damage evolution law. There are two alternative choices available for this law in the traction - seperation space, i.e. linearly or exponentialy decreasing. The respective curve is schematically shown in Fig. 9.

Concerning the initiation of damage the ABAQUS software provides four main criteria: The maximum nominal stress, the maximum nominal strain, the quadratic nominal stress and the quadratic strain [14]. Regardless of the criterion that is adopted in modeling, the results obtained are the same assuming of course that reasonable compatibility laws are applied for the transition between the various options.

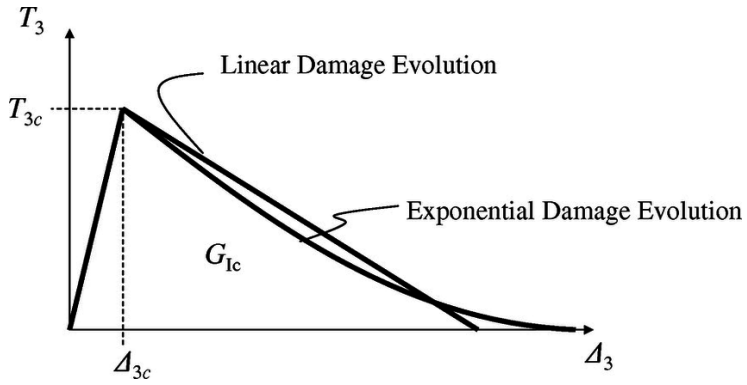

Figure 9: Schematical representation of traction-separation response [14].

4 THE NUMERICAL MODEL

4.1 Mesh density

In computational solutions, meshing is among the most significant parameters that can determine the reliability of the results. Improved mesh quality provides more accurate solutions. Unfortunately, the meshing quality is strongly related to another parameter that has to be considered, i.e. the CPU time or in other words how time-consuming the analysis is. It is generally accepted that finer meshing is related to increased computational time demands.

In this direction (and taking into account the increased number of parameters that will be investigated using the present model) the relation between the mesh quality and the CPU time was thoroughly considered. The validation of the model was achieved taking advantage of a typical experimental pull-out curve (Fig.7b). Models of different mesh densities are compared with reference to the CPU time. Four different models were constructed, for which tetrahedral elements were used for the mortar-bar complex and hexahedral elements for the marble body. The number of tetrahedral and hexahedral elements, the approximate ratio of their size and the respective CPU time for each model are recapitulated in Table 1. The mesh for the first testing case (model 01) is shown in Fig.10. The overall results of this step of the analysis are presented comparatively in Fig. 11, in juxtaposition to the respective experimental data.

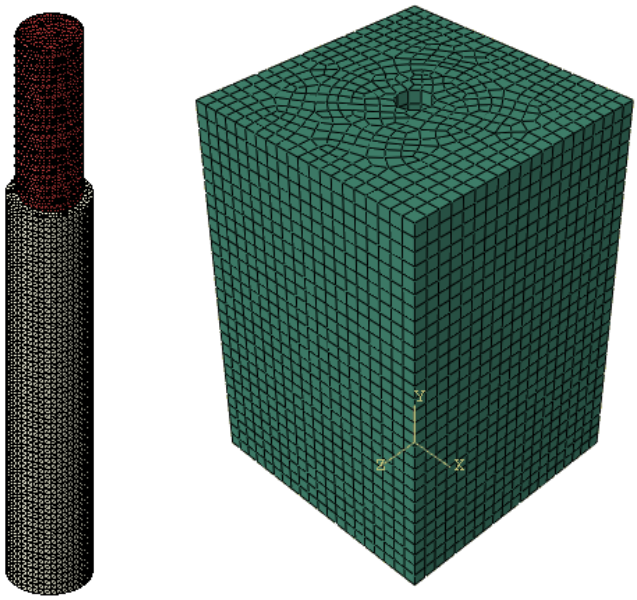

Figure 10: Mesh geometry of (a) bar-paste complex (b) marble block (model 01).

Title	CPU time (sec)	Number of tetrahedral elements	Number of hexahedral elements	Approximate size of tetrahedral /hexahedral element
Model 01	4878,8	152532	15150	1:5
Model 02	52853	352358	72350	~ 1:4
Model 03	65400	92620	93728	~ 1:2
Model 04	278673	42840	215625	1:1

Table 1: CPU time with the respective model's total number of elements.

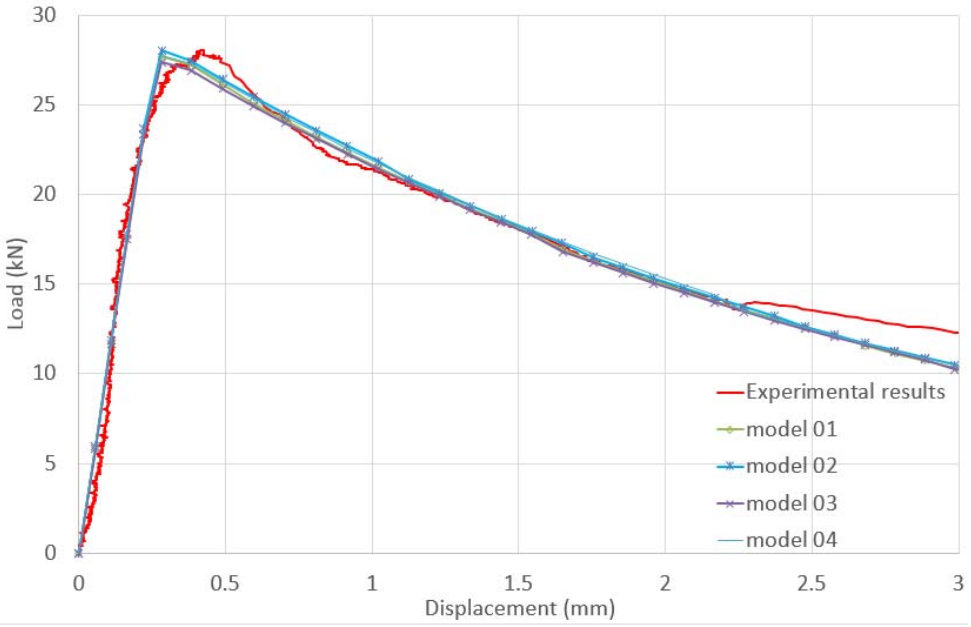

Figure 11: Load versus bar's displacement (experimental results/analyses of different mesh density).

It is definitely concluded from Fig.11 that all four numerically obtained curves are very close to each other. Moreover, their deviation from the experimental data is relatively small, despite the quite significant differences recorder for the respective CPU times (shown in Table 1).

4.2 Time increment analysis

In ABAQUS Standard, the overall convergence rate and the robustness of the progressive failure simulation of composite structures is significantly affected by the time increment of the analysis: Low time increment may give more precise results but it increases the CPU time.

For the model that was considered as the optimum one according to the results of Section 4.1 (i.e. model 01), three different time increments were considered in this step (Table2).

Title	CPU time (sec)	Time increment
Model_01	42584	0,001
Model_02	4878,8	0,01
Model_03	1508,8	0,1

Table 2: CPU time with the respective time increment.

The results of the analyses are given in Fig. 12. The larger time increment (blue curve), characterized by fewer integration points, results to deviations from the experimental data around the peak force, which may be proven critical. The medium (model_02-black curve) and fine time increments (model_01-yellow curve) provide identical curves but they differ significantly in their CPU time (Table 2). The model with finer time increments is almost 10 times more time-consuming compared to the one with medium time increments. Taking all these into account it can be concluded that the model with medium time increment is the optimum choice.

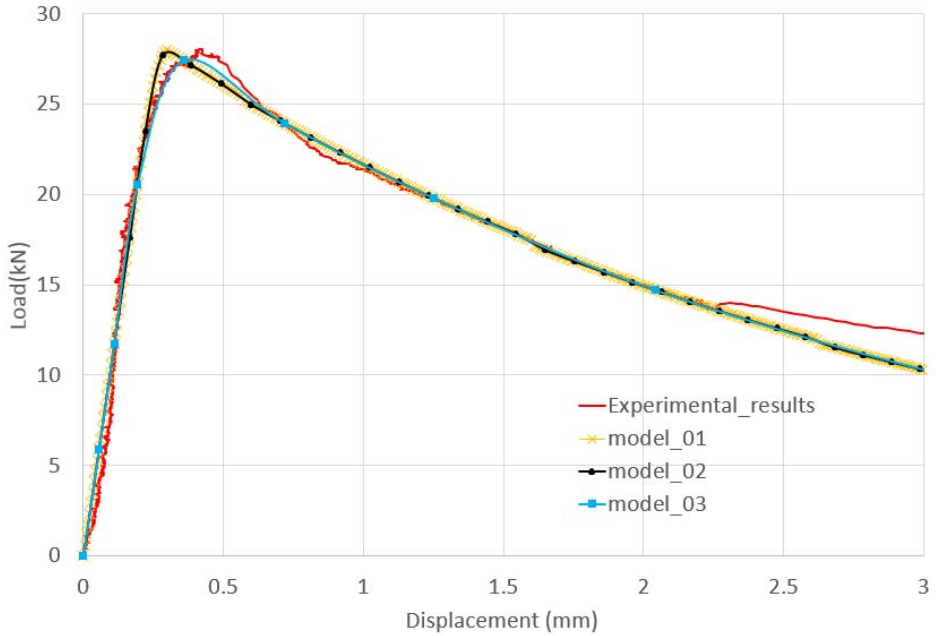

Figure 12: Load versus bar's displacement (experimental results/analyses of different time increment).

4.3 2D versus 3D models

In numerical simulations, it is important to achieve the required accuracy in the minimum possible computational time. The symmetry characterizing the specimens of the present experimental protocol permits the design of simplified numerical models, significantly decreasing the CPU time. In this direction, an axisymmetric model (with respect to the central symmetry axis of the configuration) was designed, as it is shown in Fig. 13. It is worth noticing that the computational time of the axisymmetric model is almost 10 times less than the computational time of the respective 3D one while the results seem to be well comparable (Fig. 14).

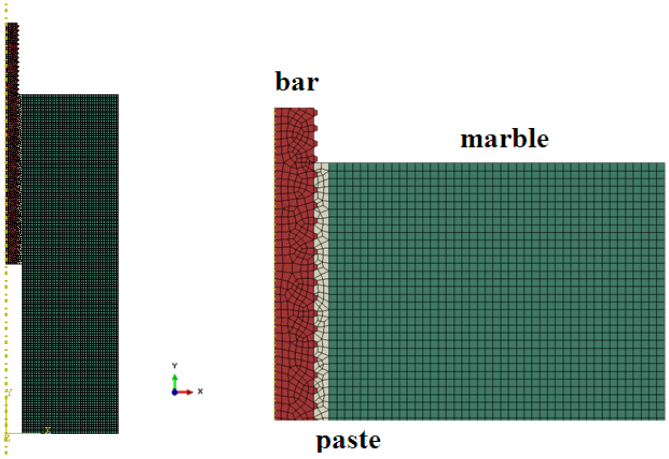

Figure 13: Axisymmetric model of pullout test

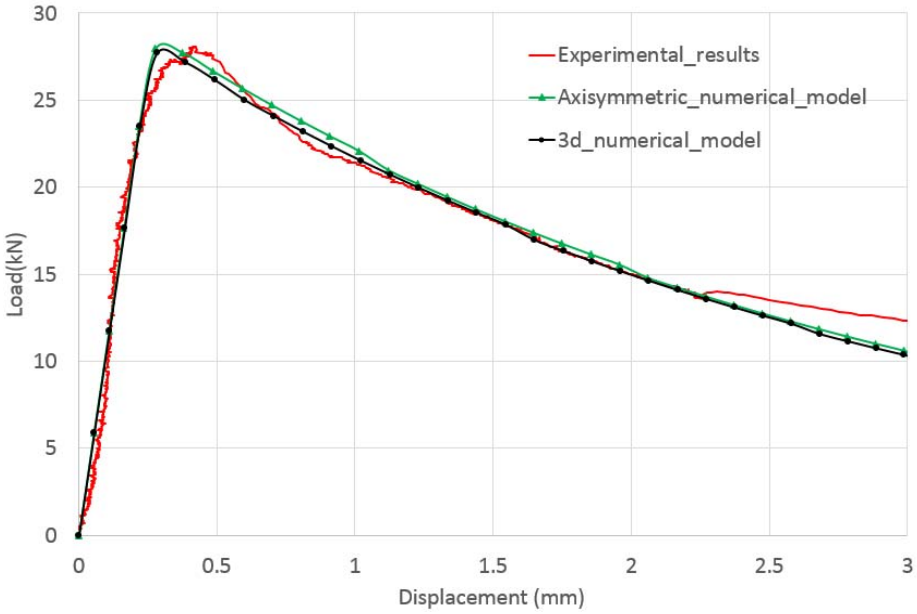

Figure 14: Load versus bar's displacement of axisymmetric and 3d pullout model.

5 DISCUSSION AND CONCLUSIONS

A finite element model was designed that will be used for the parametric study of the pull-out phenomenon observed in restored marble structural members. The model was calibrated according to the data gathered from a specially designed non-standardized experimental protocol. At this point the question could arise related to the accuracy and reliability of the experimental data themselves. In an attempt to eliminate such doubts the data of a typical test, as they were gathered by three different sensing techniques, are plotted in Fig. 15. More specifically the relative displacement of the bar with respect to the marble prism (as recorded by the respective LVDT) is plotted against the load level in conjunction to the cumulative electric load Q (as determined using the PSC technique) and the cumulative energy of the acoustic events (as determined by the AE technique). It is very intersting to observe that the data gathered by all three techniques are in excellent mutual qualitative agreement. In depth analysis of these data has proven that they are also in very good quantitative agreement [15], enhancing confidence to the reliability of the experimental results used to validate the numerical model.

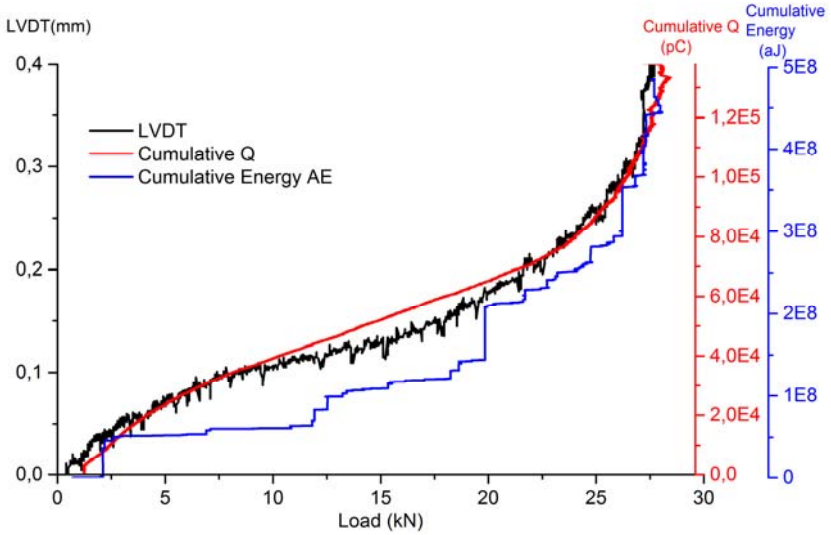

Figure 15: Comparative representation of the data gathered by the LVDT, the PSC- and AE-techniques.

The model designed was optimized in relation to two crucial aspects, i.e. meshing and time increment of the analysis. A satisfactory compomise between accurracy and CPU time consumption was achieved. Morever the model's effectiveness was assessed in case a simplified axisymmetric design is chosen against the "heavier" three dimensional version. It was concluded that the diffrences are rather negligible and, at least for this specific application, no reason exists to use three dimensional analysis.

Keywords: Masonry Infills, Out-Of-Plane Loads, Finite-Element Modelling, Discrete-Element Modelling, Non-Linear Analyses.

Abstract. *In this paper, the out-of-plane response of infill walls is investigated by means of non-linear monotonic (push-over) analyses through a combined finite and discrete modelling approach. The model accounts for material deformability, crack formation, sliding, separation and formation of new contacts. Masonry units are modelled as finite elements, and different material models are assumed for the masonry. Contact between masonry units, and between masonry and frame elements is modelled by means of interfaces, which permit tangential motion with frictional sliding. Frame elements are modelled by means of a linear-elastic material. The results of the numerical analyses are compared with those of experimental tests available in the literature. The advantages and disadvantages of the adopted modelling strategy are investigated.*

1 INTRODUCTION

Masonry walls are widely used as infills in steel and reinforced-concrete (RC) frame structures. The failure of infills, which may develop both in- and/or out-of-plane, may cause casualties and heavy socio-economic consequences.

Recent earthquakes have shown that the out-of-plane failure of infills can occur even for moderate intensity of the ground motion [1, 2, 3]. For this reason, the interest in the out-of-plane behaviour of infill walls has been growing in the last years. A number of experimental tests have been performed by different investigators to assess strength and ductility of infill masonry walls loaded in the out-of-plane direction [4]. Moreover, several analytical models have been developed for the assessment of the out-of-plane response of masonry infills [5]. Most of them are based on rigid body mechanisms [6], either with or without the description of the arching behaviour.

More complex modelling is performed when numerical solution methods are adopted. These approaches involve either a smeared-crack or a discrete-crack modelling. The former is usually adopted to model the global behaviour of a structural system, while the latter is used to model the actual interaction between adjacent elements. The discrete-crack modelling can realistically predict the structural response when the crack pattern follows the locations of mortar joints [7].

The finite Element (FE) method has been applied more extensively to predict the in-plane behaviour for infills with [8] or without [9] openings. Some numerical studies are performed through the software DIANA [9, 10]. ANSYS software has been used by several researchers as well [11]; Mohyeddin et al. [12] have developed a three-dimensional FE model of infilled RC frames at a micro-level, showing that the model can be employed to interpret the response of the infilled frame under in- or out-of-plane loading over a wide range of drifts, allowing a parametric/sensitivity analysis [13].

Two classes of models can be identified [14]: discrete-crack modelling, including unit and joint model, with detailed micro modelling, where the material properties for the different components are generally taken from experiments [13, 14]; smeared-crack models, either weak or strong, for which a Total Strain Cracking Model is used to represent the material behaviour of the masonry [10] or macro-modelling of the masonry based on concrete smeared cracking and damaged plastic material (Concrete Damaged Plasticity model in Abaqus) [15].

A FE model is used to evaluate the out-of-plane capacity of an infill wall surrounded by a RC frame [10] with 3D curved-shell elements for both frame (8-node) and interface between infill and frame (6-node); mortar and unit-mortar interface are smeared out in the continuum. For the compressive and tensile behaviour of masonry the concrete material in the FE software DIANA is used. Two models are considered, depending on the boundary conditions of the infill wall, the first one representing two-way arching action, whereas the second represents one-way action.

FE modelling has been used also for the analysis of retrofitted infill masonry under out-of-plane loads [16], with simplified micro-modelling, where units are represented by continuum elements, mortar joints by interface elements, and reinforcing bars by truss elements; a more simplified FE model with equivalent vertical bars have been studied as well, in order to evaluate the sensitivity to modelling parameters. In this case the presence of the retrofitting reduces the sensitivity to variations of the material constants, which is usually rather high.

In this paper, the out-of-plane response of infill walls is investigated by means of non-linear analyses through a combined finite and discrete modelling approach. The results of the numerical analyses are compared with those of experimental tests available in the literature.

2 MODELLING ASPECTS

In order to reproduce the main characteristics of the response of different specimens of infill walls tested in the out-of-plane direction, several models are implemented using the LS-DYNA software package [17], which is a finite-discrete element code capable of simulating three-dimensional problems. This code is used here, within an ANSYS environment, to numerically reproduce the results of experimental tests.

A combined finite and discrete modelling approach is used. Units are modelled as linear elastic 8-node solid elements with a single integration point. The major disadvantage of one-point integration is the need to control the zero-energy modes that arise, called hourglassing modes, which might enlarge and destroy the solution. A Flanagan-Belytschko stiffness-type stabilisation is used here [18].

Mortar is not explicitly considered in the model; instead contact interfaces are used. Contact interfaces allow the transmission of both compressive and tensile forces, moreover a tangential motion with friction sliding is permitted. Frictional sliding occurs when the frictional stress limit is reached. In tension, the contact interface failure criteria is based on the normal tensile stress limit. In compression, to avoid the penetration between nodes and contact surface, the standard penalty method is used. The method consists in placing normal springs between all penetrating nodes and the contact surface. The interface stiffness depends on the stiffness of the materials that are in contact and on a scale factor, named penalty factor.

With the aim of comparison, FE models resorting to a smeared-crack approach are also implemented. In these cases, the contact surfaces are used only at the interface between the masonry panel and the surrounding structure.

Vertical loads are first applied to the system. Static or quasi-static processes can be simulated resorting to dynamic relaxation or to mass damping to eliminate dynamic oscillations. Preliminary analysis have shown that, for the cases at hand, the two methods give equivalent results. To avoid high frequency oscillations during the application of the gravity loads, these are applied slowly from zero to gravity acceleration. Afterward, horizontal displacements are applied in the out-of-plane direction.

2.1 Material modelling

Different types of material have been initially examined for modelling units: linear elastic (MAT_001), Winfrith smeared-crack concrete model (MAT_084/085), smooth-surface cap model (MAT_159), damage-plastic concrete model (MAT_273).

The linear elastic material (MAT_001) is particularly suitable when no damage is expected in the units, both in tension and compression, i.e. when the cracks pattern follows the joints. The use of this material requires the definition of a very limited number of parameters and allows to reduce the computational effort. However, given that the out of plane failure of infills may occur due to excessive compression in the units, a non linear material is more adequate to represent the actual behaviour.

The Winfrith material model (MAT_084-085) is a smeared-crack model developed in [19, 20]. The mechanical parameters that have to be defined are initial tangent modulus, Poisson's ratio, uniaxial compressive and tensile strengths. Moreover, a volumetric strain versus volumetric pressure curve is required. If the curve is omitted, a default pressure versus volumetric strain curve is automatically used. The Winfrith material includes also the option of considering reinforcement in a smeared fashion.

Material type 159 (MAT_159), which is available for solid elements, is a smooth-surface cap model, i.e. with a smooth intersection between the shear surface and the hardening cap [21]. This material has been created to reproduce accurately the response of concrete subject

to impact loads. Many parameters, such as moduli, strengths, hardening, softening, and rate effects parameters, must be supplied, otherwise default values are provided. Default parameters are fit for unconfined compression strengths between about 20 and 58 MPa and aggregate sizes between 8 and 32 mm and, therefore, are not suitable for the modelling of masonry. Given the difficulties in calibrating the parameters (more than thirty) with the experimental tests available for masonry materials, this material type was not used.

The damage-plastic concrete model (MAT_273) is based on the studies in [22][23], and is aimed to simulate the failure of concrete structures subjected to dynamic loads. The model is based on effective stress plasticity, with damage based on both plastic and elastic strain measures. The definition of the model requires a large number of parameters, but several of them are directly related to one another by explicit expressions. Other parameters can be determined from certain assumptions, or taken by their recommended default values [22], so that a limited number of material properties must be specified.

With the aim of highlighting the differences between these materials, a simple two-blocks model has been tested under compression (Figure 1). Input data are reported in Table 1. As already noted, values of the compression strength lower than 20 MPa are incompatible with the material MAT_159. In this case the analysis runs out immediately. For the other material types, the vertical resultant force and the minimum principal stress are reported in Figure 2. The use of MAT_273 leads to a larger stiffness of the model and the analysis stops before the attainment of the material compressive strength, hence this material is not used in the following analyses. The Elastic (MAT_001) and Winfrith (MAT_084-085) materials give the same results in the elastic range, the latter presents a stiffness reduction when the displacements increase.

Material	RO (kg/m^3)	E MPa	ν	A_s mm	f_c MPa	f_t MPa
MAT_001	2200	2.8E+3	0.2	-	-	-
MAT_084-085	2200	2.8E+3	0.2	1	2.84	-
MAT_159	2200	-	-	1	2.84	5.69E-1
MAT_273*	2200	2.8E+3	0.2	-	2.84	5.69E-1

RO = density; E = Elastic modulus; ν = Poisson's ratio; and A_s = Aggregate size; f_c = compressive strength; f_t = tensile strength.

3 CASE STUDY

Different models have been selected and analysed, in order to replicate the tests by Modena and da Porto [24]. This experimental investigation concerns nine hollow-block masonry panels (976×2520×291 mm^3, $b \times h \times t$) loaded at mid-height by means of a horizontal rigid beam. At the top and the bottom the panels are mortared to rigid RC supports, whereas vertical edges are not restrained. Six specimens were constructed with horizontal-hole blocks, the other three specimens were constructed with vertical-hole blocks, thus achieving the masonry compressive strength necessary for arching behaviour. Consequently, out-of-plane strength of vertical-hole blockwork is almost thrice that of horizontal-hole one and is noticeably underestimated by available equations [5]. One of the vertical-hole specimens, FVC1, is considered in the following analyses.

In the numerical simulations have been used both the Elastic and the Winfrith materials, whose main mechanical characteristics are reported in Table 2. For the finite-discrete models, the mechanical characteristics of the units have been adopted, the tensile strength has been increased so that the tensile failure occurs in the contact interfaces. For the smeared-crack model, the masonry elastic modulus has been used and tensile strength is assumed equal to 20% of compressive strength. As far as the contact interfaces is concerned, the parameters that affect the global response are: the normal failure stress (in tension), the frictional stress limit, the coefficient of friction and the scale factor on default penalty stiffness (penalty factor). As observed in Section 2, the penalty factor is used to calculate the interface stiffness. For this parameter, a default value of 0.1 is recommended in the case of contact between similarly refined meshes of comparably stiff materials. However, according to [7] a value of 0.05 is expected to give reasonable results for masonry walls. To investigate the influence of this factor, three values of the penalty factor are used herein, i.e. 0.02, 0.05, and 0.10. It is noted that this values are the product of two input parameters: SFS (or SFM), which is the scale factor included in the contact card, and SLSFAC, which is the scale factor for sliding interface penalties included in the control card.

The model geometry and the adopted mesh are shown in Figure 3. With the aim of capturing the stress field across the wall thickness, four finite elements are present in the transversal direction. Top and bottom supports are modelled as rigid bodies, so as the loading central beam. Prescribed horizontal displacements are assigned monotonically to the rigid beam up to 10 mm.

	Units properties					Contact properties		
Model ID	Material	E	ν	f_c	f_t	NFLS	SFLS	Penalty factor
		MPa		MPa	MPa	MPa	MPa	
M01	Elastic	20.83E+3	0.15	-	-	0.78	0.78	0.02
M02	Elastic	20.83E+3	0.15	-	-	0.78	0.78	0.05
M03	Elastic	20.83E+3	0.15	-	-	0.78	0.78	0.10
M04	Winfrith	20.83E+3	0.15	20.83	5.22	0.78	0.78	0.02
M05	Winfrith	20.83E+3	0.15	20.83	5.22	0.78	0.78	0.05
M06	Winfrith	20.83E+3	0.15	20.83	5.22	0.78	0.78	0.10
M07(1)	Winfrith	5.22E+3	0.15	5.22	1.04	-	-	-
M08(1)	Winfrith	5.22E+3	0.15	5.22	1.04	-	-	-

E = Elastic Modulus; ν = Poisson's ratio; f_c = masonry compressive strength; f_t = masonry tensile strength; NFLS = contact normal failure stress; SFLS = contact frictional stress limit.

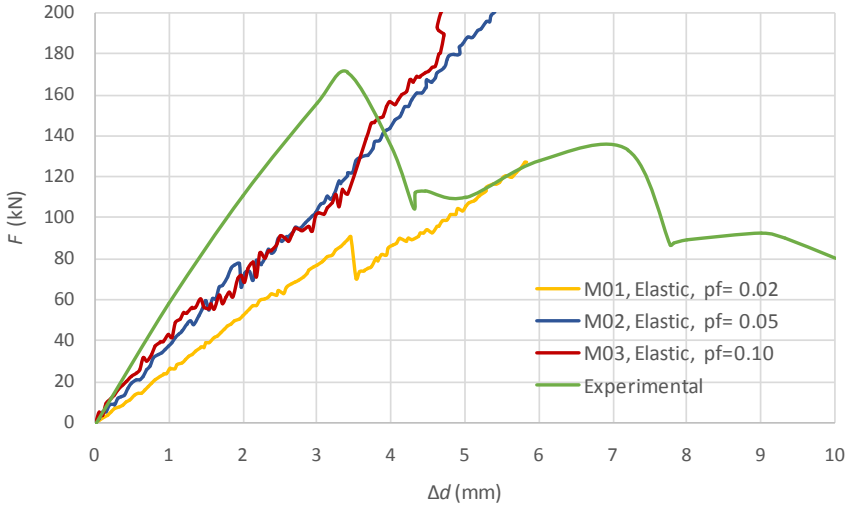
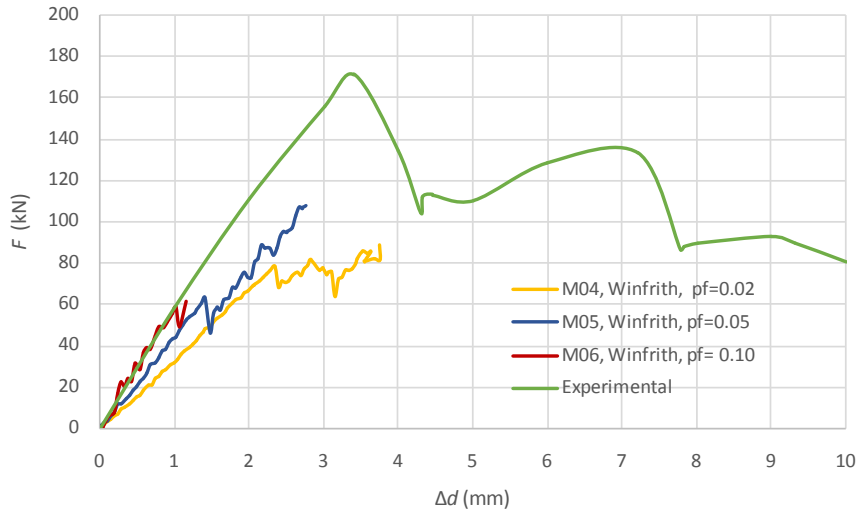
3.1 Results

Horizontal force resultant versus prescribed displacements are reported in Figure 4 for the numerical models and for the specimen. The models with the Elastic material (M01, M02 and M03) are less stiff compared to the experimental results. A moderate stiffness increase can be obtained increasing the compressive stiffness of the contact interface, i.e. with an increase of the penalty factor (Figure 4a). However, an increase of the penalty factor leads to deformations that are inconsistent with the experimental ones. The deformed shape and the principal compression stress for models M02 and M03 are reported in Figure 5. The model M02 present an horizontal crack at mid-height, in agreement with experimental results, while, in the model M03, a sliding occurs at the second course. As shown in Figure 6, the sliding starts abruptly at about 52 s, when the displacement at mid-height of the wall is about 4.5 mm.

(a)



(b)



(c)

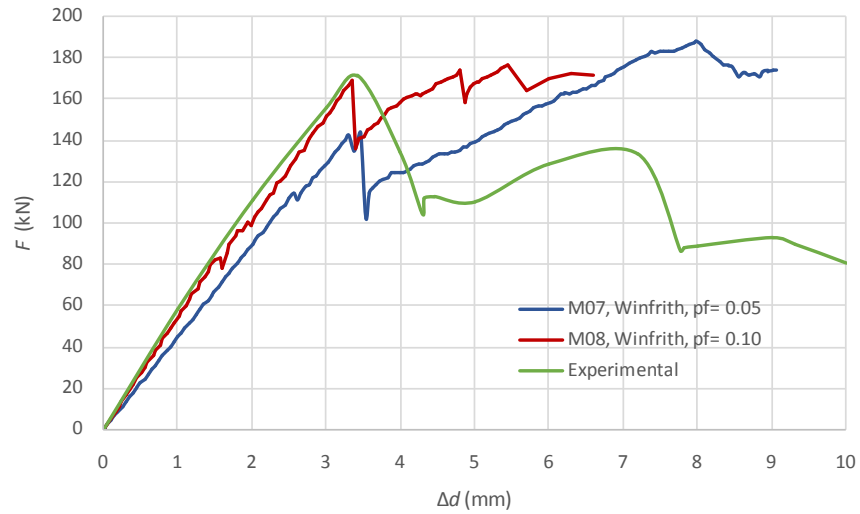


Figure 4: Horizontal force resultant versus prescribed mid-height displacements, experimental and numerical models: a) discrete-crack Elastic material; b) discrete-crack Winfrith material; c) smeared-crack Winfrith material.

In the case of the Winfrith material the increase of the penalty factor produces local stress increments and the earlier termination of the analysis. In fact, models M04, M05 and M06 do not terminate the analysis (Figure 4b) due to sudden increment of the principal compression stress, as shown in Figure 7. When the Winfrith material is used in a smeared-crack approach to model the blockwork, but interfaces are still present between masonry and RC frame, these local phenomena are avoided and the global response represents better the actual behaviour (Figure 4c). The stress distribution along the height of the walls is consistent with an arching behaviour (Figure 5c).

As observed, the finite-discrete models with higher penalty factors are not able to provide the maximum strength when the Winfrith material is adopted, whereas the smeared-crack models approximate better the experimental curve.

4 CONCLUSIONS

In this paper the out-of-plane response of infill masonry panels is modelled through a discrete-finite element approach. Interfaces are present between masonry units, as well as between blockwork and reinforced-concrete frame. For the sake of comparison a smeared-crack approach has been also used to model masonry.

It is concluded that, when using a finite-discrete method, the stiffness of the contact interfaces is one of the most important parameters affecting the solution, because modifies the global stiffness of the model, if an elastic material is used for the blocks. When a non-linear material is used, in addition to the modification of the model stiffness, a local increment of stress occurs, leading to the earlier termination of the analysis. These shortcomings are avoided in a smeared-crack approach, reproducing better the experimental results, while still resorting to contact surfaces at the interface between masonry panel and surrounding structure.

Abstract. *Palazzo La Sapienza, historical seat of the University of Pisa since the XVI century, represents one of the most important examples of the Tuscany cultural heritage, nowadays not in use due to several problems related to maintenance and structural deficiencies. The building, in its current form, is the result of several modifications, enlargements, elevations, connection with adjacent parts, resulting finally more similar to a "structural aggregate" - made up of single units connected together without specific scheme and organization - than to a single unitary building. After the earthquake of May 2012, the Palace was temporarily closed in relation to the ordinance issued by the Major's Office and then subjected to wide in situ investigations aiming at analyzing in a very detailed manner all the criticisms related to structural, nonstructural, geotechnical and maintenance problems; the deep in situ survey campaigns allowed to reach a very deep knowledge of the building, of its progressive morphological evolution and of its actual condition, including problems not directly related to the structural condition but, as an example, to the instability and heterogeneity of the ground soil and of the foundation system. All the information so obtained allowed the execution of static and seismic vulnerability assessment – according to the actual prescriptions of Italian Standard for Constructions (D.M. 14/01/2008) – through the elaboration of complex global and local models and the final elaboration of an executive retrofit design comprehensive of local interventions on significant structural elements or sub-portions of the building. In the present paper, after a short description of the knowledge analysis of the building and of its safety verification, the retrofit executed to obtain a satisfying level of safety is presented.*

1 INTRODUCTION

Recent seismic events (i.e., Umbria - Marche 1997, Aquila 2009, Emilia-Romagna 2012) evidenced the high vulnerability of existing masonry cultural heritage and the need to define operational strategies for modifying, improving or locally retrofitting structures (or portions thereof) without altering their original characteristics and ensuring a sufficient margin of structural safety. Such buildings, during the centuries, underwent changes, expansions and reconstructions transforming them from 'single buildings' into 'structural aggregates', often in a significant state of decay caused by insufficient maintenance, earthquakes, collapses, cracking scenarios and so on, consequently evidencing the need to perform extensive static and seismic safety checks to plan suitable retrofit operations.

Several methodologies exist for the execution of seismic vulnerability analysis of monumental buildings. Some of such methods [1, 2] classify the buildings basing on a wide-scale damage analysis together with macroseismic intensity maps, defining vulnerability curves and identifying those structures for which retrofit shall be immediately organized.

Current standards for constructions [3, 4, 5] foresees the determination of the "*Knowledge Level*" (KL) – achieved through historical analysis, structural and geometrical surveys, geological and geotechnical investigations and mechanical characterization of materials – intended as the degree of uncertainty to be adopted when the safety checks and retrofit are performed.

Several applications aiming at evaluating the seismic behaviour of monumental buildings can be found in the current scientific literature, adopting detailed three-dimensional finite-element models elaborated basing on the results of laser-scanner surveys and in-situ deep investigations [6, 7] analyzing the local behaviour of significant portions of the buildings accounting for the damage scenario revealed [8] or proposing a displacement-based approach considering the ability of historical buildings to sustain earthquakes as long as they have sufficient capacity to move without collapse, so determining different limit states [9, 10, 11]. The problems regarding the numerically modelling of complex structures were widely discussed by [12], finally suggesting the execution of experimental dynamic analyses and investigations of both the whole aggregate and of portions thereof to characterize the structural behaviour of existing buildings.

D.M. 14.01.2008 [3] and the Guidelines of the Ministry for Cultural Heritage [13] prescribe global checks and evaluations of the local collapse mechanisms of significant structural units, identified through the mapping of the critical points from the surveys and the results of the global checks. The assessment of the structural safety of the building shall be executed with reference to different levels of analysis, ranging from large-scale evaluations to the local macro-element models representing independent portions of the whole building. The assessment of existing complex structural aggregates cannot then follow the usual approaches included in modern standards: complex models and cumbersome numerical analyses are not always able to represent masonry structural aggregates; many of the structural and maintenance diseases can be fully understood only through detailed surveys and the correlation between the morphological evolution of the building, its modifications throughout the centuries and its current condition.

A proper methodology, accounting for its intrinsic structural, architectural, geotechnical and functional complexities and their mutual interrelationships, shall be adopted for the safety assessment of a structural aggregate. A deep, extensive and multi-disciplinary approach, combining critical historical studies of the building's evolution, morphological/structural surveys, geotechnical investigations, mechanical characterization of materials and structural/geotechnical monitoring is necessary.

The present study deals with the assessment of structural safety and seismic vulnerability of the "Palazzo La Sapienza", in Pisa, Italy. The building, site of the University since the 14th century, is currently not in use due to the pending ordinance by the Mayor's Office of May 2012 because of ensuing surveys conducted by Pisa Fire Department. The Palace is a "structural aggregate" made up of interconnected units joined together during more than eight centuries [14, 15, 16]. The building's peculiarity and its importance to the urban setting was a unique occasion for the development and adoption of the multidisciplinary approach above mentioned. Accurate critical historical studies, including reconstruction of the building's evolution over time and detailed architectural surveys through both direct and indirect techniques, allowed identifying the structural units making up the aggregate. Each unit was subjected to accurate studies aiming at determining its structural system, the constituent materials and any critical detail revealed by geometrical and historical investigations, with the following organization of suitable monitoring systems able to identify causes of local (substructures, structural elements and units) and global (structural aggregate) problems. The proper combination of local and global numerical models, used and applied critically because of building complexity, allowed an accurate interpretation of the structural problems recognized by aforementioned multidisciplinary analysis, becoming the real "core" of the assessment procedure (rather than cumbersome, complex and often not representative global, linear and nonlinear, numerical analyses) and of the retrofit interventions, planned to preserve the original nature of the Palace giving a sufficient margin of safety.

2 STRUCTURAL ASSESSMENT

2.1 General presentation of the building

The building presents a trapezoidal plan (about 80.0 m x 53.7 m) with three floors above the ground and a gable roof accessible only for maintenance. The central courtyard, surrounded by a ground-level colonnade and a first-floor arcade running roughly parallel to the ground floor sides, has maximum dimensions of 35.5 m by 21.2 m. Due to the presence of different types vaulted surfaces and storey slabs, the height of the ground floor varies between 4.30 m and 5.50 m; similar situations can be found at the first and second floors, with maximum heights respectively equal to 5.60 m and 5.20 m.

The ground floor of the building houses staff rooms, university classrooms, university department offices and the historical Aula Magna. The 1st floor, besides department offices and the double volume of the Aula Magna Nuova, houses the University Library, covering about two sides of the building (along Piazza Dante square and Vicolo dell'Ulivo at 1st floor and Via della Sapienza and Vicolo dell'Ulivo at the 2nd floor), with mezzanines and loft structures to hold the books. Figure 1 shows the plan of all floors with indication of the use destinations foreseen just before the closure of the Palace.

2.2 Analysis of the state of art of the Palace

The analysis of the morphological evolution of the Palace [17] enabled to identify a series of critical structural issues, due to the modifications, heightening, enlargements and loading changes made over the centuries, currently evidenced by the widespread cracking scenario visible in various portions of the building, to be analyzed based on in-depth knowledge of the structure. The structural complexity of the building was confirmed through the extensive campaign of in situ studies, designed on the base of the results of the historical/evolutionary analysis and aiming to reconstruct the current structural condition of the building.

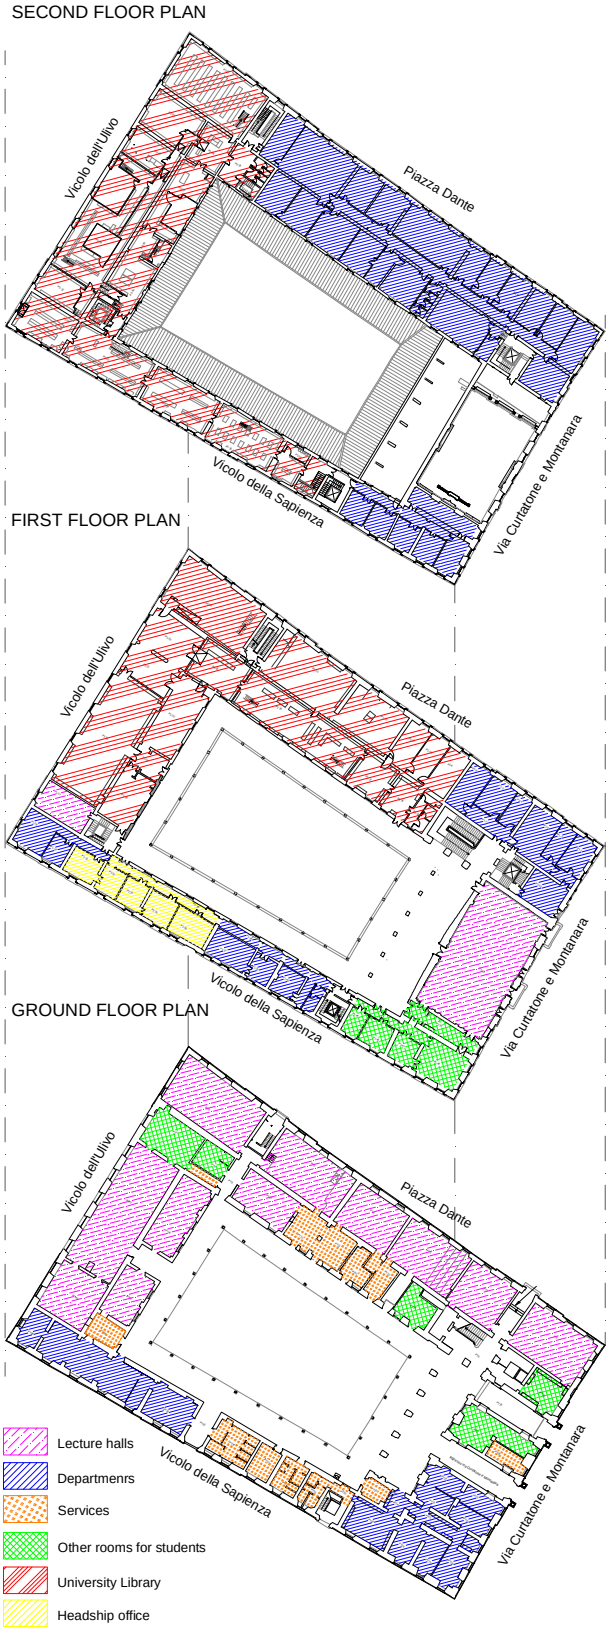

Figure 1: Plan overview of the different levels of the building and use destinations for the different rooms.

The masonry typologies of vertical walls were determined by removing the plaster on 50x50 cm portions with following endoscopic examination to check the presence of cavities or adjacent facings of different thickness and type. Figure 2 shows the periods of realization of vertical walls of the ground floor and the corresponding variability of revealed masonry typologies: six different patterns and the absence of suitable connections between perpendicular walls were determined.

Different types of horizontal structures are present in the building: the ground floor (Figure 3) shows cross or cloister vaults with solid-brick masonry, mainly located in correspondence of the ancient and not modified areas of the Palace – such as in the rooms around the internal courtyard parallel to Piazza Dante and Via dell'Ulivo. The double-height Aula Magna is topped by a masonry/r.c. vault. Floor slabs made of steel and brick blocks in single or double bonds - mainly located in correspondence of Piazza Dante at the ground floor and, in general, at 1st and 2nd floor, portions of the building that suffered for progressive modifications, enlargements and transformation due to use requirements – were also deeply surveyed to obtain information regarding structural profiles and weight of the upper filling layers.

The roofing structure, consisting of trusses of different types and materials is the result of the modifications undergone by the building over the years. On the Piazza Dante side, steel Polonceau trusses (similar to those over the double-height of the new Aula Magna, dated back to the early 20th century) are located; the other sides of the building present wooden trusses of different sizes and shapes, with various degrees of deterioration due to the poor maintenance, bad connections among elements, presence of small solid-brick walls to support the bearing elements, accumulations of debris etc., resulting from operations aiming at compensating for local deficiencies but losing sight of the building and its overall structure.

The cracking scenario present in several portions of the building (with different concentration and entity) is the result of the modifications undergone by the Palace during the centuries, with increasing acting load due to the library, to the activities developed inside the building and to the differential subsidence related to the heterogeneity of soil and foundation structure (Figure 3). The progressive growth of the cracks, especially in proximity of the separations of the structural units, is still quite evident in the building's vertical and horizontal surfaces: as an example, a wide cracking scenario was revealed in the corner between Via Curtatone e Montanara and Via della Sapienza, born by the incorporation of ancient tower houses into the current structure, and in correspondence of the vaulted surfaces of colonnade and internal arcade, characterized by the presence of different foundation settlements and by structural problems yet identified during the 18th and 19th centuries (Figure 3). Two monitoring systems (one periodic with fixed steel reference gauges and one continuous with electronic transducers) were set up in order to determine the possible evolution of the ongoing subsidence and damages (Figure 3). Analysis of the monitoring results enabled the identification of differential displacements, highlighting problems and evolution of structural cracking mainly in correspondence of the vaults of the ground floor colonnade and 1st floor arcade.

The inhomogeneous and inadequacy of the foundation structure to sustain the increasing loads due to the enlargements of the building in relation to the hosted activities was evident by the early 1900s. A deep in situ investigation of foundations was executed through micro-core samplings at different angles in the proximity of the masonry walls, at locations planned according to the evolutionary reconstruction of the building: different types of foundations (for both size and depth) were determined (Figure 3). The investigations performed in correspondence to the interior colonnade revealed the absence of connections between single columns, with an isolated square footing placed at -1.90 m from ground level, below the foundation of the portico pillars, laid at -1.75 m.

Figure 2: Hypothesis of the evolutive development of the building and plan of ground floor with indications of the various types of masonry.

Figure 3: Distribution of the floor slabs and types on the building's ground floor, Foundation plan, different typologies evidenced and ground floor plan with indication of monitoring points.

The foundation of the portico interior walls reaches different depths (between -1.0 m and -1.5 m), with width varying between 1.50 and 2.40 m. The two investigations performed along Vicolo dell'Ulivo provided similar results, with foundation depths of 2.75 and 2.10 m, and

widths of 1.75 and 1.60 m, respectively. The Piazza Dante side foundation reaches a depth of about -1.50 m below with a width of 0.90 m.

Deep investigations were executed to determine the geotechnical parameters and properties characterizing the foundation soil. Several experimental tests, including continuous core drillings, static penetration tests, tests with seismic dilatometer and dynamic penetration tests were executed. The obtained information allowed determining the local seismic response spectrum: a preliminary one-dimensional analysis under free-field conditions was performed. The procedure used for the local response seismic analysis is deeply presented in [15].

3 DISAGGREGATION AND ANALYSIS OF STRUCTURAL UNITS

3.1 Recognition of structural units

Critical issues of the structural aggregate were identified with reference to the single structural units recognized as constitutive parts of the building. The Palace was considered as composed by a suitable number of units connected by horizontal structures (foundations, floors and vaults, roof) influencing the mutual interactions among portions, preventing or activating local mechanisms. Structural units were identified in relation to the morphological/structural evolution of the Palace [17], to the modifications undergone during the centuries, to the presence/absence of connections among vertical and horizontal elements and to the interpretation of the cracking scenario. The behaviour of such units was investigated firstly separately and then the framework of the aggregate itself.

A diffused lack of connection between masonry walls was evidenced (Figure 4a) and different masonry typologies were revealed even in the same element: Figure 4b and Figure 4c, for example, show the presence of masonry arches of ancient openings nowadays closed due to the modified functional needs. The heterogeneity of masonry walls is higher at the ground and first floors (i.e. corner Via Curtatone e Montanara / Via della Sapienza, Figure 2) respect to the second level, realized at the beginning of the 19th century.

Horizontal floors and roofing systems can allow the connection among masonry walls, preventing the activation of local mechanisms; the horizontal systems of Palazzo La Sapienza are characterized by the presence of vaulted surfaces (mainly at the ground floor where no significant changes took place) and more recent floors with steel profiles (Figure 3). If vaulted structures can constitute a rather significant restraint for vertical structural elements, horizontal steel slabs cannot be considered a “rigid” diaphragm. A considerable geometric heterogeneity of foundations, influencing the mechanical response of the building and its bearing capacity in relation to the variable stiffness of the soil, was also evidenced.

Such more or less rigid systems connect several different structural units resulting from modifications executed during the centuries; according to the results of structural/architectural/geotechnical surveys, the following systems can be identified as “independent structural units inside the aggregate”, as simply summarized in Figure 5:

1. Corner between Via Curtatone e Montanara and Via della Sapienza.
2. Open gallery and arcade at the ground floor and colonnade at the first floor.
3. Aula Magna and adjacent rooms at ground floor.
4. Double volume of the Aula Magna Nuova at the first/second floor.
5. Portion of the building facing Piazza Dante.
6. Portion parallel to Piazza Dante facing the internal courtyard (ground and first floors).
7. Second floor of the Palace.

1. *Corner between Via Curtatone e Montanara and Via della Sapienza*. As visible from Figure 2, pillars characterized by the presence of full bricks and squared stones demonstrate the pre-existence of ancient tower houses incorporated and connected to adjacent masonry structures during the centuries. The discontinuity and heterogeneity of masonry belonging to different constructive typologies, realized in different periods and not connected to one another yielded, during the years, to the development and to the progressive spreading of a diffused cracking scenario visible both in vertical elements and in horizontal structures, allowing the clear identification of this structural unit.

2. *Open gallery and arcade at the ground floor and colonnade at the first floor*. The internal arcade and the open gallery facing the entrance along Via Curtatone e Montanara at ground floor are characterized by the presence of vaulted cross surfaces with different geometries and heights. The damages present in correspondence of the extrados of the vaults are the result of relative differential subsidence of foundations characterized by different width and depth (Figure 3), already demonstrated by past damages [17]. The absence of horizontal connection between the pillars of the internal arcade make the columns behave "separately" from one another, with relative displacements and rotations. Relative displacements between the wooden roof of the colonnade and the masonry walls are also clearly visible.

3. *Aula Magna and adjacent rooms at ground floor*. The portion of the building at the ground floor facing Via dell'Ulivo houses the historical Aula Magna and additional rooms once used for teaching activities. The Aula Magna and the adjacent room, actually characterized by the presence of a partition wall, present the same vaulted surface on which the masonry wall at the first floor directly loads [17]. The two teaching rooms facing the courtyard are the result of the closure of the original lodge that, on the western part of the Palace, exactly reproduced the opposite situation of the arcade, as justified by ancient plans and through the analysis of the cracking scenario and from the observation of the masonry pillars of the original colonnade (Figure 2).

4. *Double volume of the Aula Magna Nuova at the first/second floor*. The double volume of the Aula Magna Nuova, generated at the end of the 19th century in relation to the modifications of the building necessary to overcome the new use requirements, has an internal open space not provided by transversal retaining walls (demolished in 1905) and characterized by the lack of horizontal restraints between the two opposite facades. The roofing system presents brick truss with r.c. elements and masonry lightening blocks (thickness 3.0 cm) not able to constitute a rigid diaphragm.

5. Portion of the building facing Piazza Dante. The block constituted by the rooms facing Piazza Dante can be considered a separate structural unit, generated in a more recent period [17], modified at the beginning of the 20th century and clearly distinguishable from the rest of the building due to the presence of horizontal steel storey slabs and of masonry walls not connected to the pre-existences. This situation is clearly visible both at the ground and the first floor.

6. Portion parallel to Piazza Dante facing the internal courtyard. The architectural and structural surveys of the building evidenced the absence of perpendicular walls in correspondence of the first floor of the building in the portion facing the internal courtyard and parallel to Piazza Dante: the increasing need of place for the library and the new activities developed in the building leaded to the demolition of the walls perpendicular to the internal main façade, generating the activation of overturning mechanisms due to the absence of transversal restraints.

7. *Second floor of the Palace*. The 2nd floor of the building, according to the morphological and structural analyses of the Palace, can be considered a "separate" structural unit [17], characterized by a more recent edification and a more homogeneity for what concerns materials, masonry organization and floor typologies.

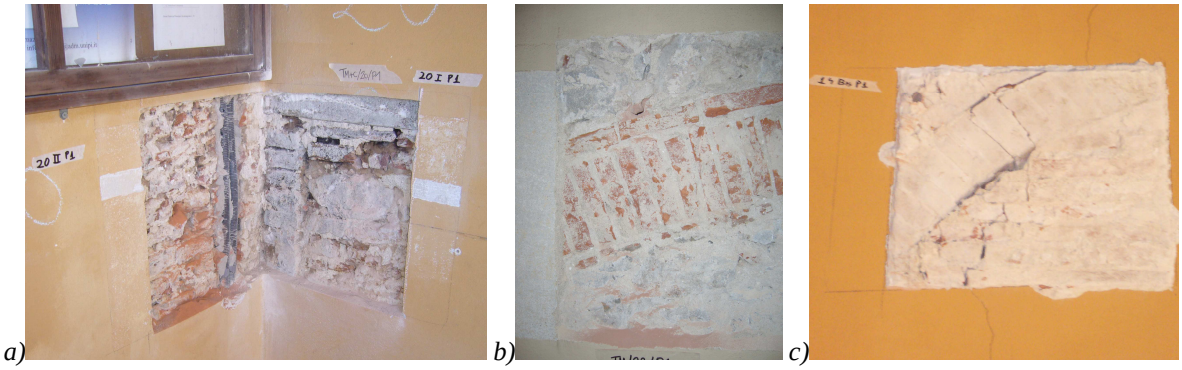

Figure 4: Discontinuities of vertical masonry walls: a) absence of connection between perpendicular walls, b-c) arches identified in correspondence of the first floor level, probably old windows currently closed.

3.2 Analysis of structural units of the building

The structural behaviour of the significant portions of the building (Figure 5) was analyzed through the adoption of local models able to reproduce their main features on the base of the knowledge obtained from in situ and experimental investigations. With reference to the list already elaborated for structural units, the following Limit States (LS) and vulnerabilities (V) can be determined.

1. *Corner between Via Curtatone e Montanara and Via della Sapienza*

A diffused cracking scenario is visible in correspondence of this area, directly related to the differential subsidence of foundations, with relative displacements that strongly affects the overall structural aggregate, and to the intrinsic nature of the masonry of vertical walls. The widespread discontinuities in the structure's geometry, materials and constraints, the presence of voids, air spaces and facings, together with the dubious degree of collaboration, lead to local stress concentrations confirmed by the results of the experimental flat jack tests and by the extensive cracking phenomena.

2. *Open gallery and internal arcade at the ground floor and colonnade at the 1st floor*

The relative displacements evidenced in correspondence of the wooden elements of the colonnade at the 1st floor and the masonry walls, as well as the diffused cracking scenario revealed in the crossed vaulted surfaces of the ground floor are the direct consequence of the differential subsidence due to the different typologies of foundations (Figure 3). The foundations of columns of the internal arcade are not connected to one another and lay at different levels respect to the masonry walls facing the courtyard: these differences result in relative subsidence evidencing the non uniformity of the overall mechanical response of the foundation system, the variability of soil stiffness and of ultimate loads. The structural analysis of foundations considering actual loads (permanent, live and seismic action) allowed the determination of the unit load-subsidence diagrams of the foundation-ground assemblage of the various analyzed sections (Figure 6a): the difference between the building's perimeter and its interior (i.e. colonnade and pillars of the interior courtyard) can expose the whole structure to considerable damages in those areas where significant differences in stiffness and loads were measured (Figure 6b).

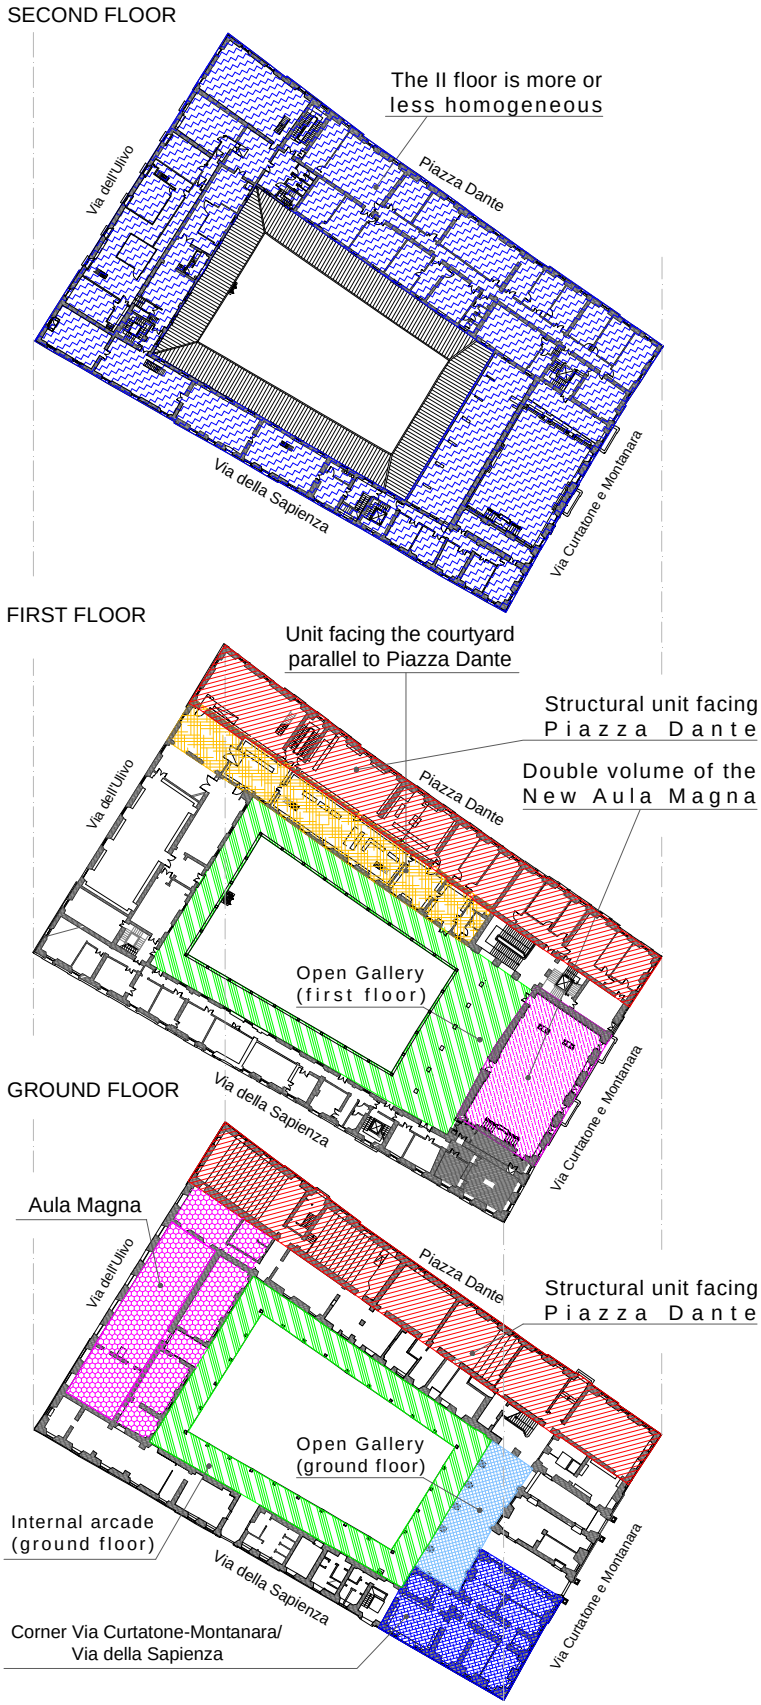

Figure 5: Structural units that can be determined as independent parts of the aggregate.

3. Aula Magna and adjacent rooms

The progressive enlargement of the building at the 1st floor necessary to house the library lead to the introduction of a solid brick curtain wall in order to separate the library rooms and those used for teaching activities. The masonry wall – with thickness equal to 17 cm, height equal to two floors – according to Figure 4 was already present at the end of the 16th century and nowadays represents the effective separation between the portion of the building belonging to the University of Pisa and the University Library. The wall directly rests upon the vaulted surface of the room adjacent to the Aula Magna, generating a critical situation especially in presence of seismic action. Moreover, the analysis of the cracking scenario affecting the Aula Magna at the ground floor, the adjacent rooms and the other areas facing the internal courtyard (Figure 5) is strictly related to the progressive modifications executed during the centuries. Severe damages can be observed in correspondence of the vertical masonry walls and in the vaulted surfaces of the two rooms facing the internal court: at the origin of the Palace, this portion was directly part of the colonnade (Figure 2) and the closure of the area was dated around the end of the XVI century; the relative displacements between the colonnade and the vertical masonry walls of the building – as well as proved by the analysis of the monitoring data – are directly connected to the evidenced cracking scenario.

4. Aula Magna Nuova: double volume at first and second floor

The analysis of the double volume (1st and 2nd floor) of the New Aula Magna evidenced cracks in the vertical masonry walls (not perfectly visible due to presence of ancient paintings) and on the vaulted surface. A deep in situ investigation allowed the determination of the effective structure of the roofing system: steel Polonceau trusses – dating back to the early 20th century – are present sustaining the roof, while the vaulted surface is made up of thin brick elements (3.0 cm) positioned between main r.c./masonry truss with a typical shape used not to transfer horizontal thrusts to the masonry walls. Cracks visible in correspondence of the vaulted surface are, mostly, due to the "geometrical" distance of light brick elements; the support of those elements in correspondence of the main bearing truss is equal, at maximum, to 3.0 cm, generating the possible detachment with the following risk to people and to the structure itself. The overturning phenomena of external and internal walls was analyzed following the linear kinematic approach: the PGA activating the mechanism was equal to 0.112g respect the design value of 0.118g.

5. Portion parallel to Piazza Dante facing the internal courtyard

The progressive increase of space due to the need to house the libraries during the last centuries – executed through the demolishing of internal walls and the introduction of mezzanines at the 1st and 2nd floors – leaded to overload the bearing structures, significantly altering their original local response towards dynamic loads and exposing the building to out-of-plane instability in correspondence of the walls to which the mezzanines' cantilever beams are anchored, characterized by the lack of adequate restraints between perpendicular walls. The out-of-plane problems were evident in correspondence of the sub-unit facing the internal courtyard and parallel to Piazza Dante (1st and 2nd floors), resulting from progressive modifications and demolitions of masonry walls as widely evidenced by the historical analysis). Since typical mechanisms were recognized (i.e., the overturning of masonry vertical walls), linear kinematic analysis was adopted for the determination of the value of horizontal peak ground acceleration (PGA) activating the mechanism. The internal masonry wall is not provided by perpendicular retains, resulting in the possibility to activate the global overturning of the wall both at first and second level: the PGA leading to the activation of the

collapse overturning mechanism were respectively equal to 0.060g and 0.079 g for the 1st and the 2nd floor, towards a foreseen design PGA equal, for the considered site, to 0.118g.

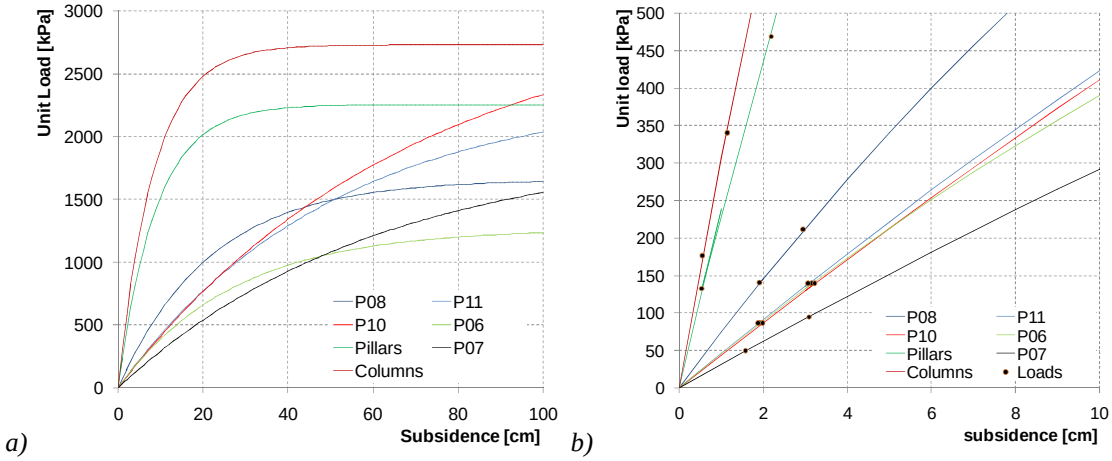

Figure 6: a) Unit load-subsidence curves for the different sections investigated, b) estimates of the subsidence of different building zones as a function of the applied loads.

3.3 Structural behaviour of the aggregate

Even if not strictly necessary for the understanding of the behaviour of a structural aggregate, in Italy the elaboration of a global three-dimensional model is nowadays required [3]) for the execution of safety checks on masonry vertical walls (i.e. shear, flexure in and out of the plane); the global model represents an improved condition respect to the effective situation of the Palace.

A simplified FEM model of the building was realized using SAP 2000, with two-dimensional elements for masonry walls and vaulted surfaces modelled as equivalent plane elements and one-dimensional elements for the steel profiles of the floor slabs, the roofing and the university library mezzanines. The soil-structure interaction was represented through the Winkler model, with elastic three-directional springs calibrated according to the results of the geotechnical investigations and in relation of foundations' shape and size. Cracking phenomena of masonry were considered by reducing the stiffness to values equal to 80% and 60% of the undamaged conditions respectively on the ground and the first and second floors [18]. Linear dynamic analysis with response spectrum was performed; a behaviour factor equal to 2.25 was adopted, conservative in comparison to the values contained in the 2010 Guidelines [13]. Global vibration modes were determined for both flexural behaviour in x and y directions; the significant periods ranged between 0.89 s (global flexural mode in y direction) and 0.59 s.

The described model it is not clearly able to include the extreme variability and strong nonlinear behaviour of constituent materials as well as complex behaviour of internal and external restraints among single structural elements and structural units, anyway can provide useful information when a critical analysis of results is executed basing on the multidisciplinary studies conducted on the building and on the results obtained on single structural units.

The safety checks were performed in agreement with D.M.14/01/2008 [3]. The most evident criticisms were revealed in correspondence of the portions of the building characterized by high heterogeneity of materials and structural typologies and in those areas that underwent the most significant changes and modifications during the centuries, confirming the considerations coming from the analysis of the structural behaviour of single

portions or units determined inside the aggregate (Figure 5), such as in correspondence of the corner Via Curtatone e Montanara/Via della Sapienza (i.e. heterogeneity of materials), of the historical Aula Magna (i.e. closure of the colonnade), of the New Aula Magna (i.e. modifications and enlargements up to the double volume).

4 RETROFIT OF THE STRUCTURAL AGGREGATE

The traditional global approach proposed by current standards for retrofit, foreseeing the possibilities of global/partial and local strengthening of the whole building or of several structural elements cannot be easily applied to historical buildings. The retrofit of cultural heritage shall pursue the preservation of the original nature of the building, maintaining its historical aspects and providing a considerable increase of the margin of structural safety. The retrofit can be considered, then, the final amount of many local interventions: local retrofit operations regarding single structural units globally cooperate to provide the aggregate with a higher level of structural safety. Many structural interventions were then planned for Palazzo La Sapienza to solve the problems evidenced through the structural analysis, related to the different structural units constituting the Palace. Some of them are briefly summarized in the following pages.

Open gallery at ground floor and colonnade at the first floor

The retrofit of the vaulted surfaces consisted in the removal of the filling material on the extrados of the vaulted surfaces – with the following decrease of the dead load – and in the restoration of cracks using specific materials for historical masonry buildings (Figure 7a); a similar retrofit procedure was also adopted for cracks present at the intrados of the vaults. A thin shaving layer of 2-3 cm of thickness with welded steel mesh (ϕ 3 mm and spacing 50x50 mm) was also foreseen provide a global behaviour without altering the structural feature of the aggregate. Some problems were revealed also in correspondence of the 1st floor colonnade, with relative displacement between the wooden secondary elements of the roof and the masonry wall, with support length equal, in some cases, only to few centimeters; in order to prevent the pull out of such elements, an additional steel profile was positioned in correspondence of the whole perimeter of the colonnade (Figure 7b), providing a final support length of about 10 cm. Several additional retrofit interventions were designed for damaged elements of the roofing system.

Aula Magna and adjacent rooms

To solve the problem of the masonry infill wall directly bearing on the vaulted surface close to the Aula Magna at the ground floor, the introduction of a steel HEA profile able to directly sustain the masonry wall and the rest of the superstructure - including the vault at 1st floor and the corresponding masonry wall at the 2nd floor - was accurately designed. The design of the bearing profile took into account both strength and stiffness aspects – this last to avoid the vertical deflection of the masonry wall – and, moreover, the analysis of the assembly procedure (Figure 8). A temporary bearing structure made up of two twin truss beams with transversal support steel beams with spacing equal to 50-70 cm was adopted, allowing safety conditions during the phases of cutting of the masonry wall and introduction of the HEA bearing beam.

Vertical masonry walls

Diffused interventions were executed on vertical masonry walls in order to solve the problems related to the diffused cracking scenario revealed and, in some cases, monitored at the different floors of the Palace, such as for example in correspondence of the corner

between Via Curtatone e Montanara, in which cracks appear mostly in relation to the progressive modifications and changes executed during the centuries as a consequence of functional requirements. Different typologies of interventions were foreseen in relation to the entity of revealed cracks.

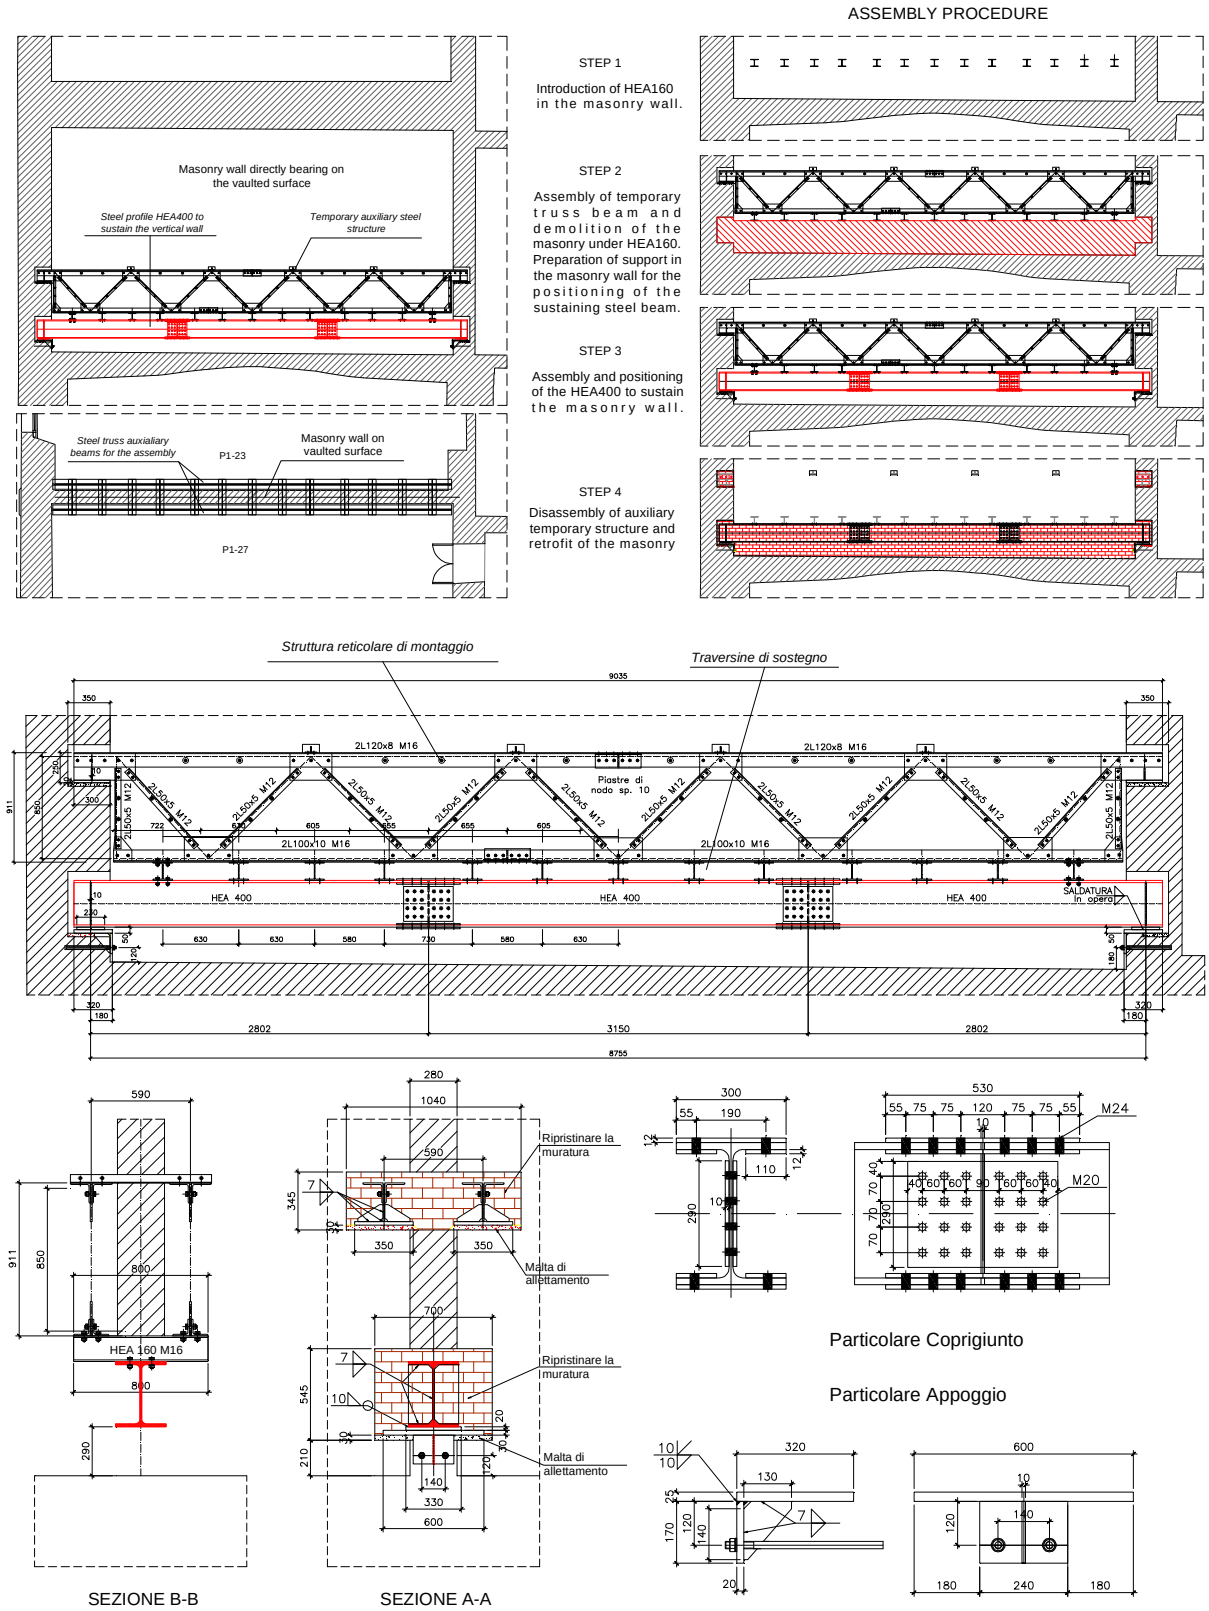

Figure 8: Introduction of stele profile and assembly procedure to avoid the load directly upon the vaulted surface near the Aula Magna.

5 CONCLUSIONS

The deep analysis of the current condition of such complex building as Palazzo La Sapienza in Pisa, including the historical and morphological investigation of its modifications and extensions during the centuries, the in situ survey of materials, walls, horizontal storeys and vaulted surfaces, the analysis cracking scenario, of foundations and roofing system, the geological and geotechnical characterization of the soil highlighted the need to consider the building not as a single structural unit, but rather as an aggregate made up of several units connected to each other and built using different techniques.

The combined analysis of the historical evolution of the Palace and of the structural survey of its current condition – especially for what concerns the cracking scenario and its main causes - allowed the determination of structural units, whose behaviour shall be deeply analyzed on the base of the progressive modifications of bearing elements, acting loads, connections and mutual influence. If, according to current standards for existing constructions a global analysis of the building is necessary for the execution of safety checks, in the present work the need of a "double" analysis including the interpretation of the structural behaviour of sub-units, their mutual interrelationships and the possible activation of significant partial/local mechanisms, and a simplified global analysis providing indications regarding static condition and relative information about the most critical and stressed portion of the building itself, is highlighted.

A critical evaluation of the building's safety, together with a clear, deep understanding and knowledge of the structure itself, constitute the basis to define the objective of any structural interventions, carefully designed to achieve appropriate safety levels, durability of relevant portions of the building and, at the same time, produce the least impact possible on this important living example of Italy's historical heritage.

Keywords: Masonry walls, discrete element model, 3D model, frictional contact, Mohr-Coulomb yield criterion.

Abstract. *The analysis of masonry structures is of particular interest in the civil engineering and architecture community due to the large amount of historical masonry constructions in Europe and in Italy in particular. Masonry is a heterogeneous material obtained by composition of blocks connected by dry or mortar joints. The use of refined models for investigating the in and out of plane nonlinear behaviour of masonry is an active field of research. Considering historical masonry, the mechanical properties of joints are usually lower than those of blocks, allowing to assume that damage occurs more frequently along joints. For this reason, discrete element models (DEMs) may be frequently adopted for representing masonry behaviour, assuming blocks as rigid bodies and joints as interfaces, with a small number of degrees of freedom and parameters involved in the analysis. As well known, masonry walls may be considered as the most important category of load-bearing elements in masonry structures and they are subject to vertical and horizontal actions generated by gravitational loads and seismic actions, respectively. Horizontal loads may act in plane or out of plane, causing two different collapse mechanisms for a masonry wall. In this work a simple and effective discrete element model, already developed in linear field for in and out of plane analysis and already extended in nonlinear field but only for in plane analysis, is here extended to the three dimensional nonlinear analysis of masonry walls. A Mohr-Coulomb yield criterion is adopted for modelling interface behaviour. A numerical experimentation is carried on in order to determine the limit load multiplier, together with the collapse behaviour, of several masonry walls. Moreover, existing results are taken in consideration in order to calibrate the proposed model and to evaluate its effectiveness.*

1 INTRODUCTION

Masonry is a heterogeneous material composed by natural or artificial blocks connected by dry or mortar joints. Masonry was the main building material for many centuries; earthquake actions are one of the main causes of collapse and the assessment of seismic performance of masonry structures remains a challenging task in the structural analysis field of research.
The strength of masonry structures is affected by geometrical configuration and constructive details. As well known, such details have effects on the two main different seismic induced damages and collapse modes of masonry walls: in-plane and out-of-plane collapse mechanisms. The former are responsible for extended shear deformations and cracks, while the latter may cause the tilting of entire wall portions, leading eventually to the partial or total collapse of the construction. These collapse mechanisms were observed in past earthquakes and adequate descriptions by means of numerical and analytical models were done and are still being developed [1,2].
Several types of numerical models may be adopted for studying masonry behaviour such as heterogeneous or homogenized Finite Element Models (FEMs) or Discrete Element Models (DEMs); moreover, several analysis types may be performed such as limit analysis or incremental analysis. For instance, an overview of the methods for modelling masonry structures may be found in the work of Smoljanović et al. [3] and a deep literature review of out of plane behaviour and models for masonry has been recently done by Ferreira et al. [4].
A DE Model, based on the assumptions of rigid blocks and joints modelled as interfaces, may be suitable for investigating masonry behaviour due to the small number of degrees of freedom (DOFs) needed for performing a numerical analysis of block assemblages. These assumptions may be suitable for historical masonry, in which block stiffness is larger than joint stiffness, allowing to assume blocks as rigid bodies; moreover joint thickness is negligible if compared with block size, especially in case of dry joints, allowing to model joints as interfaces. Discrete models were adopted in the past by many authors for studying masonry out of plane behaviour in linear and nonlinear fields [5-10]. In particular, Cecchi and Sab [7] defined a simple and effective DEM for studying the three-dimensional behaviour of masonry panels with a small computational effort due to the small number of degrees of freedom involved.
In this contribution, the original three-dimensional discrete element model (3D DEM) introduced by Cecchi and Sab [7] in the linear elastic field, is extended to the field of collapse analysis by assuming a Mohr-Coulomb yield criterion for restraining interface actions. With this aim, a nonlinear -elastic perfectly plastic- interface behaviour is considered by assuming action restraints as elastic limits. The theoretical work of Orduña and Lourenço [8] is taken as reference for defining restraint conditions relative to interface shear force, torsion and their combination. Moreover, a static solution approach characterized by the determination of the stiffness matrix of the masonry assemblage is adopted, following and extending the procedure already adopted by authors for the nonlinear incremental analysis of masonry walls in plane loaded [11] and for the in and out of plane modal analysis of masonry walls [12,13]. Several numerical experiments are carried on in order to validate the proposed nonlinear DEM with respect to existing numerical and laboratory results. For first, numeric out of plane tests performed by Orduña and Lourenço [9] are reproduced, then, the experimental campaign on scaled masonry-like specimens performed by Restrepo Vélez et al. [14] is taken in consideration and several cases are reproduced with the proposed nonlinear DEM. In general, the proposed numerical solution method turns out to be effective for the determination of limit loads and out of plane collapse mechanisms of the masonry walls considered.

2 THREE DIMENSIONAL DISCRETE MODEL

A regular masonry with standard running bond periodic pattern is considered; the generic block $B_{i,j}$ is in contact with six neighbours by means of six interfaces or joints S_{k_1,k_2}, with k_1, $k_2 = \pm 1$ for horizontal interfaces and $k_1 = \pm 2$, $k_2 = 0$, for vertical interfaces (Figure 1). Block dimensions are: *a* (height), *b* (width) and *s* (thickness).

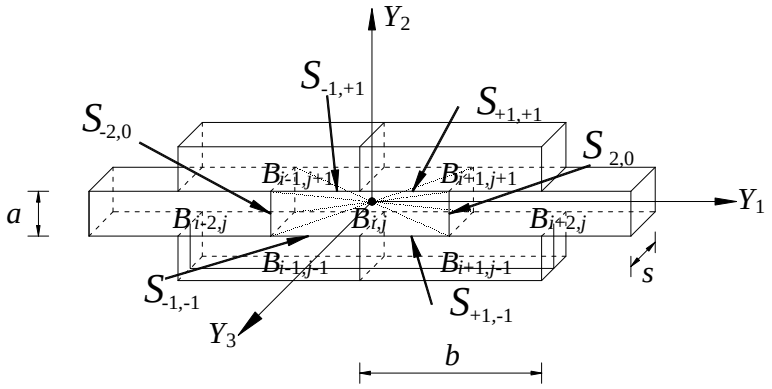

Figure 1. Discrete model, running bond Representative Elementary Volume (REV).

Assuming rigid block hypothesis, the displacement of a generic block is represented by a rigid body motion referred to the motion of its centre and the rotation with respect to its centre:

$$\mathbf{u}^{i,j}(\mathbf{y}) = \mathbf{u}^{i,j} + \mathbf{\Omega}^{i,j}(\mathbf{y} - \mathbf{y}^{i,j}). \tag{1}$$

Where $\mathbf{y}^{i,j}$ is the position of block centre in the Euclidean space: $\mathbf{y}^{i,j} = i(b/2)\mathbf{e}_1 + j\,a\,\mathbf{e}_2$; considering the three dimensional case $\mathbf{u}^{i,j} = \{u_1^{i,j}\ u_2^{i,j}\ u_3^{i,j}\}^T$ is the translation vector of $B_{i,j}$ and $\mathbf{\Omega}^{i,j}$ is the rotation skew tensor collecting block rotations with respect to coordinate axes:

$$\mathbf{\Omega}^{i,j} = \begin{bmatrix} 0 & -\omega_3^{i,j} & \omega_2^{i,j} \\ \omega_3^{j,j} & 0 & -\omega_1^{i,j} \\ -\omega_2^{i,j} & \omega_1^{i,j} & 0 \end{bmatrix} \tag{2}$$

In and out of plane block translations and rotations may be collected in $\mathbf{q}^{i,j} = \{u_1^{i,j}\ u_2^{i,j}\ u_3^{i,j}\ \omega_1^{i,j}\ \omega_2^{i,j}\ \omega_3^{i,j}\}^T$. Following the procedure described in [7], the interactions between two adjacent blocks $B_{i,j}$ and $B_{i+k_1,j+k_2}$ through a generic interface S_{k_1,k_2} are represented by interface tensions $\mathbf{\sigma}$ that are related to the relative displacement and rotations between adjacent blocks by means of a constitutive relation $\mathbf{\sigma n} = \mathbf{K}\,\mathbf{d}$, neglecting for simplicity apex k_1,k_2. Here $\mathbf{\sigma}$ is the stress tensor, $\mathbf{n}$ is the normal vector to the generic interface, $\mathbf{K}$ is the interface stiffness matrix and $\mathbf{d}$ is the vector that collects interface relative translations:

$$\begin{aligned} d_1^{k_1,k_2} &= u_1^{i+k_1,j+k_2} - u_1^{i,j} + k_2 a(\omega_3^{i+k_1,j+k_2} + \omega_3^{i,j})/2, \\ d_3^{k_1,k_2} &= u_3^{i+k_1,j+k_2} - u_3^{i,j} - k_1(b/2)(\omega_3^{i+k_1,j+k_2} + \omega_3^{i,j})/2, \\ d_3^{k_1,k_2} &= u_3^{i+k_1,j+k_2} - u_3^{i,j} + k_1(b/2)(\omega_2^{i+k_1,j+k_2} + \omega_2^{i,j})/2 - k_2 a(\omega_1^{i+k_1,j+k_2} + \omega_1^{i,j})/2, \end{aligned} \tag{3}$$

and relative rotations:

$$\begin{aligned}\delta_1^{k_1,k_2} &= \omega_1^{i+k_1,j+k_2} - \omega_1^{i,j},\\ \delta_2^{k_1,k_2} &= \omega_2^{i+k_1,j+k_2} - \omega_2^{i,j},\\ \delta_3^{k_1,k_2} &= \omega_3^{i+k_1,j+k_2} - \omega_3^{i,j}.\end{aligned} \tag{4}$$

and that may be written as $\mathbf{d}^{k_1,k_2} = \{d_1^{k_1,k_2}\ d_2^{k_1,k_2}\ d_3^{k_1,k_2}\ \delta_1^{k_1,k_2}\ \delta_2^{k_1,k_2}\ \delta_3^{k_1,k_2}\}^T$. It is worth noting that in order to better highlight the relation between relative displacements and global block translations and rotations, the above expressions may be written in matrix form as $\mathbf{d}^{k_1,k_2} = \mathbf{H}^{k_1,k_2}\mathbf{q}^{k_1,k_2}$, where $\mathbf{q}^{k_1,k_2}$ collects translations and rotations of two adjacent blocks and $\mathbf{H}^{k_1,k_2}$ may be defined as interface 'compatibility' matrix [15] that collects, following Equations (3)-(4), the relative distances between the centres of the blocks considered.

Assuming initially the hypothesis of elastic interface behaviour, the interface stiffness matrix $\mathbf{K}$ may be detailed for horizontal and vertical case: $\mathbf{K}_h^{k_1,k_2} = \mathrm{diag}\{K_t\ K_n\ K_t\ K_r\ K_t\ K_r\}$ and $\mathbf{K}_v^{k_1,k_2} = \mathrm{diag}\{K_n\ K_t\ K_t\ K_t\ K_r\ K_r\}$, collecting tangential (K_t), normal (K_n) and rotational (K_r) stiffness of the interface. It is worth noting that rotational stiffness assumes the same value of normal stiffness ($K_r = K_n$), but it is defined by a different variable given that in the following description of interface nonlinear behaviour it will be necessary to distinguish between nonlinear behaviour of normal forces with respect to that of bending moments. Assuming mortar joints with an isotropic and elastic behaviour, interfacial stiffness values are function of mortar elastic modulus E^m and Poisson ratio ν^m [7].

The elastic energy of the interface is determined by defining the product of interface stresses and interface relative displacements:

$$\Pi_{k_1,k_2} = \frac{1}{2}\int_{S_{k_1,k_2}} \boldsymbol{\sigma}^T\mathbf{d}\,dS = \frac{1}{2}\int_{S_{k_1,k_2}} \mathbf{d}^T\mathbf{K}\,\mathbf{d}\,dS = \frac{1}{2}\mathbf{d}^T(\mathbf{K}\mathbf{A})\,\mathbf{d} = \frac{1}{2}\mathbf{d}^T\bar{\mathbf{K}}\,\mathbf{d}, \tag{5}$$

where apex k_1,k_2 for vectors and matrices is omitted for simplicity, $\mathbf{A}$ is the generic (diagonal) matrix of area and inertias of the interface, that may be detailed for horizontal and vertical cases: $\mathbf{A}_h = \mathrm{diag}\{S_h\ S_h\ S_h\ I_{h1}\ (I_{h1}+I_{h3})\ I_{h3}\}$, $\mathbf{A}_v = \mathrm{diag}\{S_v\ S_v\ S_v\ (I_{v2}+I_{v3})\ I_{v2}\ I_{v3}\}$, with

$$\begin{aligned}&S_h = b\,s/2, \quad I_{h1} = b\,s^3/24, \quad I_{h3} = b^3 s/96,\\ &S_v = a\,s, \quad I_{v2} = a\,s^3/12, \quad I_{v3} = a^3 s/12.\end{aligned} \tag{6}$$

Interface forces and moments may be obtained by differentiating the expression of interface elastic energy in Equation (5) with respect to each block displacement component. Such unknown forces $f_1^{k_1,k_2}$, $f_2^{k_1,k_2}$, $f_3^{k_1,k_2}$ and moments $m_1^{k_1,k_2}, m_2^{k_1,k_2}, m_3^{k_1,k_2}$ may be collected in $\mathbf{f}^{k_1,k_2} = \{f_1^{k_1,k_2}\ f_2^{k_1,k_2}\ f_3^{k_1,k_2}\ m_1^{k_1,k_2}\ m_2^{k_1,k_2}\ m_3^{k_1,k_2}\}^T$ and it can be easily demonstrated that $\mathbf{f}^{k_1,k_2} = \bar{\mathbf{K}}^{k_1,k_2}\mathbf{d}^{k_1,k_2}$.

Extending Equation (5) to the entire masonry assemblage (i.e. masonry panel), the total elastic energy Π is obtained and the subsequent equilibrium equation for the assemblage subject to generic in and out of plane actions $\mathbf{F}^{ext}$ is:

$$\mathbf{F}^{ext} = \partial\Pi/\partial\mathbf{q} = \mathbf{K}^{panel}\mathbf{q}, \tag{7}$$

where $\mathbf{q}$ collects block displacements and rotations of the entire panel. Equation (7) may be solved by adopting a molecular dynamics algorithm [7] or directly by explicitly defining the stiffness matrix of the entire assemblage $\mathbf{K}^{panel}$, joining together the procedures already proposed by authors [11-13] for the in and out of plane cases, respectively, and used separately in

the field of in and out of plane modal analysis of masonry panels and in the field of nonlinear analysis of masonry panels in plane loaded. In particular, the determination of panel stiffness matrix is based on the definition of a 'compatibility' matrix [15] $\mathbf{H}^{panel}$ obtained by assembling matrices $\mathbf{H}^{k_1,k_2}$ over the panel and that relates relative displacements of the entire panel $\mathbf{d}^{panel}$ with block displacements and rotations: $\mathbf{d}^{panel} = \mathbf{H}^{panel}\mathbf{q}$. Then, panel stiffness matrix may be calculated as: $\mathbf{K}^{panel} = (\mathbf{H}^{panel})^T \bar{\mathbf{K}}^{panel} \mathbf{H}^{panel}$, where $\bar{\mathbf{K}}^{panel}$ is a diagonal matrix collecting interface stiffness values of the entire panel.

2.1 Yield criterion for interface

The nonlinear behaviour of interfaces is governed by a Mohr-Coulomb yield criterion, characterized by a cohesion c and a friction ratio $\mu = \tan\varphi$. For instance, dry interfaces cannot support tension and have a negligible cohesion, whereas mortar joints are characterized by a tensile strength σ_t and a cohesion value that may be determined by means of experimental tests (for instance EN 1052-3:2002). However, both interface types are characterized by a frictional behaviour and an unlimited compressive strength is assumed.
Considering a generic interface and assuming a local coordinate system $y_1y_2y_3$, with plane y_1y_2 coincident with interface mid-plane and y_3 orthogonal to it. Forces and moments exerted by two adjacent blocks at the interface centre are (Figure 2): normal force $f_3\mathbf{e}_3 = f_n\mathbf{e}_3$, shear forces $f_1\mathbf{e}_1$, $f_2\mathbf{e}_2$, bending moments $m_1\mathbf{e}_1$, $m_2\mathbf{e}_2$ and torsion $m_3\mathbf{e}_3$.

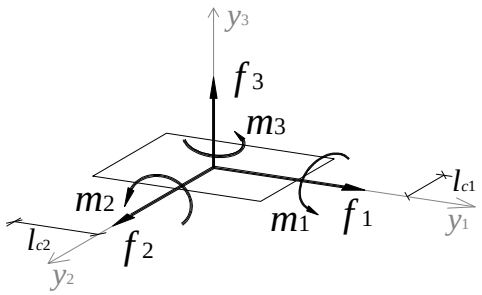

Figure 2: Generic interface with local coordinate system and interface forces and moments.

2.1.1 Normal and flexural interface strength

Considering for first interface normal force and bending moments, the nonlinear behaviour is governed by tensile strength and a simple elastic-plastic relation between actions and relative displacements is adopted. Normal force and bending moments must satisfy the following conditions:

$$\begin{aligned} & f_n = f_3 \le f_t, \\ & |m_1| \le (f_t - f_n)\, l_{c1}, \\ & |m_2| \le (f_t - f_n)\, l_{c2}. \end{aligned} \tag{8}$$

Where f_t represents the tensile strength of the interface, defined as the product of joint tensile strength σ_t and area of the interface (S_v or S_h) and l_{ci} with $i = 1,2$ is the characteristic length of the interface with respect to interface plane directions, namely the maximum eccentricity of normal force with respect to block centre that may be supported by the interface. Each value

is equal to $l_{c1} = s/2, l_{c2} = b/4$ for a horizontal interface and to $l_{c1} = a/2, l_{c2} = s/2$ for a vertical one.
First and second conditions in Equation (8) have been already adopted by authors for the in plane case [11] and they turn out to be coincident to those adopted by Trovalusci and Masiani [16]. In particular, the first condition may be defined as 'detachment' condition, whereas the second and third ones may be defined as 'rotation' conditions with respect to y_1 and y_2 axis.
The relationship between interface normal force and relative normal displacement and the relationships between interface bending moments and relative rotations follow an elastic-perfectly plastic behaviour. In particular, if the interface is subject to excessive moment, only its rotational stiffness is set equal to zero, whereas if the interface is subject to detachment, all interface stiffness values are set equal to zero:

$$\begin{aligned} &f_n > f_t \rightarrow K_n = K_t = K_r = 0, \\ &|m_i| > (f_t - f_n) l_{ci} \rightarrow K_r = 0 \quad i = 1,2. \end{aligned} \tag{9}$$

2.1.2 Shear and torsion interface strength

Differently than the in plane case, characterized by interface shear force acting together with a normal force and a bending moment, in the three dimensional case shear stresses are generated by two components of shear force f_1 and f_2 and by a torsion m_3 and such stresses act together with normal stresses generated by normal force and bending moments. Limit conditions for shear forces and torsion adopted here follow the expressions introduced by Orduña and Lourenco [8]. In particular, if torsion is not present, uniform shear stresses are assumed over the interface and the well-known Mohr-Coulomb yield criterion is applied to the resultant of interface shear forces as follows:

$$|f_s| = \sqrt{f_1^2 + f_2^2} \leq (f_t - f_n)\tan\varphi \quad \text{if} \quad m_3 = 0. \tag{10}$$

The condition above may be defined as 'sliding' condition and the quantity $[(f_t - f_n)\tan\varphi]$ represents the shear strength of the interface. It is worth noting that in this case the cohesion of the interface is represented by the shear strength in absence of a normal action, hence it can be assumed that such strength is equal to $[c\,S_h = f_t \tan\varphi]$ for a horizontal interface and to $[c\,S_v = f_t \tan\varphi]$ for a vertical one.
If shear forces over the interface are equal to zero, the torsion generates shear stresses depending on relative rotation and on the distance from interface centre, that represents the twisting centre. Torsion over the interface must be less than the torsion strength as follows:

$$|m_3| \leq C_t (f_t - f_n)\tan\varphi \quad \text{if} \quad f_s = 0, \tag{11}$$

where C_t is the torsion constant defined in [8], that is based on an interface subdivision into eight rectangular triangles. If shear forces and torsion act together over the interface, the twisting centre moves away from interface centre and the shear-torsion interaction may be defined analytically by integrating shear stresses over the interface. The simplified shear-torsion interaction curve defined by Orduña and Lourenço [8] is adopted. An elastic-plastic behaviour is assumed also in this case and if restraint conditions for shear force and torsion are not respected, the interface tangential stiffness K_t is set equal to zero, whereas normal and flexural stiffness values are not modified.
In order to appreciate the correct adoption of shear and torsion nonlinear behaviour in the proposed DEM, a simple specimen of two blocks connected by an interface modelled with DEM is tested by applying to the interface an increasing torsion with several fixed values of

shear force and by applying an increasing shear force with several fixed values of torsion. Friction ratio μ = 0.7 is assumed and a normal force f_n = 240 N is applied over the interface. Interface size are 0.2 m × 0.3 m. The following Figure 3 shows separately the torsion-relative rotation incremental curves for varying shear force and the shear force-relative displacement incremental curves for varying torsion. As expected, torsion strength decreases for increasing the applied shear force and similarly shear strength decreases for increasing the applied torsion. Both groups of incremental curves allow to obtain the simplified shear-torsion domain proposed by Orduña and Lourenço [8].

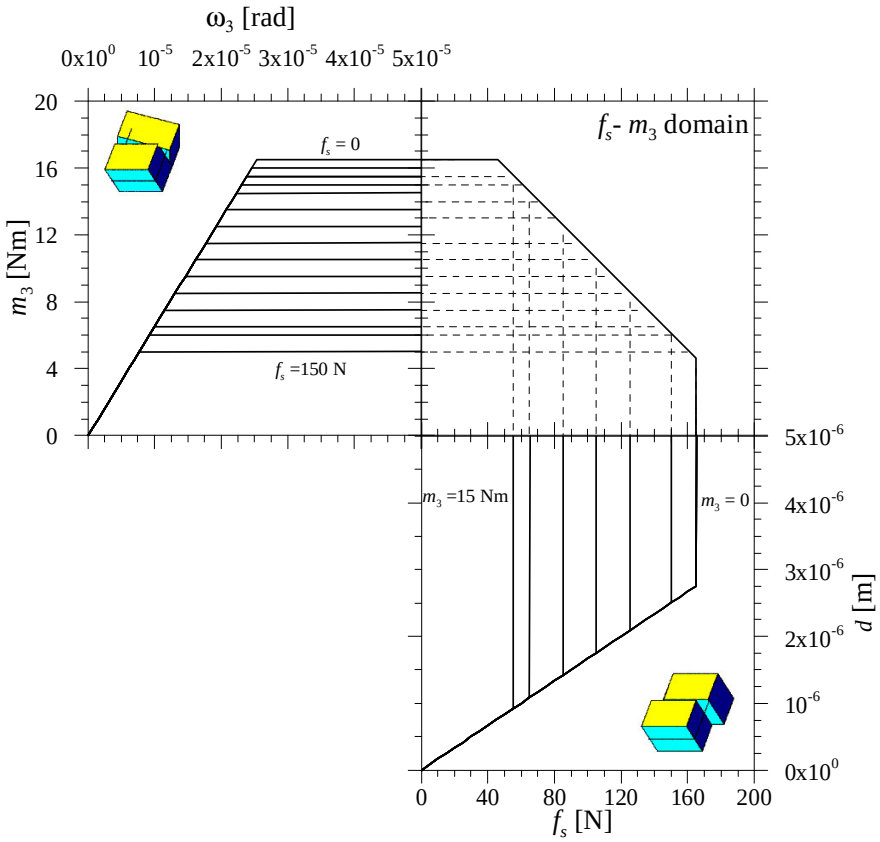

Figure 3: Incremental analyses of a simple specimen subject to increasing torsion with several values of fixed shear force and subject to increasing shear force with several values of torsion.

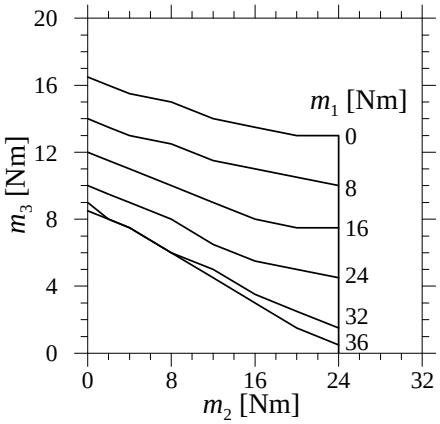

Figure 4: Torsion strength-bending moment interaction curves.

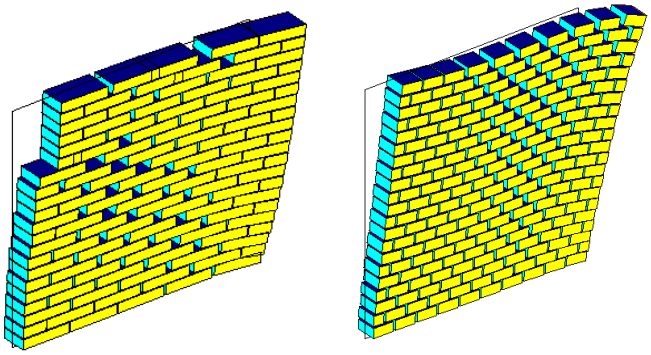
Finally, if bending moments act over the interface together with shear force and torsion, the effective area of the interface is reduced taking into account eccentricity values $e_1 = m_2/f_n$ and $e_2 = m_1/f_n$, then the torsion constant C_t gets smaller, leading to a smaller torsion strength with respect to the case without bending moments. Considering again a simple specimen made of two blocks connected by an interface and varying both values of bending moments over the interface, Figure 4 shows the corresponding torsion strength values and the curves obtained numerically are in excellent agreement with those obtained analytically by Orduña and Lourenço [8].

2.2 Nonlinear DEM

As previously stated, restraint conditions for interface forces and moments allow to define the elastic limits of force-relative displacement and moment-relative rotation constitutive laws, that are assumed to be elastic-perfectly plastic. Then, incremental analyses may be performed by applying incremental load steps to the discrete model and updating the stiffness matrix accounting for local interface nonlinear behaviour. For instance, the stiffness matrix at a generic load step, needed for the evaluation of the corresponding increment of displacements $\delta\mathbf{q}_i$ and internal forces $\mathbf{F}_i^{int}$, is based on interface damage at the previous step as follows: $\delta\mathbf{q}_i = (\mathbf{K}^{panel}_{(\mathbf{q}_{i-1})})^{-1}\delta\mathbf{F}^{ext}$ and $\mathbf{F}_i^{int} = \mathbf{F}_{i-1}^{int} + \mathbf{K}^{panel}_{(\mathbf{q}_{i-1})}\delta\mathbf{q}_i$. Then, internal forces are corrected accounting for the yield criterion adopted and residual forces $\mathbf{R}_i = \mathbf{F}_i^{int} - \mathbf{F}^{ext}$ are determined as a starting point of an iterative process of residuals minimization.
In the following paragraphs, numerical tests are performed considering masonry panels subject to self-weight and increasing lateral loads (in or out of plane). Such loads are proportional to the weight ($P = \gamma a b s$, where γ is block volumetric weight) and are identified by the load multiplier λ; then, the vector collecting the total forces applied at block centres may be defined as $\mathbf{F}^{ext} = \mathbf{F}_D + \lambda\mathbf{F}_L$, where $\mathbf{F}_D$ represents dead loads, collecting block weight P and $\lambda\mathbf{F}_L$ represents unknown horizontal live loads (in or out of plane).

3 IN PLANE NUMERICAL EXPERIMENTS

In order to appreciate the effectiveness of the proposed nonlinear DEM, several numerical experiments of masonry panels in plane loaded by self weight and increasing lateral loads are performed. For instance, the numerical tests originally performed by Baggio and Trovalusci [17] and already studied by authors [11] are reproduced, obtaining the same results of previous in plane analyses (Figure 5).



$\lambda^{DEM} = 0.49$; $\lambda^{REF\ [17]} = 0.50$ $\lambda^{DEM} = 0.36$; $\lambda^{REF\ [17]} = 0.34$

Figure 5: Failure mechanisms for masonry panels subject to self weight and increasing in plane lateral loads.

4 OUT OF PLANE NUMERICAL EXPERIMENTS

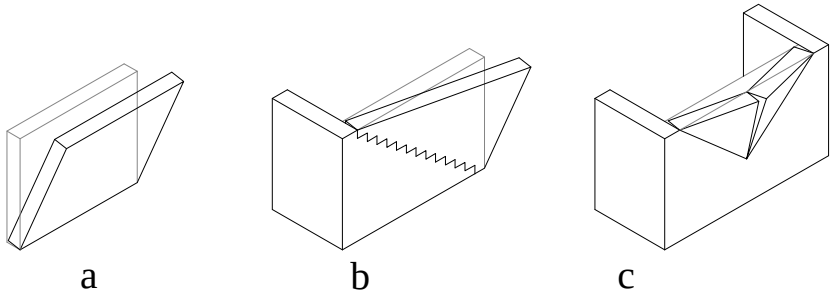


Figure 6: Typical out of plane collapse mechanisms for a masonry wall [18].

In this paragraph, several numerical experiments are carried on in order to evaluate the effectiveness of the proposed nonlinear DEM in the determination of out of plane collapse mechanisms and limit loads of masonry panels. In particular, the typical mechanisms described by Rondelet [18] are going to be reproduced numerically and several existing results, both numerical and experimental, are taken as reference. In particular, the first mechanism type defined by Rondelet is the typical out of plane rigid rotation of a free masonry wall with respect to its base (Fig. 6a), whereas the second mechanism regards a masonry wall restrained along a vertical edge by an orthogonal wall, leading to the formation of a diagonal crack and to a roto-translation of a triangular portion of the wall (Fig. 6b). This mechanism is characterized by a larger ultimate load with respect to the previous case. Finally the third mechanism regards a masonry wall restrained by two orthogonal walls at both vertical edges; in this case a vertical crack along panel axis of symmetry forms together with two diagonal cracks starting from panel upper corners (Fig. 6c), leading to two triangular portions that rotate with respect to diagonal cracks. In this last case, the ultimate load is larger than those of the previous mechanisms.

4.1 Case studies proposed by Orduña and Lourenço

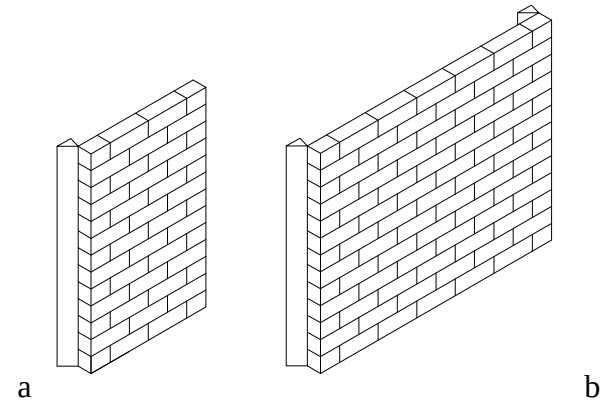

Figure 7: Case studies considered originally by Orduña and Lourenço [9].

Two simple examples of masonry panels out of plane loaded are taken into account for first, by assuming as reference the numerical tests performed by Orduña and Lourenço [9]. In both cases masonry panels are made of blocks assembled following a running bond pattern and having dimensions a = 0.081 m, b = 0.210 m, s = 0.07 m and volumetric weight equal to 20 kN/m^3. Contacts between blocks are dry, with μ = 0.7 and null cohesion. In the first example, panel overall dimensions are: length L = 0.630 m, height H = 1.053 m and thickness s =

0.07 m, obtained by assembling 3 blocks along panel length and 13 blocks along its height; moreover block translations are fixed along panel left column (Figure 7a). In the second example panel dimensions are: L = 1.260 m, H = 1.053 m and s = 0.07 m, obtained with 6 blocks along panel length and 13 blocks along its height. In this case, block translations are fixed along external columns (Figure 7b).
Figure 8a shows a collapse mechanism characterized by a diagonal crack starting from the right side of the panel after the 2nd row of blocks. Such mechanism is in quite good agreement with the one showed in the original analysis and the limit load obtained with the proposed nonlinear DEM is included between FEM and limit analysis performed by Orduña and Lourenço (Table 1). Figure 8b shows a collapse mechanism characterized by a symmetric flexural deformation with large displacements along vertical axis of symmetry. Similarly to the previous case, collapse mechanism and limit load (Table 1) are in quite good agreement with reference solutions.

4.2 Restrepo Vélez, Magenes and Griffith experiments

In this paragraph, several experimental tests performed by Restrepo Vélez et al. [14] are taken as reference. Original tests were performed on scaled masonry-like specimens with dry joints, subject to self-weight and increasing out of plane loads by means of an inclined plane machine, in order to obtain out of plane failure mechanisms. Block dimensions are a = 28.24 mm, b = 79.78 mm and s = 39.68 mm and block volumetric weight is 26.8 kN/m^3. Dry joints are characterized by friction ratio μ = 0.7 and null cohesion. All cases are characterized by 21 block courses along panel height and varying number n of blocks along panel length (from 4 to 14, for instance). Panel restraints at one or both lateral edges were obtained with one or two orthogonal walls (Figure 9a and b, respectively); for this reason, several mechanisms turned out to involve also blocks in orthogonal walls. In the present campaign, the effect of orthogo-

nal walls is simply modelled by restraining block translations and rotations along one or both lateral columns (Figure 9d and e, respectively). Then, the present model will not be able to represent complex collapse mechanisms involving orthogonal walls, leading to small differences between proposed numerical results and experimental tests. Moreover, an additional specimen type considered a panel without orthogonal walls simply supported at the base and loaded by several wooden beams (Figure 9c).

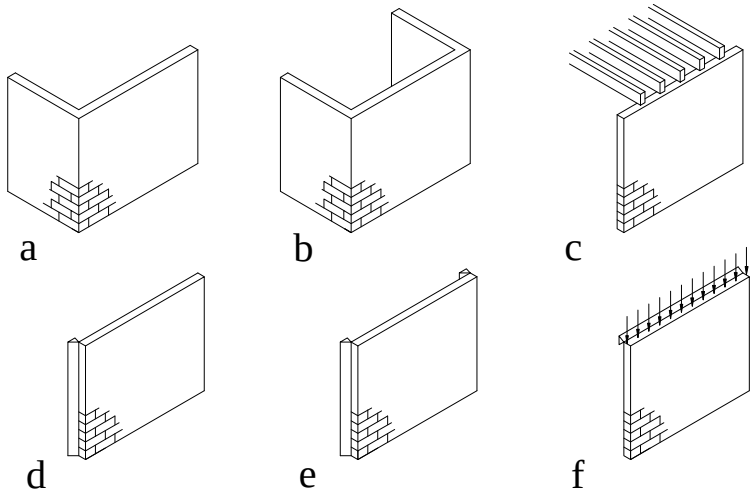

Figure 9: Masonry specimen types considered in the experimental campaign by Restrepo Vélez et al [14] (a-c); corresponding specimens modelled with DEM in present analysis (d-f).

Figure 10 shows failure mechanisms of several panels restrained along left column, varying the number of blocks along panel length (for further details about block number see the first row of Table 2). Mechanisms are characterized by a diagonal crack starting from lower-right panel corner, directed towards the upper-left panel corner and a triangular/trapezoidal portion of panel is subject to a roto-translation with respect to such diagonal crack. These mechanism types are in quite good agreement with experimental tests, moreover numerical results obtained with the proposed nonlinear DEM are in quite good agreement with experimental results (Table 2), especially for specimens S11, S12 and S13, thanks to the large number of blocks of the models, whereas for specimen S15, characterized by a small number of blocks along panel length, limit load obtained with DEM is quite far from experimental result with respect to other cases.
Figure 11 shows failure mechanisms of several panels restrained along both lateral vertical edges. Such mechanisms are characterized by a vertical crack along the axis of symmetry of the panel and diagonal cracks starting from lateral edges and moving down to panel axis of symmetry. Mechanisms are similar but not coincident with respect to those obtained experimentally, due to the real restraint adopted for masonry specimens; however limit loads obtained numerically with nonlinear DEM are still in quite good agreement with experimental results.
Finally figure 12 shows the failure mechanism of a simply supported panel loaded by eleven wooden beams (16.46 N transmitted by each beam) and subject to increasing out of plane loads (see Figure 9c for the corresponding specimen type and Figure 9f for the corresponding DEM representation). The mechanism is characterized by a horizontal hinge in the upper portion of the panel, along the joints between the 15^{th} and 16^{th} block courses and it is almost coincident with the real mechanism obtained during laboratory tests; similarly, the collapse load is close to the one evaluated experimentally.

5 CONCLUSIONS

- In this contribution, the three-dimensional DEM introduced by Cecchi and Sab [7] for modelling regular masonry in the linear elastic field has been extended to the collapse analysis field by adopting a Mohr-Coulomb yield criterion and following the work of Orduña and Lourenço [8] for defining the interaction between interface shear forces, torsion and bending moments.
- The proposed nonlinear DEM for three-dimensional analysis turned out to be simple and effective in the determination of limit loads and collapse mechanisms of masonry panels having regular texture and dry joints, subject to self weight and out of plane loads.
- Several numerical tests reproduced the laboratory campaign carried out by Restrepo Vélez et al. [14], in this case the nonlinear DEM simulated correctly limit loads of the specimens taken into account. Moreover, considering collapse mechanisms, the ones relative to panels restrained by a lateral orthogonal wall have been reproduced correctly by the DEM, whereas small differences have been found in collapse mechanisms relative to panels restrained by orthogonal walls along panel lateral edges.
- Further developments of the model will regard the assessment of nonlinear analysis of more complex masonry specimens, characterized for example by blocks arranged irregularly, openings, lintels and also by real orthogonal walls and roofs.

Keywords: Masonry, URM walls, Equivalent-Frame models, seismic vulnerability.

Abstract. *In the last decades increasing attention has been devoted to masonry structures both from researchers and professionals. This is due to the awareness of the great importance of these structures in the historical urban context, together with the great risk that they suffer in seismic areas.*

Growing success has been obtained by a simplified approach that models masonry walls through "equivalent" plane frames, with concepts and procedures drawn from the study of reinforced concrete and steel frames. In this approach, known as Equivalent Frame Method (EFM), each masonry resisting wall is modelled as a system of linear (frame) elements representative of the behaviour of finite portions of the wall (pier and spandrel panels).

Up to now EFM has proven to be effective in the case of new buildings characterized by regular geometrical configurations and with openings' dimensions for which the frame-like assumption is suitable. Critical issues emerge from existing buildings in European historical centres, where irregularities are almost always present and geometrical anomalies can be detected even in the case of regular walls.

For the specific case of geometrically regular URM walls, this paper presents sample cases tested with linear and non-linear analyses, with the aim to explore the applicability of EF procedures and to identify its limits. A comparison between an EFM procedure with a fiber approach and a more detailed FEM method with plane elements, is adopted as a validation tool, to evaluate the accuracy of the results provided by the EFM for walls characterized by different geometrical configurations.

1 INTRODUCTION

Unreinforced masonry (URM) structures are a worldwide recurring element in the huge variety of building local traditions. Associated to different construction techniques and structural materials, URM buildings make up a large part of the built heritage, having at the same time an enormous cultural and historical value but also a high seismic vulnerability. In general, masonry structures were not designed for seismic resistance. Moreover, they may have had over the time modifications altering their structural performance and increasing their vulnerability.

With the aim to provide effective tools for the modelling of this heterogeneous set of existing structures, researchers and professionals have dedicated significant efforts to investigate the behaviour of masonry structures [1]. Among the various methods, the Equivalent Frame Method (EFM) has become one of the more successful ones due to its compromise between accuracy and efficacy [2-4].

EFM is a simplified modelling procedure based on the assimilation of masonry walls in-plane behaviour to a plane frame structure. In this approach, each resistant masonry wall is discretized in finite portions whose structural behaviour is simulated by means of one-dimensional beam elements connected to each other by fully rigid nodes.

The EFM has been employed till now both in the case of new and existing buildings. In the first case, the structure is characterized by regular geometrical configurations and by openings' dimensions such that the *frame-like* assumption is suitable for modelling the resisting walls. On the other hand, in the case of existing constructions, the structure may show significant irregularities making the *frame-like* assumption hard to be accepted. In addition to these geometrical aspects, the application of the EFM to existing masonry constructions faces critical points related to the quality of masonry materials, the presence of deformable diaphragms and the interaction with other structures in aggregate configurations.

Considering the great popularity of EFM in professional practice, there is the need to validate the EF approach by means of a numerical comparison with the more detailed FEM approach. In this paper the attention is focused on the regular geometrical configurations. For these types of walls the EF discretization is generally considered reliable and suitable. However, as discussed here, also in the case of regular URM walls it is possible to identify some limit cases that cannot be readily represented by the frame-like scheme.

2 EQUIVALENT-FRAME MODELS FOR URM WALLS

EFM is currently one of the most popular tools adopted for structural modelling of masonry structures in professional practice, due to its remarkable simplicity of application and interpretation of the results.

As it is well known, EFM is based on the discretization of each masonry wall in macro-elements, namely masonry panels distinguishable for mechanical and geometrical properties and modelled as beam-column elements connected by rigid nodes. The wall is studied as a plane frame, with a consequent remarkable reduction of the number of degrees of freedom and hence of the computational effort, with respect to more detailed and accurate methods, such as FEM.

The macro-elements discretization of masonry walls on which the EFM procedures is based is compatible with the observed damages suffered by masonry structures under seismic catastrophic events. It is in fact recurrent the concentration of damages in such parts of the wall modelled as deformable mono-dimensional elements (piers and spandrels). Only minor damage is usually observed in correspondence of the connection area between piers and spandrels (node panels), suggesting the idea of a greater strength and stiffness for these elements.

The accuracy of the EFM procedures is strictly connected to the capability to correctly simulate all the failure mechanisms and the damaging phenomena that can affect a masonry wall subject to in-plane actions, namely flexural and shear failure mechanisms.

However, and generally speaking, the EFM can be considered suitable and realistic only in the case of masonry walls characterized by a regular distribution of openings with "standard" dimensions. In these cases, the identification of the structural elements composing the ideal frame is straightforward, while in the case of walls characterized by an irregular arrangement of openings (irregular walls) or by very small windows, the definition of the frame configuration is more uncertain and problematic.

2.1 Discretization of walls in macro-elements and definition of their characteristic dimensions

In the EF idealization, masonry walls are considered as an assemblage of mono-dimensional structural components that can be geometrically identified by extending the contours of openings. In this way, it is possible to identify the following macro-elements (Figure 1):

- **Pier panels**: vertical structural panels whose function is to carry the gravitational and seismic actions and to transfer them to the foundation system;
- **Spandrel panels**: horizontal panels whose function is to transfer the floors' loads to the piers and to connect piers;
- **Node panels**, connecting spandrels and piers, modelled as fully rigid nodes.

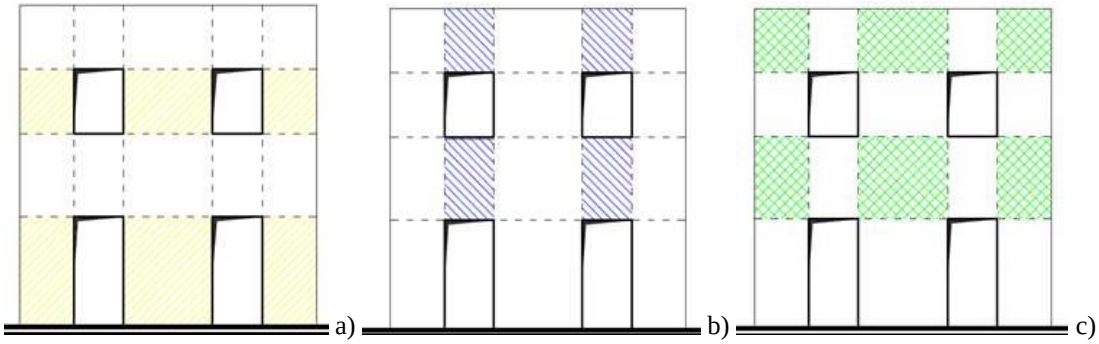

Figure 1: Identification of macro-elements in a masonry façade: piers (a), spandrels (b) and node panels (c).

Looking to the ideal frame configuration proposed in the EF approach, an important role in the walls' structural behaviour is played by spandrels. Such elements represent the horizontal resisting elements of the ideal frame configuration and can give an important contribution to the seismic performance of the wall by behaving as coupling elements and/or restraints for pier panels. The strength and stiffness of the spandrels, in fact, influence the mechanical behaviour of the adjacent piers, which can be modelled with static schemes ranging between the two extreme conditions of cantilever and double-fixed member. The activation of damaging mechanisms in the spandrels can also dissipate energy.

For what concerns the geometrical definition of spandrels, their characteristic width is usually assumed as equivalent to the average width of the openings that include it.

A more important role is played by pier panels, whose stiffness deeply influences the total stiffness and the global seismic behaviour of the wall. The definition of the effective height of the pier was actually one of the first important problems addressed in structural modelling of masonry buildings by the EFM.

The POR method [5] represents one of the first modelling procedures proposed for URM structures anticipating the EF approach, in which only the shear failure of piers is taken into account, with a simplified constitutive shear-deformation law. No clear rules are provided by the POR method about the piers' effective height, even though it strongly affects both their stiffness and shear strength.

A geometrical criterion was introduced by Dolce [2], taking into account the boundary conditions of each piers. The pier's behaviour and stiffness are in fact influenced by the mutual interaction with the surrounding spandrels and by their deformability.

Starting from these consideration and from a previous theoretical study carried out for coupling beams in reinforced concrete structures [6], Dolce proposed an empirical formula for the definition of the piers' effective height as a function of a geometrical parameter (*h'* in Figure 2a). This parameter is defined as the distance between the midpoints of the line connecting the vertices of two consecutive openings, fixing a limit value for the inclination of these lines equal to 30° [2]. The criterion proposed by Dolce was validated by numerical FEM simulation on different pier-spandrel systems. The formula provided by Dolce represents, with some simplifications, the main reference adopted in the most common EF methods actually available for structural modelling of URM structures [3, 4].

Recovering and updating the assumption of "strong spandrel and weak piers" contained in FEMA 356 [7], a different proposal was provided by Augenti [8] by assuming the piers' effective height equal to the height of the openings computed from the side of the earthquake loading. This assumption leads to the need for considering two different models for asymmetric walls, taking into account both the possible horizontal directions of the earthquake, as shown in Figure 2.

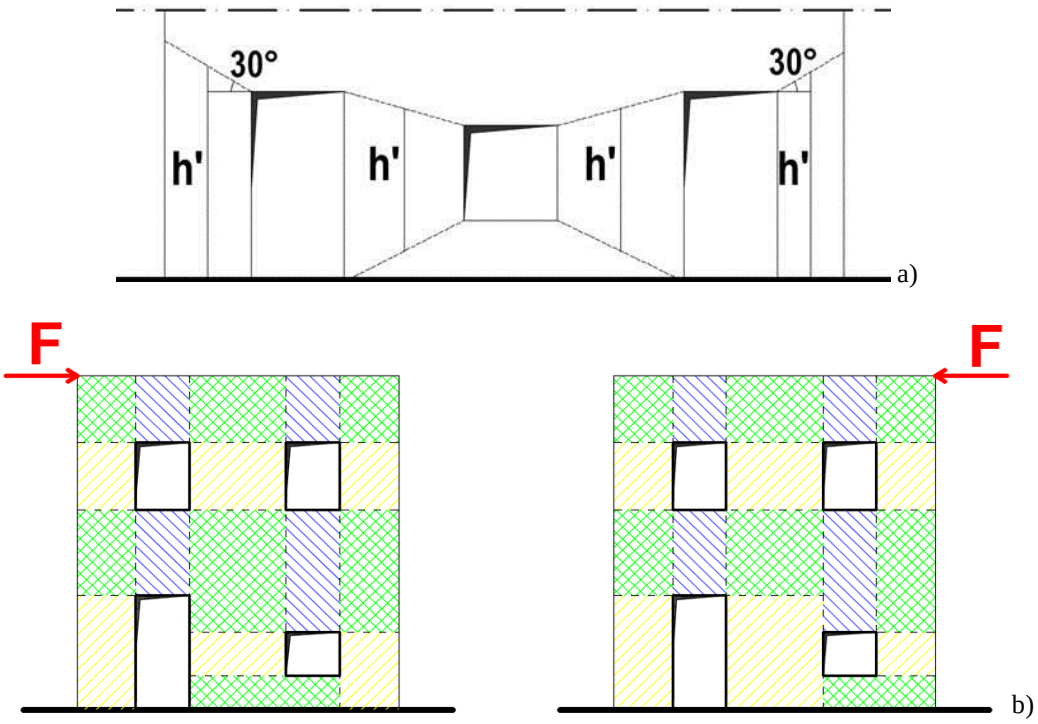

Figure 2: Proposals for piers' effective height by Dolce [2] (a) and by Augenti (b), as a function of the horizontal forces direction [8].

Augenti's proposal is based essentially on direct observation of recurrent damages and failure mechanisms caused by past earthquakes to ordinary masonry buildings. In most of the

cases it is usually possible to observe diagonal shear cracks starting from the corners of the openings, which suggest the idea of different structural responses depending on the direction of the seismic actions. This proposal was validated by experimental tests carried out on masonry building prototypes, whose damage patterns appeared in good agreement with Augenti's assumptions [9].

A comparative analysis between the two proposals for piers effective height has been recently presented by Marques and Lourenço [10]. They have compared the well-known EF methods and then tested on simple regular URM structures. In particular, non-linear static analyses have been carried out by the authors on a two-storey masonry wall by using several EFMs (SAM [4], 3MURI [3] and RAN [11]) related to Dolce's and Augenti's assumptions for piers' effective height and with different boundary conditions (double-fixed and cantilever schemes). The results of the analysis were compared in terms of capacity curves. The comparison showed an important aspect that has been confirmed in the present work. Augenti's assumption presents a better accuracy in evaluating the base shear capacity and the forces distribution among the vertical elements, while the global stiffness of the wall was is strongly overestimated. On the other hand, Dolce's approach obtaines better results for stiffness approximation, while base shear capacity is underestimated.

Due to the fundamental importance of the definition of piers' effective height for structural modelling of URM buildings, the assumptions provided by Dolce and Augenti have been taken into account in the present work and assumed as alternative criteria for the implementation of EF models. The aim of the present work is the evaluation of the accuracy of the EFM in simulating the structural behavior of regular masonry walls. For this purpose, some sample cases of regular masonry walls have been tested in linear and non-linear field. The models studied with EF approach have been modelled considering both the assumptions for piers' effective height formulated by Dolce and Augenti. The results have been compared with reference to corresponding FE models. This comparison gives the possibility to evaluate the effect of different geometric modellings of the piers on the results of the EF models.

2.2 Equivalent-Frame model with fiber approach

In the present work the EFM approach is implemented with a recent formulation for the mechanical characterization of walls' structural components, namely a fiber model initially implemented for reinforced concrete structures [12] and then extended also to URM structures [13]. Fiber approach represents in fact a good compromise between the accuracy of a tridimensional FE procedure and the computational convenience of a simplified uni-dimensional modelling approach.

Differently from other currently available EFM procedures, the use of the fiber approach allows the implementation of the non-linear behavior with a spread plasticity model.

The fiber model is based on the discretization of the beam elements' cross-section into longitudinal fibers, which allows the simulation of the flexural behaviour of the structural element by means of *ad hoc* non-linear constitutive $\sigma-\varepsilon$ laws. The fiber is assumed as having only axial deformation and, for this reason, with this model it is not possible to simulate the flexural and the shear behaviour at the same time. Given the importance of the shear failure mechanisms in masonry structures, the model has been therefore completed by introducing a non-linear spring with shear constitutive law into the fiber discretization [13].

The resulting model is composed therefore of three springs working in series. The central one is a non-linear spring calibrated according to a multi-linear V-γ law, to simulate the possible shear mechanisms than can affect masonry panels, i.e. diagonal cracking and shear sliding. The two extreme springs are defined by fiber discretization, so by means of a spread

plasticity model. For what concerns the simulation of the flexural behaviour, the uniaxial constitutive law provided by Kent and Park [14] has been adopted.

The models adopted in the present work for non-linear simulations have been implemented in the software Midas GEN © [15], where it is possible to combine the fiber discretization of beam elements with non-linear springs simulating shear constitutive laws.

3 REGULAR AND FRAME-LIKE MASONRY WALLS

The concept of structural regularity is usually referred to the global configuration of the structures. Making reference to the prescriptions provided by the Italian technical code [16], a generic construction can be defined regular if it fulfils requirements based on the stiffness, geometrical and inertial properties of the whole structural system.

In the case of URM buildings, namely structural systems composed by the intersection of vertical load-bearing walls and horizontal slab diaphragms, the global seismic performance is strongly dependent on the in-plane response of the single load-bearing walls, once ensured a low probability of activation of out-of-plane failure mechanisms. In this case, the global seismic vulnerability of a URM building is due to the in-plane performances of its load-bearing walls, each of them working for the horizontal forces transferred by the slab diaphragms. As a consequence, it is important to extend the concept of regularity to the single load-bearing wall and in particular to such structural features that can affect its in-plane response. The definition of regularity adopted in this work is therefore a purely geometrical concept referred to the configurations of single masonry walls. The arrangement of the openings in a URM wall is strictly connected to the definition of regularity. A URM wall can be defined regular if its openings are perfectly aligned in both vertical and horizontal directions [17], as for the sample schemes of Figure 3.

As already explained in section 2, the EFM is essentially based on the identification between a single load-bearing wall and an ideal plane frame. In this sense, it is possible to distinguish between configurations that appear clearly consistent with the frame idealization, here denoted as “frame-like”, and configurations for which the affinity with a frame system may be questionable, namely “non-frame-like” ones.

Two schemes are reported in Figure 3 to clarify the distinction between *frame-like* and *non-frame-like* walls, with reference to a two-story masonry wall. Both the sample schemes fulfill the definition of regular wall. However, only the scheme of Figure 3a is characterized by piers and spandrels having geometrical properties compatible with the assumption of mono-dimensional elements. For this scheme a good degree of affinity with a plane frame can be recognized, so the definition of *frame-like* is suitable to describe its configuration.

On the contrary, the extremely small dimensions of the windows in the scheme of Figure 3b induce anomalies in the geometrical properties of piers and spandrels. This scheme appears strongly in contrast with the frame idealization and hence with the previous definition of *frame-like* masonry walls.

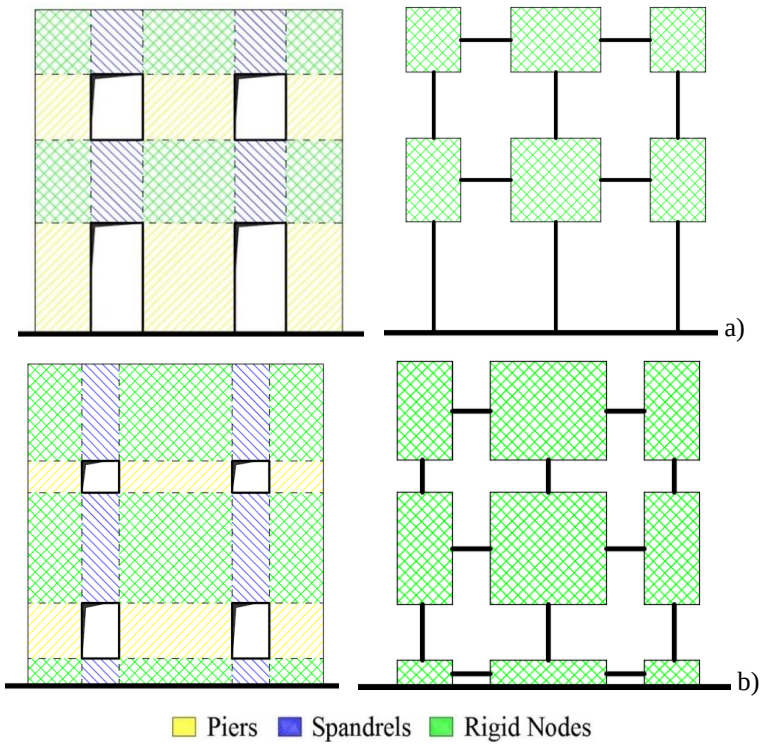

Figure 3: Identification of the equivalent-frame model for *frame-like* (a) and *non-frame-like* (b) URM walls.

4 NUMERICAL VALIDATION OF EQUIVALENT-FRAME METHOD FOR URM WALLS

This section discusses the accuracy of EFM for regular URM walls depending on their geometry. The study is part of a wider research on regular and irregular walls characterized by an increasing level of complexity [18]. The first results are discussed here with reference to the models introduced in Figure 4. Both the walls have been submitted to a linear static analysis under the same loading, mechanical and boundary conditions. A distribution of horizontal loads proportional to the first mode of vibration has been computed and distributed over the nodes of the wall in order to avoid any stress concentration.

The EF models have been built using the two aforementioned approaches for piers' effective height, i.e. the modelling scheme by Dolce [2] and the scheme of "strong spandrel and weak piers" by Augenti and co-workers [11].

The results given by the EF and FE models have been compared in terms of forces and displacements. The base shear reactions and the absolute horizontal displacements have been assumed for comparisons because of their importance in the evaluation of the wall's structural performance. The percentage difference between the predictions provided by EF models and by FE models, in terms of reactions and displacements, has been assumed as a measure of the accuracy of EFM in simulating the actual structural behaviour of URM walls.

Figure 4 shows the percentage differences between EF and FE results for the two sample schemes with regards to the base shear and the top displacement of one of the external piers of the wall.

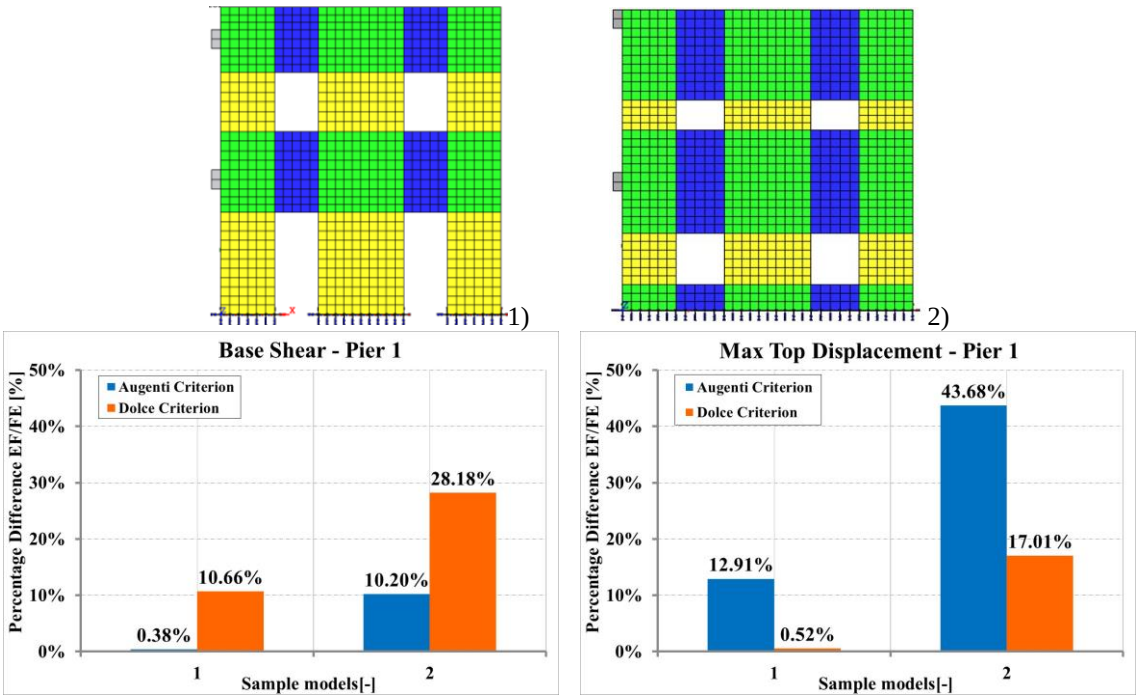

Figure 4: Percentage difference between EF and FE predictions of Base Shear and top Displacement for a frame-like (1) and a non-frame-like (2) URM wall.

Given the strong non-linearity of masonry structures, the validation of a numerical approach for the structural modelling of such structures cannot be limited only to the linear field. Masonry structures show in fact a non-linear behaviour also under low states of stress. Although the study of linear models can be helpful to check the capability of a numerical simulation to predict the elastic stiffness and the distribution of internal forces induced by gravitational loads, it is necessary to extend the study also to the non-linear field in order to have a complete overview of the critical points affecting the modelling method under consideration. For this reason, a non-linear analysis of the same regular schemes has also been performed. The results provided by FE models have been assumed as reference for the evaluation of the EFM accuracy. The FE models have been defined as two-dimensional systems composed by plane-stress rectangular elements implemented in MIDAS FEA © [15].

For what concerns the mechanical characterization of masonry non-linear behaviour, in the EF approach a fiber discretization has been adopted to simulate the flexural behaviour of the uni-dimensional beam elements (piers and spandrels). A non-linear element, located in the midsection of each structural element, has been also added to simulate the two possible shear mechanisms than can affect the masonry panels, i.e. diagonal cracking and shear sliding [13].

The definition of loading conditions has been made by steps, separating the application of gravitational and horizontal loads in both the modelling procedures adopted. An initial loading step has been defined to apply gravitational loads, that have been introduced by assuming a unit weight equal to γ =18.0 kN/m^3 and a slab load equal to 15.90 kN/m for both the levels. A second loading step has been defined to apply horizontal actions directly on the deformed shape obtained at the end of the first loading step. A monotonic incremental time function has been used to apply a distribution of horizontal forces proportional to seismic masses. Finally, a displacement controlled procedure has been adopted to carry out the non-linear static analysis by assigning the value of the horizontal displacement for a control node located at the second floor level of the wall. The iterative solution procedure applied is based on the "initial stiffness" method.

Figure 5 shows the comparison of the capacity curves obtained by the EFM and FEM approaches for the two sample schemes under consideration.

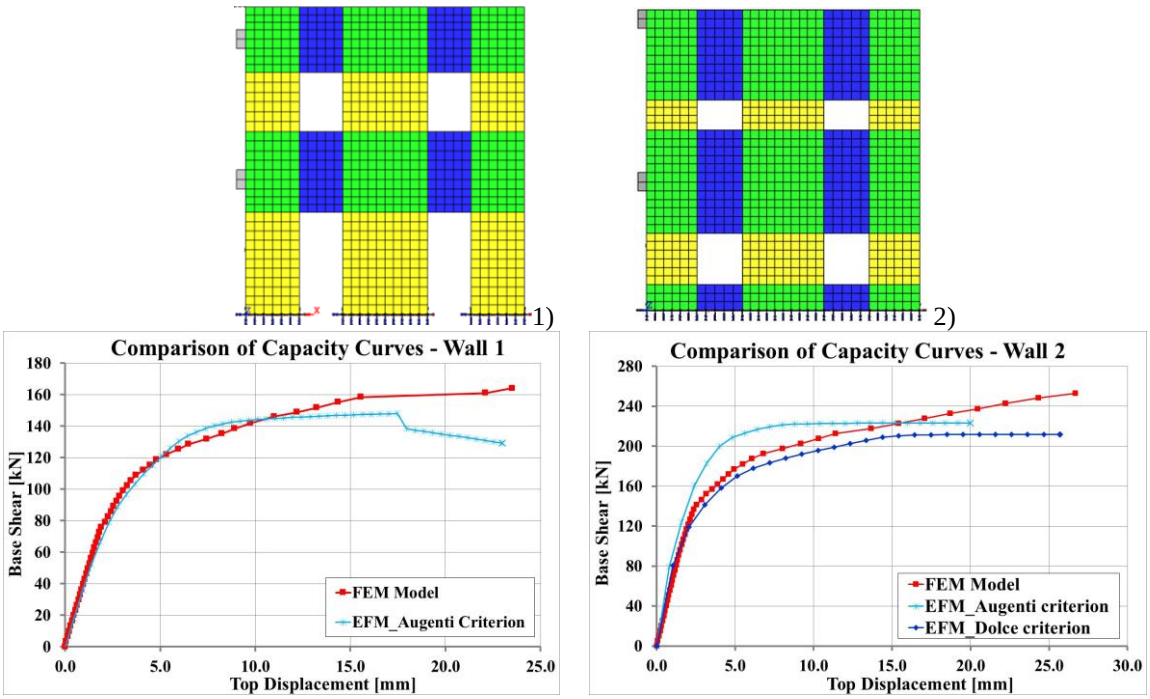

Figure 5: Comparison of the capacity curves obtained with EF and FE models for a frame-like (1) and a non-frame-like (2) URM walls.

4.1 Discussion of results

The two sample schemes analysed in this work show different levels of similarity with the ideal configuration of a frame structure. In particular, the analogy with a frame seems hardly applicable in the case of the second scheme. According to the distinction between *frame-like* and *non-frame-like* walls introduced in Section 3, the results obtained in both the linear and non-linear fields confirm that a regular geometry is not sufficient to justify the assumption of the EF discretization in the modelling of URM walls. As expected, the percentage differences associated to EF models predictions, with respect to FEM results, tends to increase for the second wall.

Figure 4 shows the different level of accuracy that characterizes the two assumptions for the piers' effective height in the EF models, namely the Dolce's and the Augenti's criteria (Section 2.1). As already observed by Marques and Lourenço [10], the criterion adopted by Augenti estimates better the actual distribution of forces among piers than the criterion provided by Dolce. As for the prediction of the base shear, the models defined according to Augenti's criterion provide percentage differences up to 10% with respect to the corresponding FEM results. An opposite trend is shown by the models defined according to Dolce's criterion. For such models a negligible error can be recognized with respect to FE models in the horizontal displacements predictions, while the difference increases significantly for what concerns the forces distributions among the piers.

Such observations about the prediction of shear distributions and horizontal displacements are confirmed by the theoretical bases of the two criteria. The rule provided by Dolce [2] to define the effective piers' height, in fact, is derived by equivalent stiffness considerations among EF and FE models. The effective height of masonry piers was defined following a principle of statistic equivalence between the elastic stiffness expressed by EF and FE models

for several examples of pier-spandrel modules. On the other hand, Augenti's criterion is tailored on observed damage and therefore provides better results for the evaluation of the strength.

The observations made in linear field have been generally confirmed also by the non-linear analyses, although the differences between the results provided by EF models and the FE ones are smaller in the non-linear cases. The higher accuracy shown by the EF approach in the non-linear field demonstrates a better performance of the approach in reproducing the redistribution of forces among the structural elements as a consequence of incremental damaging conditions.

5 CONCLUSIONS

This work presents a comparison between Equivalent Frame Method (EFM) and FEM in the simulation of URM existing buildings. The accuracy of EFM is treated as a function of the degree of similarity between the effective masonry wall's geometry and an ideal frame configuration. A distinction between *frame-like* and *non-frame-like* configurations is introduced with the aim to delimit the set of URM walls' configurations for which EFM approach can be applied.

Two sample URM walls are considered, in order to provide a measure of the EFM applicability. For both walls the definition of regular configuration can be assumed, i.e. a configuration characterized by openings aligned in both horizontal and vertical direction, but they differ in terms of "frame-like" or "non-frame-like" geometry. A comparison is discussed between EFM and FEM results for both models, with the purpose of measuring the applicability of EFM with respect to the predictions provided by the more detailed FE models.

The models are investigated using both linear and non-linear static analyses. The results of these analyses, expressed in terms of shear distributions and displacements, are compared with predictions provided by FE models. The study shows that the differences in results by EF and by FE models increase as the URM walls and the frame schemes are unlike.

The effects of different assumptions for the definition of the piers' effective height are also evaluated following the procedures proposed by Dolce [2] and Augenti [11]. Augenti's criterion shows a greater accuracy in predicting the distributions of shear forces among the piers. On the other hand, Dolce's criterion yields more accurate predictions of the horizontal displacements.

The models presented in this work are part of a broader research [18] aimed at exploring the range of applicability of EF procedures in the case of regular and irregular URM walls. In particular, it is aimed at further verifying the capability of EFM to simulate the main irregularities that can affect the in-plane structural behaviour of existing URM walls, such as those caused by misalignments of the openings or anomalies in their dimensions.

ACKNOWLEDGEMENTS

CSP Fea is deeply acknowledged for providing the software MIDAS Gen© and MIDAS Fea© [16] used in this work for the implementation of the numerical models.

The financial support of University "G. D'Annunzio" of Chieti-Pescara (MIUR ex 60% funds) is acknowledged by the authors. Partial support by the ReLUIS program 2014-2016 is also acknowledged by the authors.

Keywords: Masonry towers, FE model, non-linear dynamic analysis, pushover analysis.

Abstract. *In the present paper a comprehensive seismic vulnerability assessment of several historical masonry towers, mainly built during the medieval age and located in the North-East region of Italy, is carried out by means of simplified and advanced FE approaches. Three-dimensional finite element models of the masonry towers are created on the basis of geometrical data deduced from both existing available documentation and in-situ surveys. Nonlinear static (pushover) and dynamic full 3D analyses are carried out to investigate the seismic performance of the towers. A comparison between non-linear dynamic analyses and non-linear static procedures, even at a global level, can provide useful information about the seismic vulnerability of such type of structures. Numerical results provide an accurate understanding of the behavior of the towers under horizontal loads and highlight the effects of some geometrical features, such as slenderness, thickness of the perimeter walls, presence of perforations, internal vaults, irregularities and inclination.*

1 INTRODUCTION

The protection of historical masonry constructions against seismic actions is of strategic importance in many European countries, especially in Italy, which are prone to earthquakes. Ancient masonry towers are widely disseminated in Italy and represent one of the main elements of the local cultural heritage. In ancient times these structures were usually conceived mainly to resist vertical loads and are particularly vulnerable to earthquakes because of the limited ductility of masonry combined with the slenderness of the towers that are sometimes characterized by complex geometry and irregularities. The axial stresses due to gravity loads could be of the same order of magnitude as the compression strength of the old masonry and, when combined with the dynamic loads induced by earthquakes, can produce heavy damage and even local collapse. The prediction of the seismic response of historical masonry buildings represents a crucial issue and a challenging research item. An effective seismic vulnerability assessment of such structures can be obtained through non-linear dynamic and static analyses by means of suitable finite element (FE) models. In recent times, national and international codes have imposed the evaluation of the structural performance under horizontal loads, encouraging the use of sophisticated non-linear methods of analysis.

The paper, which can be considered as a thoughtful collection of case studies useful to infer general considerations, presents a comprehensive numerical study on the seismic performance assessment of eight historical masonry towers located in the North-East region of Italy. The towers exhibit different geometrical characteristics in terms of slenderness, cross-section area, openings, wall thickness and internal irregularities, but they are built with similar technologies and masonries presenting similar mechanical properties. Their structural behavior under horizontal loads may be therefore thought to be influenced mainly by geometrical issues.

Detailed three-dimensional finite element (FE) numerical models are created through the software package Abaqus to represent the geometry of the towers. The main geometrical features of the towers are deduced from both existing available documentation and in-situ surveys. The evaluation of the seismic response of the historical masonry towers is carried out through non-linear dynamic analyses. A damage plasticity material model, exhibiting softening in both tension and compression, already available in the commercial code Abaqus, is used for masonry. The seismic performance assessment of the towers is carried out in terms of displacement time-history and tensile damage distribution. The effects of different geometrical characteristics and local irregularities on the seismic response of the towers are investigated.

A non-linear static procedure based on pushover analysis is also used for the seismic vulnerability assessment of the masonry towers. The results obtained by the two methods are compared in order to verify whether the simplified approach may represent the seismic behavior of the towers. A comparison between non-linear dynamic analyses and non-linear static procedures, even at a global level, can provide useful information about the seismic vulnerability of the towers.

2 TOWERS UNDER STUDY AND FE MODELS

This section provides a concise overview of the main geometrical features of the towers under study, along with some rough details on the FE discretization adopted. The elevation views and the FE models of the eight towers are presented in Figure 1 and Figure 2. The FE models of the eight towers (bell, clock or battle towers) are created directly in the commercial code Abaqus. Three-dimensional elements are used to model masonry, with different material properties where necessary, to suitably take into account the presence of infill over the vaults

or the possible central layer in multi-leaf walls. The choice of the element size is done in order to share the advantages of sufficiently reliable results and numerical efficiency during the non-linear dynamic analyses that usually needed very long time to be performed, even in workstations with large RAM. A preliminary size equal to 0.4-0.5 m is chosen for the sides of the 3D elements, with local or global refinements, depending on the specificity of the structure. Still, reasonable values of the mesh distortion are obtained, with a worst aspect ratio ranging between 2 and 3.

3 MATERIAL MODEL

The 3D FE models of the towers are implemented into Abaqus taking into consideration geometrical (large displacement effects) and material non-linearity by means of the Concrete Damage Plasticity (CDP) model, fully available in the standard package.
Concrete Damage Plasticity model is based on the assumption of a scalar isotropic damage with distinct damage parameters in tension and in compression. It is particularly suitable for applications in which the material exhibits damage, especially under loading-unloading conditions, and therefore for seismic analyses. A different inelastic behavior in tension and compression is then introduced.
To describe the multi-dimensional behavior in the inelastic range, masonry is assumed to obey a Drucker-Prager strength criterion with non-associated flow rule. The strength domain is a standard Drucker–Prager surface modified by means of the so-called K parameter, representing the ratio between the second stress invariant on the tensile meridian and that on the compressive meridian. This parameter is set equal to 0.666 in the numerical simulations.
A value equal to 10° is adopted for the dilatation angle, which seems reasonable for masonry subjected to a moderate-to-low level of vertical compression. This value is in agreement with experimental evidences available in the literature. To avoid numerical convergence issues, the tip of the conical Drucker-Prager strength domain is smoothed using a hyperbola. Abaqus code allows for smoothing the strength domain by means of the so-called eccentricity parameter, which represents the distance between the points of intersection with the p-axis of the cone and the hyperbola in the p-q plane, where p is the hydrostatic pressure stress and q is the Mises equivalent stress. A value equal to 0.1 is adopted for the eccentricity parameter in the numerical simulations.
The available experimental results on regular masonry wallets show a moderate orthotropy ratio (around 1.2) under biaxial stress states in the compression-compression region. Obviously, such feature cannot be taken into account when an isotropic model, like the present one, is utilized. However, it is commonly accepted in the literature the utilization of isotropic models (like concrete smeared crack approach available in both Ansys and Adina) after an adaptation of the parameters to fit an average behavior between vertical and horizontal compression. A suitable model should also take into account the ratio between the ultimate compression strength in biaxial stress states and in uniaxial conditions. Such a ratio, which exhibits similar values for concrete and masonry, is reasonably set equal to 1.16.
The final stress–strain relationship in tension adopted for the dynamic analyses follows a linear-elastic branch up to the peak stress σ_{t0}. Then, micro-cracks start to propagate within the material, leading to a macroscopic softening. In compression, the response is linear up to the yield stress σ_{c0}. Then, a linear hardening is assumed up to the crushing stress σ_{cu}, followed by a linear softening branch.
The damage variables in tension d_t and compression d_c are defined by means of the following standard relationships:

$$\begin{aligned} \sigma_t &= (1-d_t)E_0\left(\varepsilon_t - \varepsilon_t^{pl}\right) \\ \sigma_c &= (1-d_c)E_0\left(\varepsilon_c - \varepsilon_c^{pl}\right) \end{aligned} \quad (1)$$

where $\sigma_t(\sigma_c)$ is the uniaxial tensile (compressive) stress, E_0 is the initial elastic modulus, ε_t (ε_c) is the uniaxial total strain in tension (compression), $\varepsilon_t^{pl}(\varepsilon_c^{pl})$ is the equivalent plastic strain in tension (compression). In the present study, only tension damage is assumed to be active, because the adopted tensile strength of the material is significantly lower than the compressive strength. When the strain reaches a critical value, the material starts to degrade

showing, in the unloading phase, a modulus equal to $E < E_0$. In particular, in the numerical simulations conducted in this study a reduction equal to 5% of the Young modulus with respect to the initial value is assumed for a plastic deformation equal to 0.003.

.

4 ANALYSES PERFORMED

Two different numerical approaches, namely non-linear static procedure based on pushover analyses and non-linear dynamic analyses, are carried out in this study, with a level of numerical complexity that can be considered ranging from moderately high to high in common design practice.

4.1 Non-linear dynamic analyses

The real accelerogram registered in Mirandola on the 20th of May 2012 during the Emilia-Romagna seismic event is used to investigate the seismic response of the towers under study. The accelerogram is appropriately scaled in order to obtain two acceleration time histories with different values (0.1g and 0.2g) of the peak ground acceleration (PGA). Figure 3 shows the acceleration time history with PGA=0.1g along with some meaningful instants identified with different letters and colors.

The dynamic analyses are performed applying the accelerogram, separately, along the two principal (X and Y) directions of each tower. The horizontal displacement time histories of some control points, normally the nodes at the top of the towers, along with the damage state at the end of the simulations, are used to qualitatively determine if the structure is in a state of incipient collapse or not.

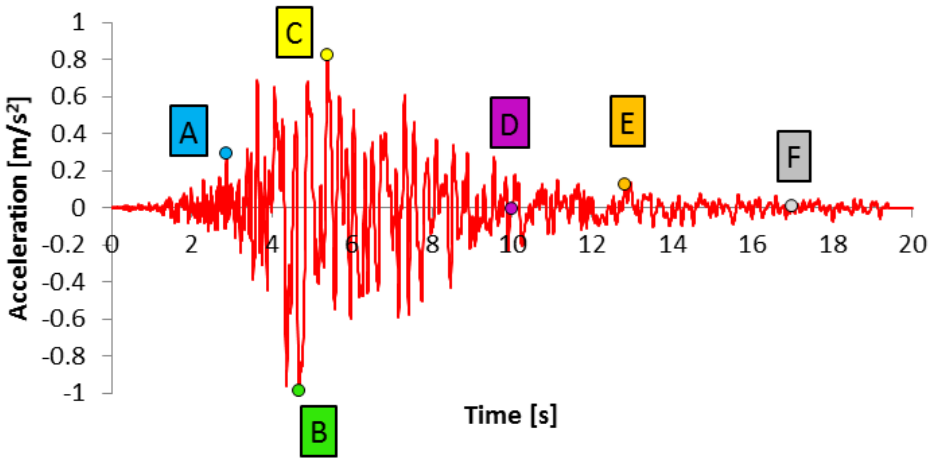

Figure 3: Scaled real accelerogram used in the non-linear dynamic analyses and meaningful points used to evaluate the state of damage of the towers under study.

4.2 Simplified procedure based on pushover analysis

A simplified assessment procedure is also adopted for the seismic verification of the global structural behavior of the towers under study. The procedure was developed at the University of Ljubljana by Fajfar and is based on pushover analyses and on inelastic demand spectrum. This simplified method of analysis is an effective technique for the seismic assessment of existing structures and combines pushover analysis of a multi-degree-of-freedom (MDOF)

model with the response spectrum analysis of an equivalent single-degree-of-freedom (SDOF) model. The method is formulated in the acceleration-displacement (AD) format, which enables the visual interpretation of the results. By means of a graphical procedure, the capacity of a structure is compared with the demand of an earthquake ground motion on the same structure, Figure 4.

The capacity of the structure is represented by a force-displacement curve obtained by non-linear static analysis. The capacity curve of the structure is transformed into the capacity curve of an equivalent SDOF system by means of the transformation factor $\Gamma = \sum m_i \phi_i / \sum m_i \phi_i^2$, where ϕ_i is the i^{th} component of the eigenvector $\mathbf{\Phi}$ deduced from modal analysis and m_i is the mass of the node i. The capacity curve of the equivalent SDOF system is then reduced to a bilinear elastic-perfectly plastic force-displacement diagram on the basis of the equal energy concept (the areas underneath the actual and bilinear curves are approximately the same, within the range of interest).

The displacement capacity corresponds to the end point of the bilinear curve. The inelastic demand in terms of accelerations and displacements is provided by the intersection point of the capacity curve with the demand spectrum corresponding to the ductility demand μ, as schematically shown in Figure 4. In this study, the seismic demand is computed with reference to the Eurocode 8 response spectrum (soil type C). The theoretical predictions are performed for Sa_g levels equal to 0.1g and 0.2g. The displacement demands refer to the equivalent SDOF system. The displacement demands of the structure are obtained by multiplying the displacement demands of the SDOF system by the transformation factor Γ. Seismic assessment is performed by comparing displacement capacity and demand. The main results of the non-linear static procedure are reported for a direct comparison with the results of the non-linear dynamic analyses.

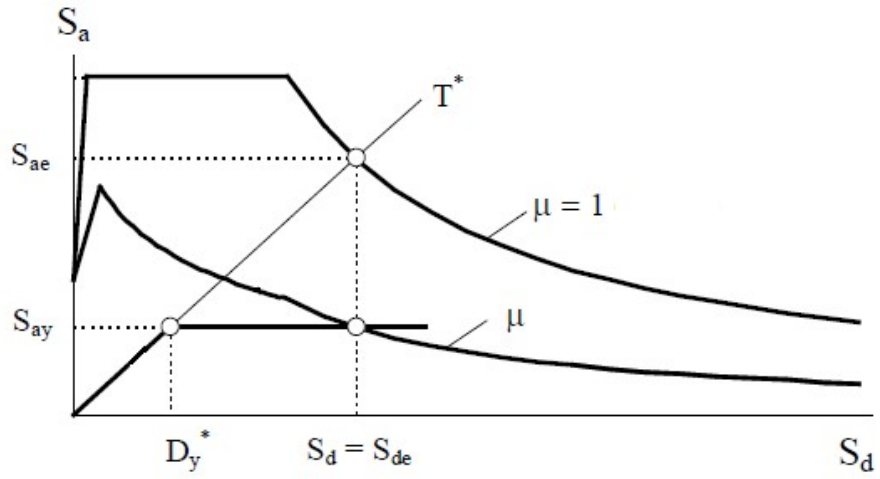

Figure 4. Elastic and inelastic demand spectra versus capacity diagram in acceleration-displacement (AD) format.

5 RESULTS OF NON-LINEAR DYNAMIC ANALYSES

It can be roughly stated that if a residual deformation, defined as the ratio between the horizontal inelastic residual displacement and the height of the tower, ranging between 0.4% and 0.8% is reached, the structure may be reasonably considered in incipient state of collapse. Values of 0.4% and 0.8 % of residual deformation are taken with reference to masonry piers behavior at failure under in-plane bending and shear, respectively, in agreement with Italian

code specifics. While such a choice is rather debatable, because masonry towers can be hardly thought to behave as single piers, it is probably the only quantitative indication that can be attempted in this case.

The inelastic residual deformations obtained for all the cases investigated are synoptically shown in Figure 5, where threshold values of 0.4% and 0.8% are also indicated. The maximum values of the top displacements normalized to the height of the towers are summarized in Figure 6.

From an overall analysis of the results of the dynamic simulations with two different PGAs, the following remarks may be drawn.

Under seismic excitation with PGA=0.1g, it can be noted that Tower I, Tower II, Tower III, Tower IV and Tower VIII exhibit values of residual deformations smaller than 0.4% of the height. It can be observed that the values of residual deformation are critical (within 0.4%-0.8%) for Tower VI and Tower VII; Tower V can be considered as prone to collapse. These results are confirmed in terms of non-dimensional top displacements.

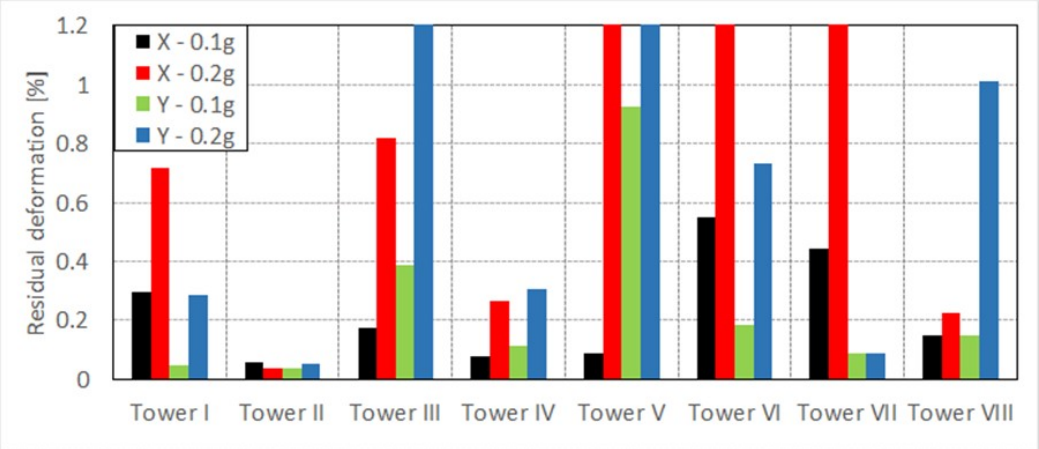

Figure 5: Non-linear dynamic analyses: residual deformations at PGA=0.1g and PGA=0.2g in the X and Y directions for the different towers.

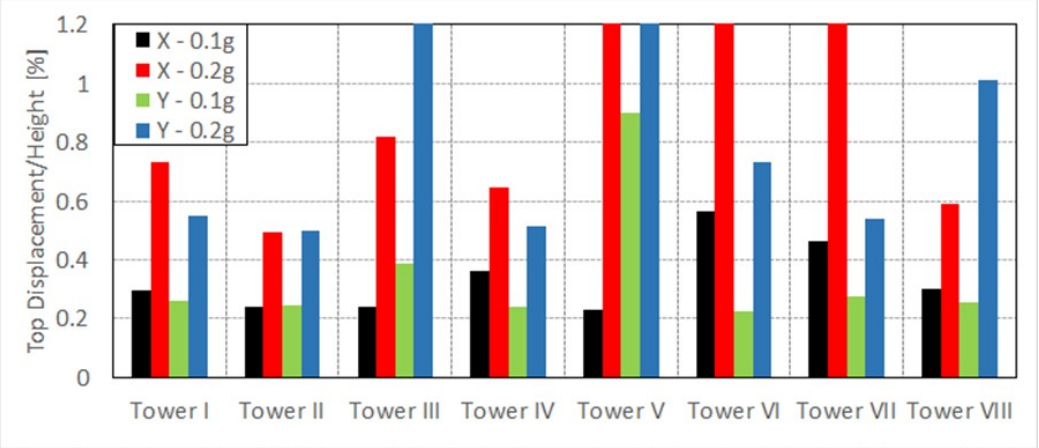

Figure 6: Non-linear dynamic analyses: maximum normalized top displacement (top displacement/height) at PGA=0.1g and PGA=0.2g in the X and Y directions for the different towers (values of normalized top displacements are interrupted at 1.2%).

Under seismic excitation with PGA=0.2g, basing on the criterion of inelastic residual deformations, a collapse mechanism is activated for Tower III, Tower V, Tower VI, Tower VII and Tower VIII. The values of residual deformations are critical (within 0.4%-0.8%) for

Tower I; Tower II and Tower IV exhibit acceptable residual deformations (smaller than 0.4% of the height). These results are confirmed in terms of normalized top displacement, but also Tower II and Tower IV present non-dimensional top displacement within 0.4%-0.8%.

6 SIMPLIFIED PROCEDURE BASED ON NON-LINEAR STATIC ANALYSES

The results of the non-linear static procedure in the acceleration-displacement response spectrum plane are illustrated in Figure 7. The capacity curve of the equivalent SDOF system, transformed in a bilinear curve, is reported and the seismic demand corresponds to two values of the effective peak ground accelerations equal to Sa_g=0.1 and Sa_g=0.2g; for the sake of clarity, only the elastic demand spectrum is shown. The seismic vulnerability is evaluated by comparing the displacement demand and the displacement capacity obtained through the pushover analyses. The displacement capacity and demand in the X and Y directions are then summarized for the towers under study in Figure 8 and Figure 9 for two different seismic intensity levels.

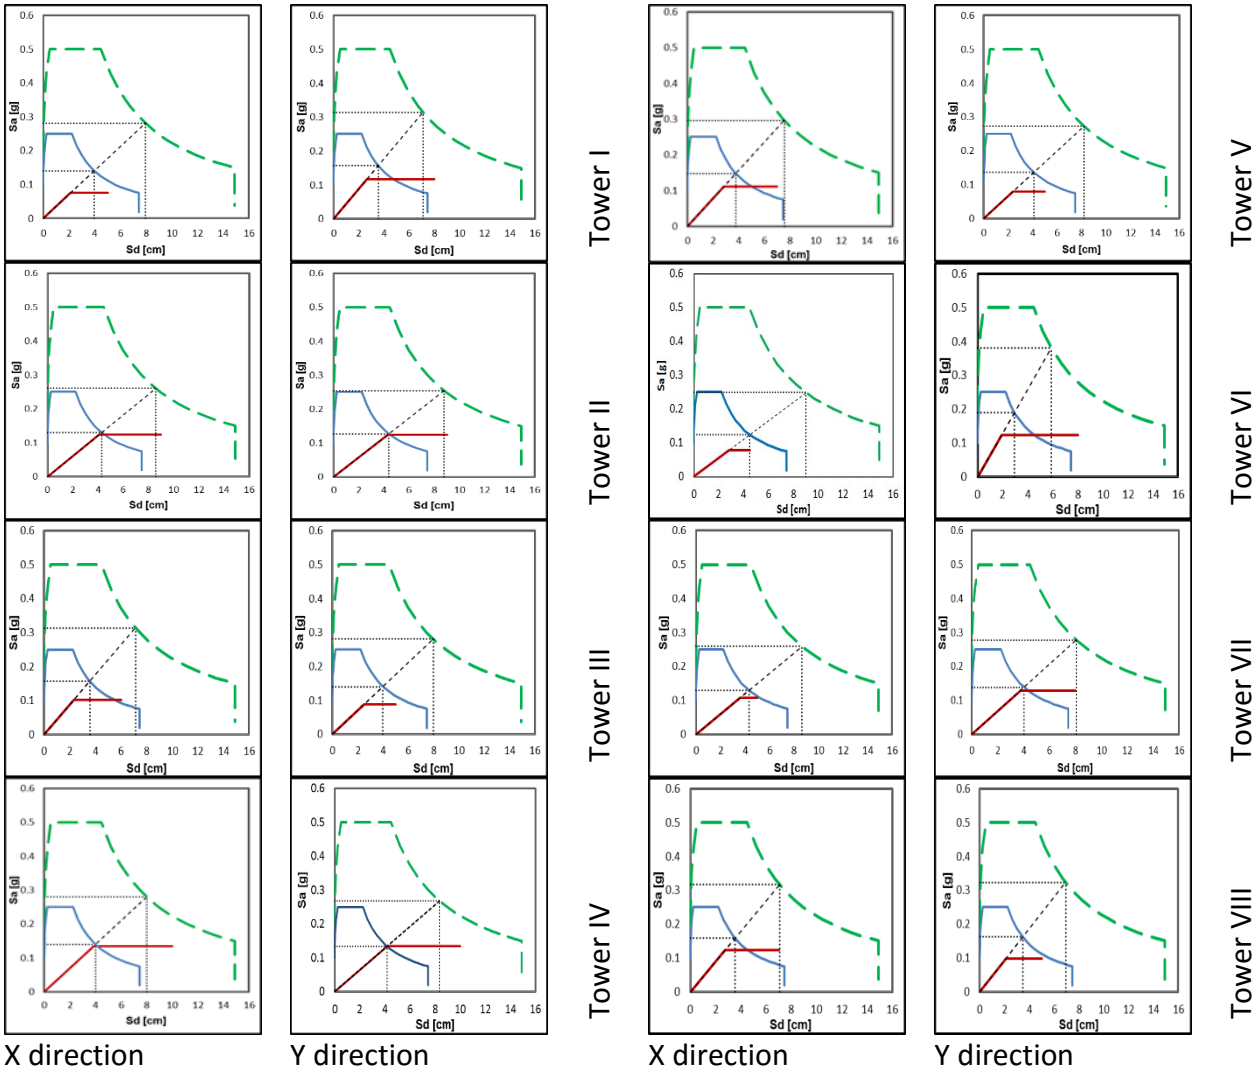

Figure 7: Non-linear static procedure in the acceleration-displacement response spectrum plane (X and Y directions) for different seismic intensity levels: Sa_g=0.1g (continuous blue line) and Sa_g=0.2g (dashed green line).

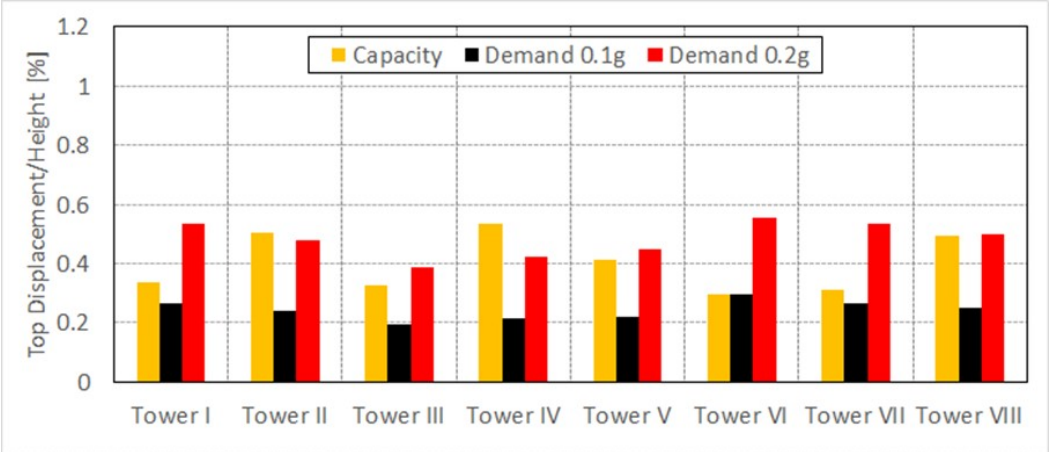

Figure 8: Non-linear static procedure, X direction: displacement capacity and displacement demand at different seismic intensity levels for the different towers.

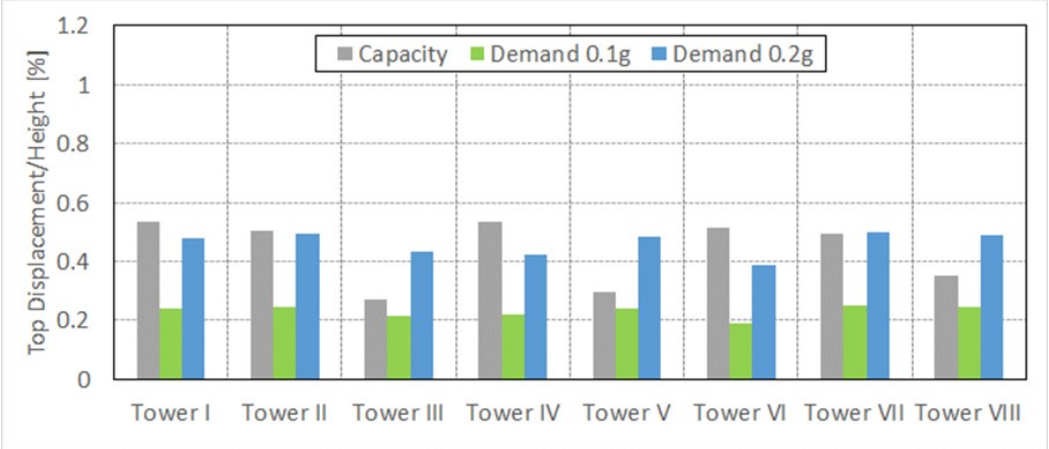

Figure 9: Non-linear static procedure, Y direction: displacement capacity and displacement demand at different seismic intensity levels for the different towers.

The results obtained from the non-linear static procedure are also synoptically summarized in Table 1 for a direct comparison with the outcomes of the non-linear dynamic analyses. As can be noted, the seismic safety assessment provided by the two methods is very similar for almost all the towers, in some cases with a very satisfactory agreement. The non-linear static procedure may provide reasonable synthetic predictions of the seismic vulnerability of the towers. A slightly more conservative trend for the non-linear dynamic simulations can be noticed after a detailed analysis of individual cases. The non-linear static procedure provides smaller values of displacement demand than those resulting from the non-linear dynamic analyses. The simplified static approach is not able to capture the inertial effects associated with seismic excitation that can lead to heavy damage and premature collapse of the structure.

7 DISCUSSION OF RESULTS

7.1 Comparison between the procedures

The displacement demands obtained by the non-linear static procedure are in a good agreement with those obtained by the non-linear dynamic analyses when the check of the structural safety is verified. When the check is not satisfied according to the non-linear static procedure, the seismic demand is smaller than the maximum value of the top displacement

experienced by the structure during the non-linear dynamic analyses. In the majority of cases this result can be explained by the large increase of the displacements registered in the non-linear dynamic analyses when a collapse mechanism occurs. From an overall analysis of the results, it can be noted that the non-linear static procedure generally gives reliable results in terms of displacements. Large differences are observed in the cases of Tower V and Tower VI, where local collapse mechanisms are registered during the non-linear dynamic analyses and for this reason the displacement distribution differs significantly. In the case study of Tower V, the non-linear static procedure does not catch the collapse of the upper vaults, which is registered at the end of the non-linear dynamic analyses. In the case study of Tower VI, a local collapse of the upper part of the thin wall is clearly observed during the non-linear dynamic analysis: moreover the presence of this type of irregularity triggers non-uniform displacement demands at the top of the structure. Non-linear dynamic analyses are able to account for higher mode effects that may be introduced by local irregularities.

Table 1. Comparison on the collapse state of the towers evaluated through the non-linear static procedure and the non-linear dynamic analyses: X and Y directions, PGA=0.1g and PGA=0.2g.

	X direction				***Y direction***			
Collapse √ YES × NO √/× Borderline	Non-linear static procedure		Non-linear dynamic analysis		Non-linear static procedure		Non-linear dynamic analysis	
Tower	PGA 0.1g	PGA 0.2g	PGA 0.1g	PGA 0.2g	PGA 0.1g	PGA 0.2g	PGA 0.1g	PGA 0.2g
I	×	√	×/√	√	×	×	×	×/√
II	×	×	×	×	×	×/√	×	×
III	×	√	×	√	×	√	×/√	√
IV	×	×	×	×/√	×	×	×	×/√
V	×	√	×	√	×	√	√	√
VI	×/√	√	√	√	×	×	×	√
VII	×	√	×/√	√	×	×/√	×	×
VIII	×	×/√	×/√	×/√	×	√	×	√

The tensile damage distribution corresponding to the displacement demand is generally similar to the damage pattern observed at the end of the non-linear dynamic analyses, but the numerical values of damage are always smaller. The only exception is the severe damage observed at the base of the towers during the pushover analyses: it is less evident at the end of the non-linear dynamic analyses. However, the damage pattern detected by the pushover analysis can represent a good indicator of the vulnerable parts of the structure.

The choice of the control point, representative of the global behavior of the structure, is a fundamental issue for the application of the non-linear static procedure. The results of the procedure significantly depend on the selection of the control point and, in some cases, show quite large variations. Therefore, the results obtained by the non-linear static procedure should be evaluated with caution in function of the control point chosen for the procedure. This result is proven by the study of the Tower VI, where torsional effects are evident. It is shown that the results obtained with a control point which is not part of the local collapse overestimate the capacity of the structure. On the contrary, if a point belonging to the vulnerable part of the structure is chosen as a control point, the results underestimate the capacity of the structure.

The non-linear static procedure can give a satisfactory representation of the seismic behavior of the towers in terms of structural safety verification and displacement demands when significant irregularities are not present. In slender towers with presence of irregularities the contribution of higher modes to the global response may be considerable. Structures with higher mode effects exhibit a complex dynamic response that necessitates the use of more sophisticated methods of analyses.

7.2 Seismic safety assessment and failure modes of the towers

The check of the seismic safety of the analyzed towers is satisfied according to the non-linear static procedure under Sa_g=0.1g, with the exception of Tower VI that is a borderline case. Similar results are obtained through the non-linear dynamic analyses. Only Tower V and Tower VI present large residual deformations, indicating the activation of local failure mechanisms, mainly due to the geometrical irregularities, even for peak ground acceleration equal to 0.1g.

According to the non-linear static procedure, the analysed towers are not able to accommodate the seismic demand under Sa_g=0.2g, with the exception of Tower IV and Tower II. These results are supported by the outcomes of the non-linear dynamic analyses.

The peculiar geometrical characteristics and configurations are the main reasons of the larger seismic resistance of these two towers than the one of the other towers. In the case of Tower IV, the thickness of the four perimeter walls is larger than the one of the other towers and it remains constant along the height of the structure. In addition, at the top of the tower there are no large openings, which can represent a vulnerable upper part, when compared to the majority of the other towers. Tower II is symmetrical both in plan and in elevation and presents a regular internal distribution. The tower has a square plan and its weight is much smaller than the one of the other towers, leading to a great reduction of the seismic forces.

For the other towers under study, different failure modes can be observed. The role played by both the geometrical characteristics and the presence of irregularities on the possible collapse mechanisms is highlighted by the results of the analyses. Problems relative to the structural configuration, especially asymmetry and inadequate arrangement of openings, can affect the level of damage in the towers.

A non-uniform stiffness and strength distribution, in plan and elevation, and torsional effects can be some of the main causes for a widespread damage and even collapse of the towers. Tower VI is characterized by a wall with small thickness and a large opening at the top. A failure mechanism involving the detachment of the wall is registered.

For Tower V and Tower VIII, the role played by the internal vaults in modifying the load path for gravity and earthquake loads is evident and unexpected stress concentrations may arise. Localized and severe damage as a result of a redistribution of internal actions transferred by the vaults is highlighted by the analyses. Moreover, Tower V exhibits sudden variations of the walls thickness along the height and Tower VIII presents some irregularities within the perimeter walls.

The quite marked inclination, the high slenderness and the plan asymmetry are the main causes for the widespread damage of Tower VII.

A significant reduction of stiffness and strength of a wall is observed when multiple openings are present, like in the cases of Tower I and Tower III. Tower I has several openings on two parallel walls and Tower III presents large openings both at the base and at the top. A damage concentration with cracks propagating vertically is observed near the openings.

8 CONCLUSIONS

A comprehensive numerical study conducted by means of advanced FE simulations (non-linear dynamic and static analyses) on eight historical masonry towers located in the North-East region of Italy is presented. From an overall analysis of the results obtained in this study, the following conclusions may be drawn.

-The results of the non-linear dynamic simulations show the high vulnerability of historical masonry towers under horizontal loads. It can be roughly stated that if a residual deformation ranging between 0.4% and 0.8% is reached, the structure may be reasonably considered near collapse.

-Some geometrical characteristics, such as plan and elevation irregularities, presence of belfry, large openings, sudden variation of cross-section, internal vaults and tower inclination, play a crucial role on the seismic performance of the towers. The correlation between local geometrical issues and possible failure modes of the towers is clearly highlighted by the numerical analyses.

-The seismic demands obtained by the non-linear static procedure are generally in a good agreement with those obtained by the non-linear dynamic analyses, above all when the check of the structural safety is verified according to the non-linear static procedure. When the check is not satisfied according to the non-linear static procedure, the seismic demand is smaller than the maximum value of the top displacement experienced by the tower during the dynamic simulations. The simplified static approach is not able to capture the inertial effects associated with seismic excitation that can lead to heavy damage and premature collapse of the structure.

-The non-linear static procedure may provide reasonable synthetic predictions of the seismic vulnerability of the towers. The two approaches provide similar results in terms of seismic safety assessment, with slightly less conservative predictions for the non-linear static procedure. A comparison between the results obtained by the two approaches shows that the non-linear static procedure is able to assess the structural safety only when local collapse failures are not involved.

Abstract. *This study presents some results of advanced numerical investigations carried out on the Nativity Church in Bethlehem in order to study the seismic response of the structure and identify possible causes of damage. Detailed three-dimensional finite element models of the church are developed and a damage plasticity material model, exhibiting softening in both tension and compression, is used for masonry. Non-linear bidirectional dynamic analyses are first performed on the model of the entire church in the actual configuration. From an overall analysis of the numerical results, it is possible to observe damage in the vault system, in the semi-domes and near the interlocking of the orthogonal walls. Then, the narthex is separated from the church and is analyzed under seismic excitation applied only in the longitudinal direction. The numerical simulations carried out provide some results that fit reasonably with the actual deformed configuration and can be considered as a useful tool for future rehabilitation interventions.*

1 INTRODUCTION

Very little is known about the history of the transformations of the narthex of the Nativity Church since its construction. The narthex that we see now, or at least the narthex that we can imagine on the basis of the current volumes or of the traces of some ancient and still visible openings on the walls, replaced in the second half of the VI century AD a larger cloister belonging to the previous Church, wanted by Queen Helena, mother of Emperor Constantine, in the IV century. From the outcomes of some archaeological excavations made in the thirties of the last century by R.W. Hamilton and from the results of the studies that have followed, it was possible to go back to the original form of the narthex that, unlike as it is now, was composed of a single volume, had a bigger central door flanked by two smaller side doors in both longer walls and two windows placed symmetrically with respect to the front door, Figure 1.

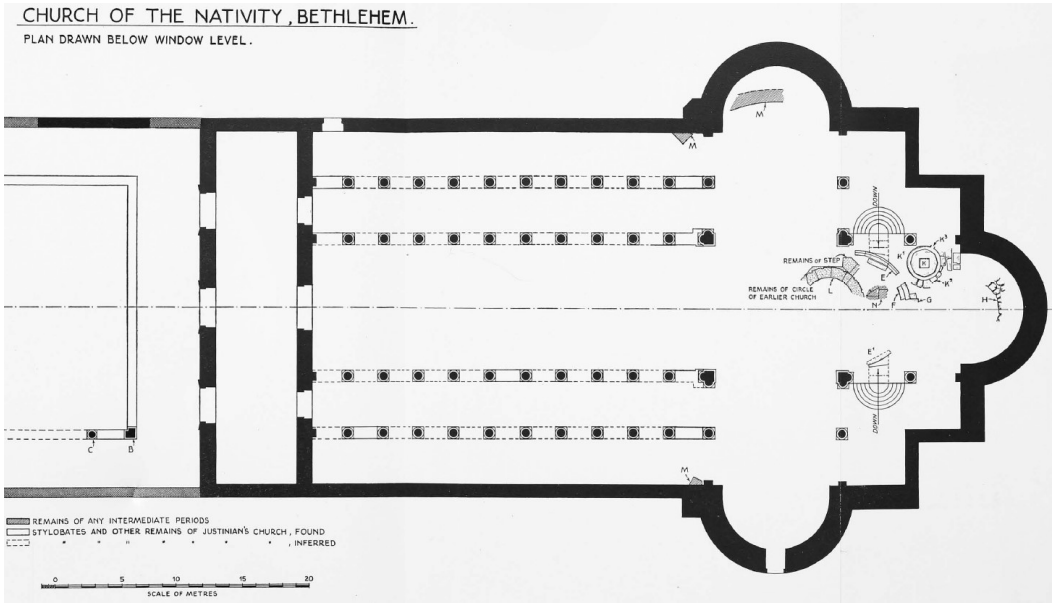

Figure 1: Original narthex of the Church of the Nativity.

From some traces found in the walls during the restoration works still in progress, it was possible to deduce that the original roof of the narthex was made of timber, with a single pitch, as in almost all early Christian and Byzantine basilicas with narthex. The typology of this wooden roof is still unclear, although the traces left on the walls suggest that it consisted of a series of simply supported beams arranged according to the slope of the roof. Anyhow it was a light roof. Over the centuries, especially during the Middle Ages, the Church increasingly took on the appearance of a fortress equipping itself with walls and towers for defense. Some traces of these additions are visible today even in the narthex, in particular in a small protective parapet above the façade and in two thick interior walls, perpendicular to the façade, probably the base of two outer towers, Figure 2 and Figure 3. Maybe, in order to allow these transformations for protective purposes, or in consequence of some destructive earthquakes, the original timber roof was replaced by a system of masonry cross vaults and some openings were infilled or reduced in size. The two internal walls are made of masonry of poor quality, or at least lower than that of the external walls, and they are simply adhering to the façade walls of the narthex and Church without any effective connection.

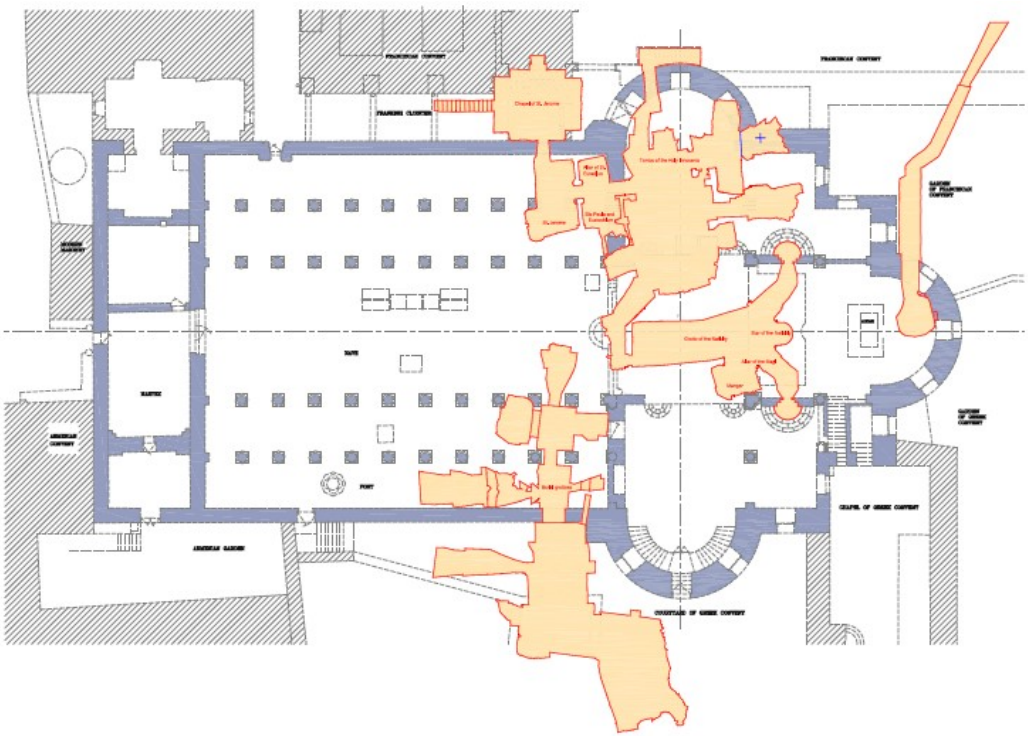

Figure 2: Plan of the Church with the current narthex.

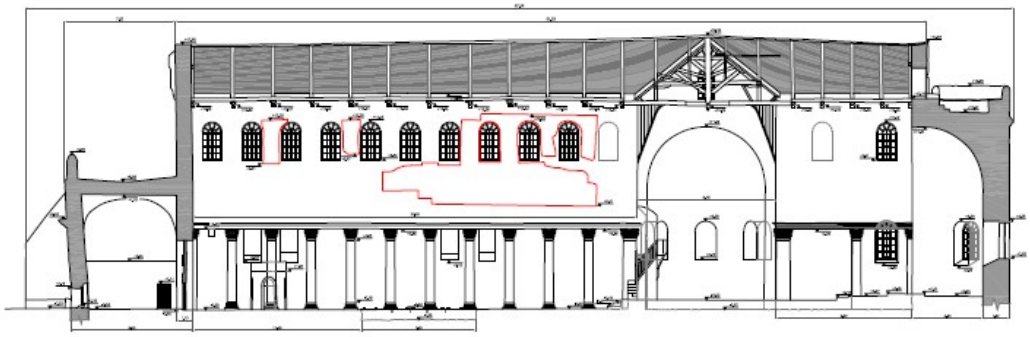

Figure 3: Longitudinal section of the Church

Also the vaults, made of irregular and roughly cut stones, are connected to the façade walls of both narthex and Church only in correspondence of the corbels at the base of the arches and for a height of about 1,10 – 1,30 m. Instead, such vaults are well connected with each other in the direction East-West (the longitudinal direction of the Church) by means of arches, orthogonal to the façade and built with greater and more regular stones; such stones have two different lengths, which alternate to allow for a greater connection between arches and vaults. Even the diagonal arches of the vaults are made with more regular stones, although not as the ones of the arches mentioned before. The thickness of the vaults is not constant everywhere and it varies between 35 – 40 cm. Before starting the restoration the space between the external paving and the extrados of the vaults was filled with sand and remains of a medieval paving. Some inspections made on site have shown that the walls of the narthex continue downwards with a constant thickness up to a depth of 94 cm from the floor; then they have an enlargement of 20 cm on each side up to a depth of 141 cm and continue with a compact layer of stones and mortar for other 150-165 cm before reaching the bedrock. The two side walls of the narthex are 1,00 m thick and have an inner core of undefined thickness; the façade wall,

like the façade of the Church, is 1,15 thick, made of regular stones and with limited or null inner core. The narthex is now connected with the monasteries of the Franciscans Friars (North) and of the Armenian religious community (South), Fig. 2, who, together with the Greek-Orthodox one, manage the activities in the Church according to the current *status quo*. On the external front, towards the square, there is a big buttress probably built after the XVI century: in fact some drawings by Fr. Bernardino Amico, dating back to 1609, show the façade of the narthex still without the buttress, Figure 4.

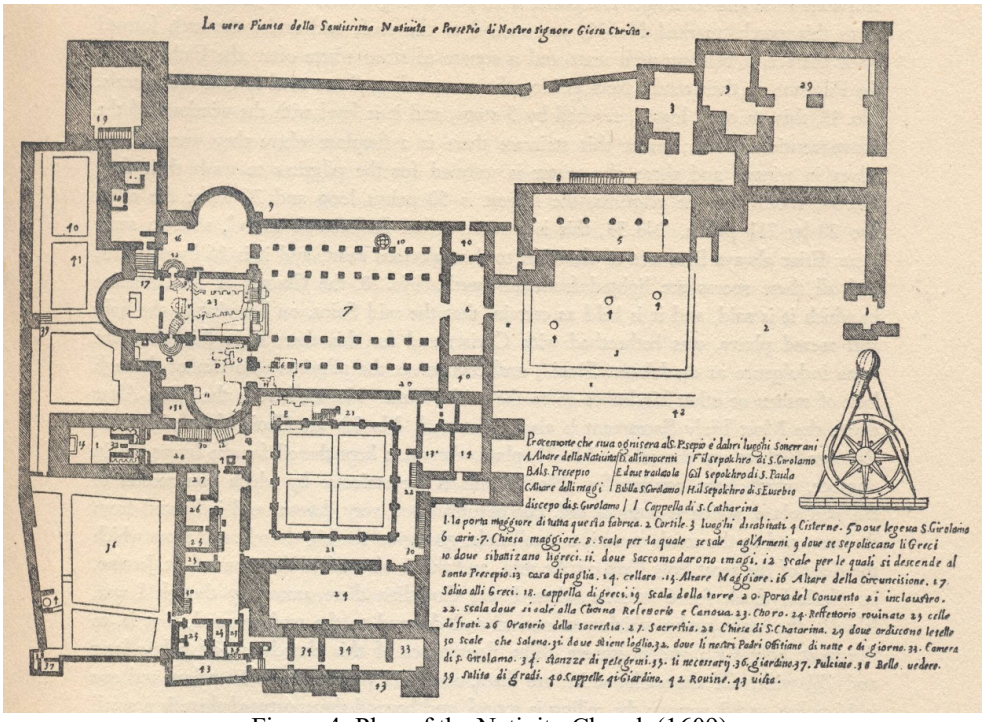

Figure 4: Plan of the Nativity Church (1609).

2 STATE OF STRUCTURAL DAMAGE AND CAUSES

The structure of the narthex is today strongly deformed. The façade wall exhibits a rotation towards the square more pronounced in the middle of its length and starting approximately from the architrave of the Humility door, about one meter above the ground. In consequence of this rotation, the façade wall has undergone a maximum horizontal displacement at the top, approximately in the middle of the wall, of about 40 - 42 cm measured from the base of the parapet. It is a very high value when compared with the height of the wall, about 8.70 meters. If some fractures have occurred in the past, these are now closed due to local interventions of cleaning and consolidation made over the centuries, which shows that the damage evolution is now over and that it was probably over even when the external buttress, still perfectly vertical, was added. The façade of the Church, opposite to the one of the narthex, exhibits a light out-of-plane deformation which starts from the roof of the narthex and achieves 10 cm at the top of the tympanum. In consequence of the rotation of the façade of the narthex the three central vaults, and in particular the one in the middle, underwent vertical displacements downwards in the central zones, detachments from the façade walls and cracks both at the extrados and the intrados. Especially the central vault, propped since the thirties of the last century, exhibits detachments 17-19 cm wide from the narthex façade and 10-11 cm wide from the Church façade Figure 5. Moreover big cracks, parallel to the façades, are visible at the extrados Figure 6.

Figure 5: Detachments from the wall.

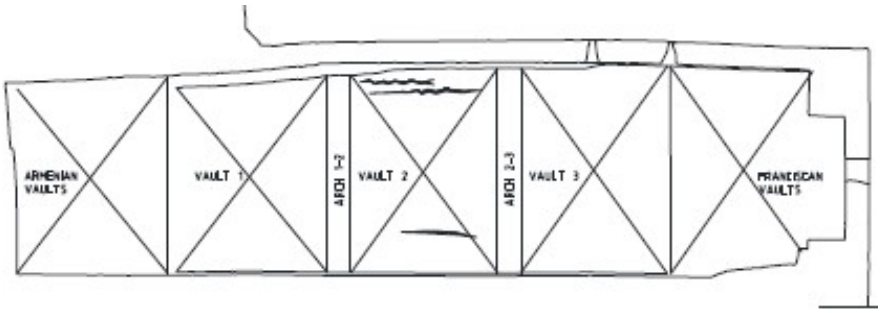

Figure 6: Cracks at the extrados of the central vault.

The arches connecting the vaults to each other (in the East – West direction) and also the ones along the diagonal planes of the vaults are strongly deformed. The causes of these damages have never been clarified. The replacement of the original wooden roof with a set of thrusting masonry vaults probably gave a significant contribution to the rotation of the façade towards the square. It is believed, however, that such thrusts alone cannot have been able to cause maximum horizontal displacements as large as those measured. Therefore, since Bethlehem is in a seismic area which over the centuries underwent several earthquakes, some of them even severe, it is very probable that a seismic event, occurred before the construction of the buttress, was one of the main causes of damage. The external buttress, added in the last centuries, as mentioned above, shows no sign of rotation and no differential vertical displacement.
The aim of this work is to identify, through a proper numerical simulation, the seismic event that, together with the thrust of the vaults, might have caused damage in the vault system and the present out-of-plane deformation of the narthex façade and of the tympanum of the main entrance. To this purpose, a 3D finite element model of the entire Church was built and analyzed by using the commercial software ABAQUS. The model reproduces the actual configuration of the church, but without the external buttress and without connections with the monasteries of the Franciscans Friars and of the Armenian religious community. The vaults at both ends of the narthex (North and South) were not modelled because their survey had not been yet carried out at the time of the present analysis. The presence of the three internal walls was taken into account. It is worth noting that a three-dimensional structural analysis of the entire Church is significant when a good level of interlocking among the structural elements is guaranteed. If such connections are not reliable, as in the case of the Church of the Nativity, it is, on the other hand, advisable to perform numerical analyses on smaller portions that may be affected by local collapse mechanisms.
A detailed finite element model of the narthex was then created by using a finer discretization. The model reproduces, with some approximations and simplifications, the structure of the narthex as depicted by Fra Bernardino Amico at the beginning of the XVII century, without the external buttress, with a unique access door (the Humility door) and only two small

windows on the façade, with masonry cross vaults instead of the original wooden roof. The side walls of the narthex are supposed clamped to the Church, the height and thickness of the vaults have values computed as an average of the real ones and the vaults are connected to the façade walls of both narthex and Church. Moreover they are connected to each other in the East - West direction (longitudinal direction of the Church) by means of arches similar to the real ones, Figure 6, and clamped to the façades of the narthex and Church. The façade of the Church is supposed to be clamped at the intersection with the orthogonal walls of the nave and the aisles. Figure 7 shows a view of the system of masonry cross vaults in the model of the narthex.

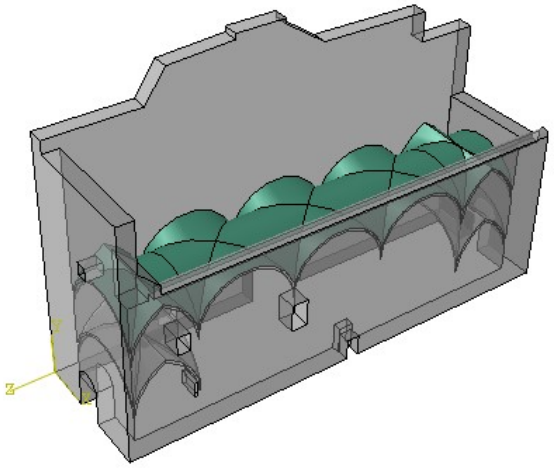

Figure 7: The system of masonry cross vaults in the model of the narthex.

3 FINITE ELEMENT NUMERICAL MODELS

With the aim of reproducing the actual state of damage on the narthex it is chosen to study the effects of a possible earthquake by non-linear dynamic analyses by applying spectrum compatible acceleration time-histories at the base of the structure. Such a method of analysis is very time consuming, but it is much more accurate and reliable than other approaches for its capability to identify in- and out-of-plane, as well as local and global failure mechanisms. Different three-dimensional finite element models of the church and the narthex are implemented in Abaqus, taking into consideration geometrical (large displacement effects) and material non-linearity (elastic-plastic with damaging behavior of the masonry material). Despite the general drawbacks regarding non-linear dynamic analyses, the use of sophisticated 3D models requires a relatively reasonable computational effort on sufficiently powerful workstations, if the discretizations are not excessively refined and the material models do not exhibit strong softening.

On the other hand, Italian Guidelines for the built heritage specify that such analyses can be conducted using finite element models and considering suitable constitutive models. Such models should be capable of reproducing the typical strength and stiffness degradation exhibited by the masonry material in the inelastic range. Italian Code on Constructions NTC 2008 and subsequent explicative notes underline that the aim of dynamic analyses would be the evaluation of the structure in the non-linear range under an expected accelerogram, allowing for a comparison between required and available ductility. Also, it is possible to verify the integrity of the structural elements which can potentially show brittle behavior.

When dealing with material properties assumed and available in Abaqus software code, the so-called “Concrete Damage Plasticity” model was adopted. Such a model is based on the assumption of a scalar isotropic damage with distinct damage parameters in tension and

compression. It is particularly suitable for applications in which the material exhibits damage, especially under load-unload conditions and hence for dynamic analyses. An elastic-plastic behavior in both tension and compression can be also taken into account.
To describe the multi-dimensional behavior in the inelastic range, masonry is assumed obeying a Drucker-Prager strength criterion with non-associated flow rule. A value equal to 10° is adopted for the dilatation angle, which seems reasonable for a masonry material subjected to moderate-low levels of vertical compression, also in agreement with experimental evidences available in the literature. To avoid numerical convergence issues, the tip of the conical domain of the Drucker-Prager strength domain is smoothed with a function having hyperbolic shape. Abaqus code allows ruling smoothing by means of the so-called eccentricity parameter, which represents the length of the segment between the points of intersection of the cone and of the hyperbola with the p axis in the p-q space. A value equal to 0.1 is adopted for the eccentricity parameter.
Experimental results reported by Page on regular masonry wallets and successive numerical models show that such a material exhibits a moderate orthotropy ratio (around 1.2) under biaxial stress states in the compression-compression region. Obviously, such feature cannot be taken into account when an isotropic model, like the present one, is used. However, the use of isotropic models (like concrete smeared crack approach available in both Ansys and Adina) is commonly accepted in the literature after adapting the parameters to fit and average behavior between vertical and horizontal compression. A suitable model should also take into account the ratio between the ultimate compression strength in biaxial stress states and in uniaxial conditions. Such a ratio, which exhibits some similarities between concrete and masonry, is reasonably set equal to 1.16.
In tension the stress-strain response follows a linear-elastic relationship until the peak stress σ_{t0} is reached. Then, micro-cracks start to propagate in the material, a phenomenon which is macroscopically represented by softening in the stress-strain relationship. Under axial compression, the response is linear up to the value of the yield stress σ_{c0}. After the yield stress, the response is typically characterized by hardening, which anticipates compression crushing, represented by a softening branch beyond the peak stress σ_{cu}.
Damage variables in tension and compression are defined by means of the following standard relationships:

$$\sigma_t = (1-d_t)E_0\left(\varepsilon_t - \varepsilon_t^{pl}\right)$$
$$\sigma_c = (1-d_c)E_0\left(\varepsilon_c - \varepsilon_c^{pl}\right) \quad (1)$$

where σ_t (σ_c) is the mono-axial tensile (compressive) stress, E_0 is the initial elastic modulus, ε_t (ε_c) is the total strain in tension (compression), ε_t^{pl} (ε_c^{pl}) is the equivalent plastic strain in tension (compression). When strain reaches a critical value, the material elastic modulus degrades in the unloading phase to $E < E_0$. In particular, within the simulations, a reduction equal to 5% of the Young modulus with respect to the initial value is assumed for a plastic deformation equal to 0.003.
The issue of mechanical properties to adopt for the constituent materials results particularly difficult, especially in the absence of ad hoc experimental campaigns and specific indications by local building codes. It is common opinion, however, that the major damages registered in historical churches are a consequence of very poor mechanical properties of joints, whereas clay bricks exhibit a quite high strength. In the absence of specific indications, it was chosen to refer to what stated by Italian Code for existing masonry buildings.

As a matter of fact, masonry is a material which exhibits distinct directional properties due to the mortar joints, acting as planes of weakness.

Considering the well-known limitation of use of both micro-modelling and homogenization at large scale, isotropic macro-models are adopted for masonry. The reason for adopting an isotropic material stands in the impossibility to evaluate many parameters

necessary for anisotropic materials in the inelastic range, in the absence of ad-hoc experimental characterizations. Finally, it is worth noting that commercial codes rarely make available to users anisotropic mechanical models suitable to describe masonry with regular texture in the non-linear range.

According to Italian Code NTC 2008 and subsequent Explicative Notes, the mechanical properties assumed for masonry material depend on the so-called knowledge level LC, which is related to the so-called Confidence Factor FC. There are three LCs, labeled from 1 to 3, related to the knowledge level about the mechanical and geometrical properties of the structure. The knowledge level LC3 is the maximum, whereas LC1 is the minimum. For the cases at hand, a LC1 level is assumed in the absence of specific in-situ test results.

Confidence Factor FC summarizes the knowledge level regarding the structure and the foundation system from a geometric and mechanical point of view. It can be determined defining different partial confidence factors FCk (k=1,4), on the basis of some numerical coefficients present in Italian Code (Table 4.1 Italian Guidelines). Due to the limited knowledge level achieved in this case, the highest confidence factor (FC = 1.35) was used.

The values adopted for cohesion and masonry elastic moduli are taken in agreement with Table C8A.2.1 of the Explicative Notes, assuming a masonry typology with very poor mechanical properties of the joint and quite regular courses. With the lowest knowledge level LC (confidence factor FC=1.35), Italian Code requires to select, in Table C8A.2.1, the lower bound values for strength and the average values between lower and upper bound for elastic moduli.

The application of the acceleration time-history occurs at the second step, where the structure is unrestrained using trailers, thus allowing it to move along the direction of the seismic action. The numerical analyses are carried out by means of a dynamic approach with implicit integration in the time domain, using a time step equal to 0.005 s, which corresponds to the accelerogram registration time interval. The results of the analyses conducted in this study are reported in the following sections.

4 NON-LINEAR DYNAMIC ANALYSES OF THE CHURCH

A detailed three-dimensional finite element model of the entire Church was developed by means of ABAQUS code, Figure 8, with the aim of investigating the seismic behavior of the structure through non-linear dynamic analyses. A finite element discretization, based on four nodes tetrahedral elements presenting an average size of 0.40 m, was adopted. The total number of elements of the model was equal to 131551. In particular, the mesh was refined near the regions where the main failure mechanisms were likely to start. Since not negligible out of plane displacement may occur during a seismic event, large displacement effects were considered. Perfect connection was assumed between perpendicular walls.

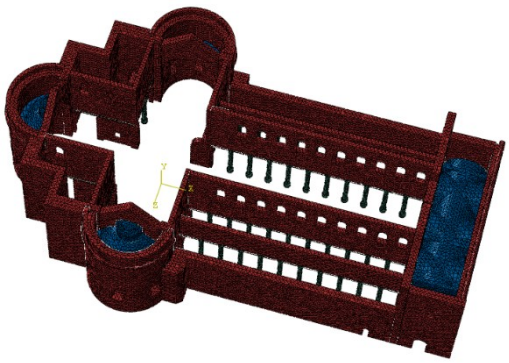

Figure 8: Finite element model of the entire Church of the Nativity.

The bidirectional non-linear dynamic analyses were performed by using artificial accelerograms generated by means of the software code SIMQKE. In this study the Church was subjected to spectrum compatible accelerograms corresponding to a peak ground acceleration equal to 0.15g according to Eurocode 8. The area where the Church is located is a medium-intensity seismic area with a_g = 0.15g, where a_g is the maximum horizontal acceleration occurring in the area, with a 10% of probability of exceeding this value over 50 years. Due to the complexity of the model and the high computing time of this type of analysis, the duration of the accelerograms was set equal to 10 s. In Figure 9 the contour plots of tension damage (red color is associated to full (1) damage and blue color to zero (0) damage), are shown from different points of view at the end of the numerical simulation. From an overall analysis of the numerical results, it is possible to notice that the Church exhibits significant damage under the expected earthquake excitation. It is evident that the damage spreads very quickly in the vault system, in the semi-domes and near the interlockings of the orthogonal walls. The damage in the vaults starts in the lateral right corner and then propagates towards the middle.

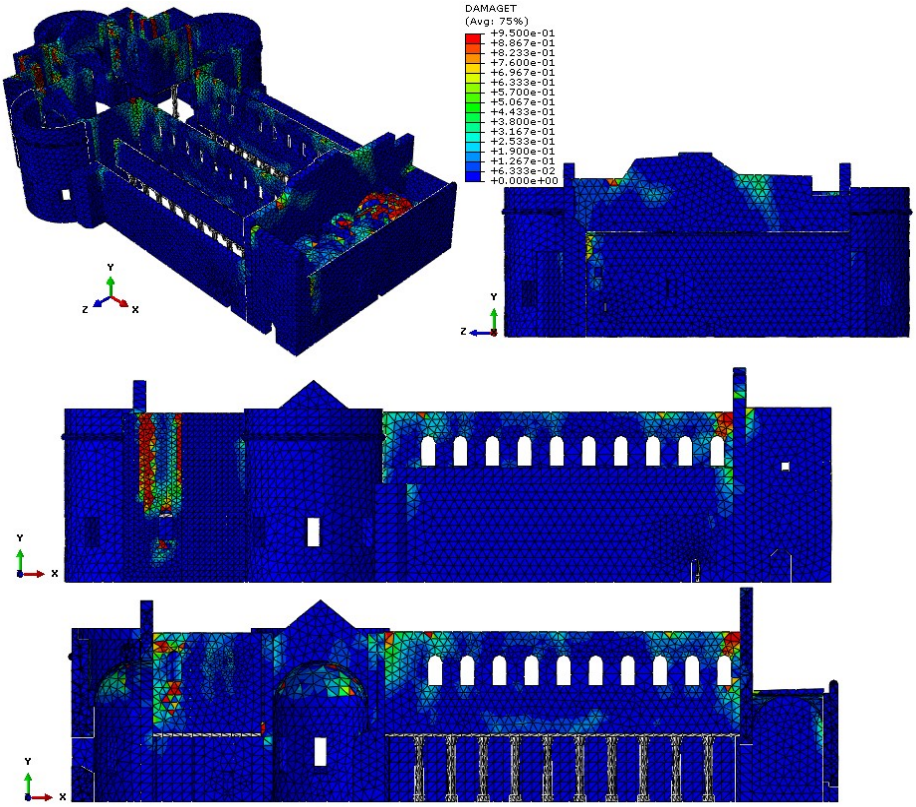

Figure 9: Contour plots of tension damage at the end of the non-linear dynamic analysis (red, 1: full damage; blue, 0: no damage).

Figure 10 shows the horizontal displacement time history for various control nodes of the Church along both the longitudinal and transversal directions. The main control nodes of the Church model monitored during the numerical simulations are shown in the same figure. In the longitudinal direction a maximum top displacement equal to 6 cm was computed for the top of the tympanum (control node P1) after about 7 s from the beginning of the ground motion. The stiffening presence of the internal walls of the narthex have the effect of reducing the out-of-plane rocking of the narthex façade during the application of the accelerograms. The maximum top displacement measured on the top of the narthex façade is about 5.5 cm.

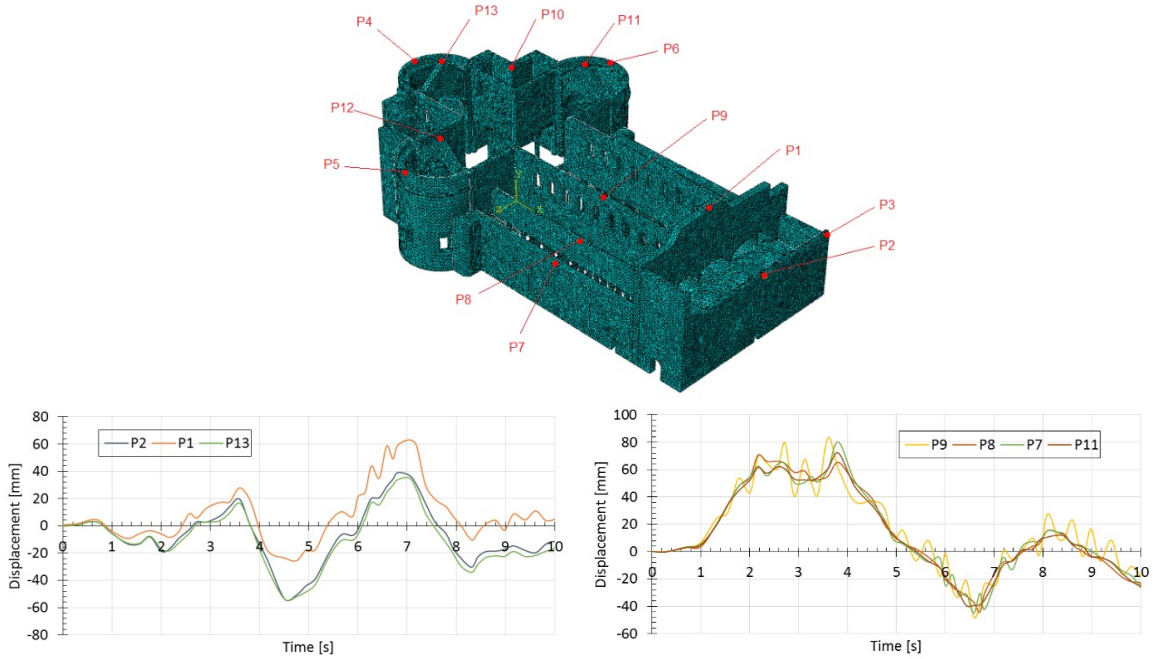

Figure 10: Displacement time history of some control nodes along the longitudinal and transversal directions during non-linear dynamic analyses.

5 NON-LINEAR DYNAMIC ANALYSES OF THE NARTHEX

The results of the non-linear dynamic analyses performed on the model of the whole Church showed the vulnerability of the structure under horizontal loads pointing out some critical regions. It is worth noting that the use of sophisticated three-dimensional finite element models requires a large computational effort and the model of the entire Church proved to be very-time consuming under bidirectional non-linear dynamic analyses. A finite element model of the narthex only was created in order to perform different non-linear dynamic analyses with various peak ground accelerations.

Then, the seismic performance of the narthex was assessed through non-linear dynamic analyses with response spectrum-compatible artificial accelerograms. A finer mesh, consisting of about 85000 tetrahedron elements and depicted in Figure 11, could be used for the narthex in this model. The internal walls were not modelled in order to reproduce the original configuration of the narthex and to neglect the stiffening effect provided by these elements.

The evaluation of the seismic response of the narthex was carried out using an artificial accelerogram, with duration equal to 20 s. For sake of simplicity, numerical analyses were carried out only in the longitudinal direction. The accelerogram used was generated by means of the software code SIMQKE in order to match the Eurocode 8 response spectrum. Different peak ground accelerations ranging between 0.15g and 0.25g were considered for the analyses.

This finite element model was used to identify the possible different collapse mechanism that can occur in the narthex. A ground motion applied in the longitudinal direction can determine the detachment of the narthex façade from the façade of the church, creating tensile stresses in the vault system. The vault system represents a critical element for the narthex and it is expected to undergo significant damage at the beginning of the numerical simulation.

Figure 11 describes the tensile and compression damage evolution, respectively, during the non-linear dynamic analysis. The results are reported at the end of the analysis (20 s). It can be noted that damage concentrates mainly in the cross vault system and, to a small extent, on

both the façades. In particular, the tensile damage starts at the base of the vault system and then propagates to the middle part involving the whole system of vaults.

On the contrary, the compression damage starts at the top of the vault system and then propagates to the base. It can be noted that the interlocking of the longitudinal walls with the western façade of the Church tends to experience considerable damage.

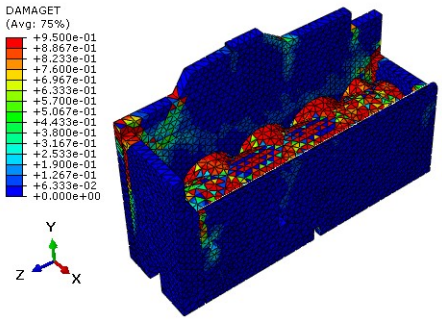

Figure 11: Contour plots of the tensile damage in the narthex at the end of the numerical simulation (red, 1: full damage; blue, 0: no damage).

The horizontal and vertical displacement time histories for some control nodes are reported in Figure 12. All the control nodes of the narthex model monitored during the numerical simulations are shown in the same figure. The horizontal displacements of three meaningful control nodes are measured during the numerical simulations: they are located on the top of the narthex façade, of the tympanum and of the central cross vault. The maximum horizontal displacement (about 10 cm) is observed for the control node N14 at the top of the tympanum of the main entrance. The narthex façade exhibits a peak horizontal displacement equal to about 6 cm. As regards the vertical displacement, the maximum value, equal to 9 cm, is registered for the central vault.

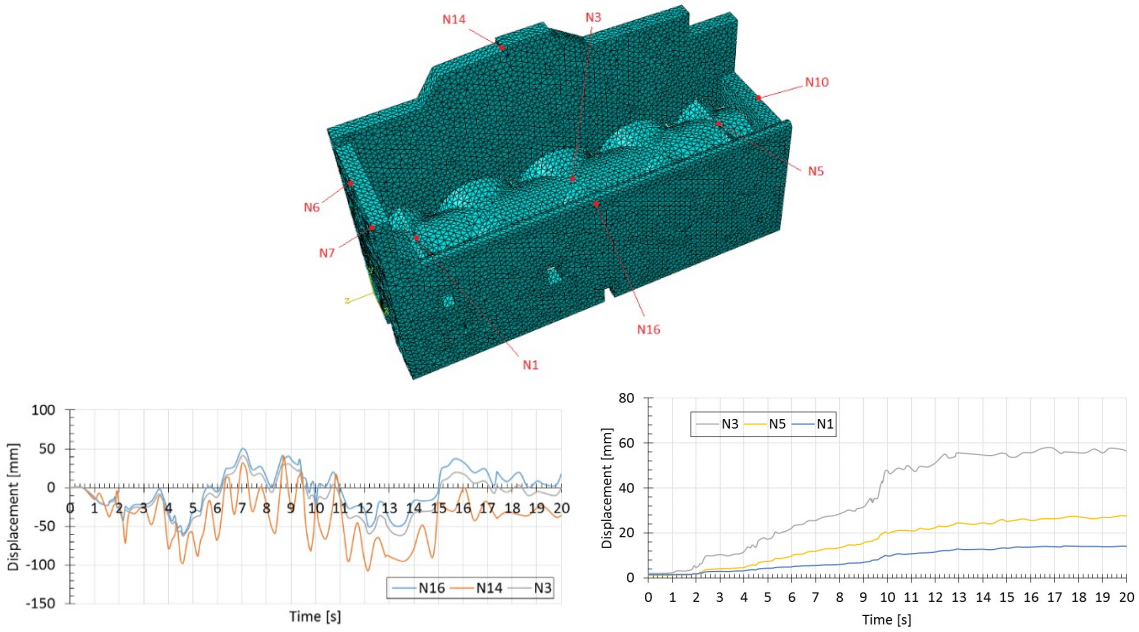

Figure 12: Horizontal and vertical displacement time-history of some control nodes during non-linear dynamic analyses.

The maximum values of the vertical displacements of the control nodes of the cross vaults are shown in Figure 13 for different peak ground accelerations. As can be noted, the maximum vertical displacements of the central vault is always larger than the other vaults. For higher values of seismic intensity levels (a_g=0.25g), the central vault presents a maximum value of vertical displacement equal to 15 cm.
The maximum values of the horizontal displacement of three meaningful control nodes are shown in Figure 14 for different peak ground accelerations. It can be noted that the peak values of the horizontal displacement of the narthex façade are always smaller than the top of the tympanum of the western façade. Under a seismic intensity level of 0.25g the tympanum exhibits peak displacements equal to about 35 cm, whereas the maximum displacement registered for the narthex façade is about 20 cm.

Non-linear dynamic analyses are able to provide, among other information, residual displacements of the control nodes. The maximum values of the residual displacements (35 cm) are registered for the western façade of the Church when subjected to seismic excitation with a_g=0.25g. As can be observed, the residual displacement found for the façade of the narthex is about 20 cm, still lower than the real ones, but indicating that a seismic event may be the cause of the present state of degradation. Probably larger residual displacements might be achieved by simulating the occurrence of a sequence of ground motions, as confirmed by the chronicles of the earthquakes in the area.

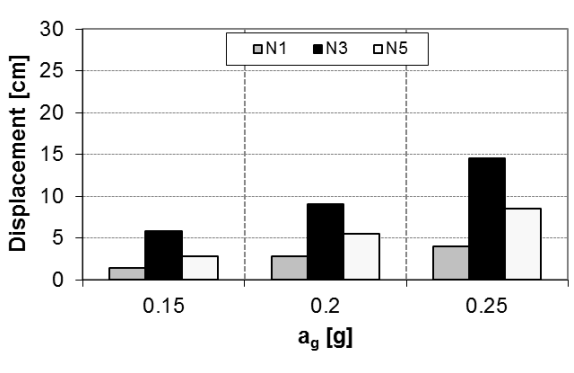

Figure 13: Maximum values of vertical displacement of some control nodes for different peak ground accelerations.

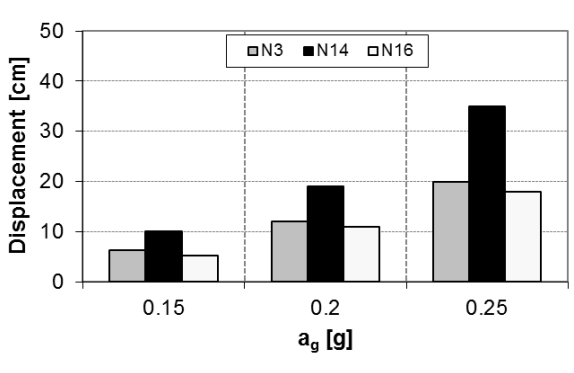

Figure 14: Maximum values of horizontal displacement of some control nodes for different peak ground accelerations.

6 CONCLUSIONS

This study summarizes the numerical investigations carried out on the narthex of the Nativity Church in Bethlehem. Advanced finite element numerical models accounting for

masonry damage and softening have been used within demanding non-linear dynamic simulations in order to identify the possible causes of damage in the narthex.
Non-linear bidirectional dynamic analyses were first performed on the model of the entire Church in the actual configuration. From an overall analysis of the numerical results, it is possible to notice that the Church exhibits damage for the expected earthquake excitation. It is evident that damage spreads very quickly in the vault system, in the semi-domes and near the interlocking of the orthogonal walls. The damage in the vaults starts in the lateral right corner and then propagates towards the middle.

Then, the narthex was separated from the Church and was analyzed under seismic excitation applied only in the longitudinal direction. Numerical results show the behavior of the narthex is considerably affected by the presence of the vaults that act as connecting element between the western façade of the Church and the façade of the narthex. During a moderate intensity earthquake, the vault system is subjected to significant stresses and consequently to severe damage. The second critical element of the narthex is the western façade that tends to show a local overturning mechanism due to the gradual accumulation of damage near the base of the vault system. Moreover, the façade of the narthex can reach significant displacements under seismic actions with a_g=0.25g. The results seem to indicate that the rotation of the narthex façade, with a consequent maximum out-of-plane displacement of 40 cm approximately, is probably due to a seismic event of great intensity or to several seismic events occurred in sequence over time. Certainly, results closer to the measured data can be obtained by introducing proper unilateral contact conditions at the interface between vaults and façade walls or between longitudinal walls and façade walls.

DYNAMIC BEHAVIOUR AND EARTHQUAKE PERFORMANCE OF GREEK BASILICA CHURCHES WITH FOUNDATION DEFORMABILITY

George C. Manos[1], **Evaggelos Kozokipoulos**[1], **and Lambros Kotoulas**[1]

[1] Laboratory of Strength of Materials and Structures, Aristotle University of Thessaloniki, Greece, gcmanos@civil.auth.gr

Keywords: Greek Basilicas, Dynamic Behaviour, Earthquake Performance, Stone Masonry, Soil Foundation Deformability.

Abstract. *This paper attempts to address the earthquake performance of Basilica churches in parts of Greece during the last 30 years. Towards this objective use is made of in-situ observations together with relatively simple numerical tools. The numerical study includes soil-foundation deformability. The earthquake performance of three specific stone masonry Basilica churches is investigated. The second and third of these churches are simply covered by a wooden roof whereas the first has also a stone masonry vaulted superstructure under its wooden roof. All three churches developed significant structural damage typical of churches of this Basilica typology as was observed in Greece during the last 30 years. It has been observed that such churches develop structural damage to the masonry walls and vaults, in certain cases quite serious, that is believed to arise from the amplitude of the gravitational and seismic actions combined with the deformability of the foundation which is included in the current investigation. The numerical models simulating the main structural system of these churches are supplemented at the foundation level with flexible springs in an effort to capture the influence of such soil-foundation deformability. Simple numerical analysis results together with assumed strength values are utilized to predict the behaviour of the various masonry parts that belong to the longitudinal and transverse peripheral wall in in-plane shear and normal stress as well as out-of-plane flexure. The recorded ground acceleration during the Kozani 1995 earthquake for the first two churches and the 1978 Thessaloniki earthquake for the third church, as it was recorded at a relatively close distance, is used in this numerical investigation. Towards this end, the dynamic characteristics in terms of eigen-modes and eigen-frequencies of the examined structural systems are also utilized.*

1 INTRODUCTION

During the last thirty years various parts of Greece have been subjected to a number of damaging earthquakes ranging from Ms=5.2 to Ms=7.2 on the Richter scale [1]. One of the most demanding tasks for counteracting the consequences of all these seismic events was the effort to ensure the structural integrity of old churches that were built in periods ranging from 400 A.D. up to today; in many cases they sustained considerable damage ([1], [2], [3], [4], [5]). The earthquake behaviour of churches belonging to the so-called Post-Byzantine period (16th to 19th century A.D.) has been studied numerically in some detail ([2], [3], [4], [5], [6]) In all these cases the foundation was considered to be non-deformable. However, this is a gross approximation as in most cases these churches are founded on deformable soil. In some instances, the deformability of the soil caused considerable damage as is the case of the church of The Assumption of the Virgin Mary at Dilofo-Voio-Kozani, as will be presented in section 2 ([7], [8]). In some other cases the main cause of recent damage is the earthquake activity that is accentuated by the deformability of the soil ([9], [10], [11], [12]). This is presented in the section 3, where the damage of the church of Agia Triada at Vithos-Kozani and of Profitis Elias at Siatista-Kozani is also included, as well as in section 4 where the earthquake performance of the old Byzantine church of Achiropoiitos in Thesalloniki is examined. It must be noted that all these churches were built in a number of phases on old existing sacred sites. During the Turkish occupation the most prominent Christian churches were transform to mosques or prohibitions were imposed forbidding the construction of new churches but allowing the maintenance of existing ones, after special permit [13]. In what follows an overview of three specific cases of Greek Byzantine churches where the foundation deformability influenced the dynamic and earthquake behaviour is presented and discussed.

Figure 1. Damage to the South-East corner

Figure 2. Partial collapse of the central dome

2 THE CHURCH OF THE ASSUMPTION OF THE VIRGIN MARY AT DILOFO

The West part of this church is founded on hard soil (weathered flysch layers) whereas the East part is founded on relatively soft soil that was deposited on top of the layers to compensate for the natural slope at this location ([7], [8]). The unequal settlement of the foundation of the stone masonry walls as well as of the internal columns that supported the vaulting system, which covered this church, caused considerable damage. A very wide crack initiates at the top of the East peripheral wall near the apse and propagates towards the bottom of this wall being inclined to the South-East corner (figure 1). Furthermore, a similarly wide crack propagates through the North peripheral wall from top to bottom. It must be noted that

the thickness of these masonry walls varies from 750mm to 800mm. From this extensive peripheral wall damage, the vaulting system that is supported by these peripheral walls also suffered extensive cracking that eventually caused the partial collapse of a part of the central dome, as shown in figure 2.

Initially, the 3-D numerical simulation of this church, including the peripheral walls, the vaulting system of the superstructure and the wooden roof, assumed that the foundation was non-deformable. The results of the modal analysis for the church supported on the non-deformable foundation are shown in a summary form in figures 3a and 3b. In these figures the most significant eigen-modes are depicted together with the corresponding values of the eigen-periods as well as the modal mass participation ratios either in the x-x direction (Ux) or in the y-y direction (Uy). As can be seen the longest eigen-period is, as expected, for the fundamental x-x direction translational mode, with a value equal to 0.228seconds that mobilizes 72.48% of the total mass. The next longest eigen-period is for the fundamental y-y direction translational mode, with a value equal to 0.132seconds that mobilizes 59.37% of the total mass.

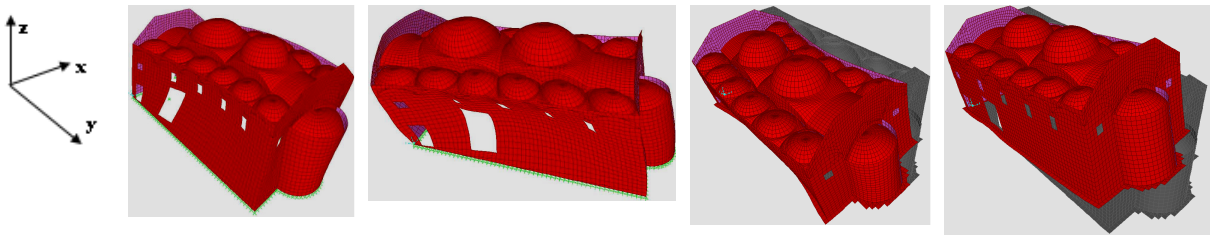

Figure 3. Eigen-modes

a) Mode 1, T1=0.228sec Ux=72.48%

b) Mode 2, T2=0.132sec Uy=59.37%

c) Mode 1, T1=0.391sec Ux=83.48%

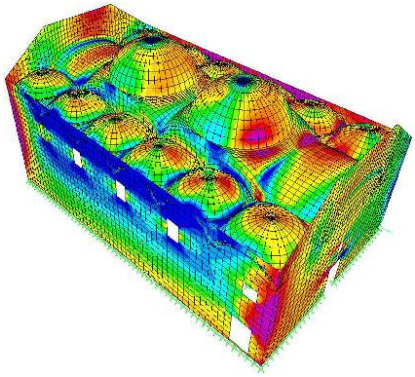
d) Mode 2, T2=0.276sec Uy=78.37%

Next, layers of deformable soil were introduced beneath the foundation of all the peripheral walls and internal colonnades. The stiffness of these soil layers was varied with the depth as well as in plan in order to simulate the relatively hard soil at the West part of the church and the relatively soft soil at the North-East part of the church. The results of the modal analysis for the church (low-stiffness soil layers) supported on the deformable foundation are shown in a summary form in figures 3c and 3d. In these figures the most significant eigen-modes are depicted together with the corresponding values of the eigen-periods as well as the modal mass participation ratios either in the x-x direction (Ux) or in the y-y direction (Uy). As can be seen the longest eigen-period is, as expected, for the fundamental x-x direction translational mode, with a value equal to 0.391 seconds that mobilizes 83.48% of the total mass. The next longest eigen-period is for the fundamental y-y direction translational mode, with a value equal to 0.276seconds that mobilizes 78.37% of the total mass. As can be seen, apart from the lengthening of the fundamental eigen-period values, the deformable foundation resulted in a larger portion of the mass being mobilized for the first two translational eigen-modes in the x-x and y-y direction than for the case of non-deformable foundation.

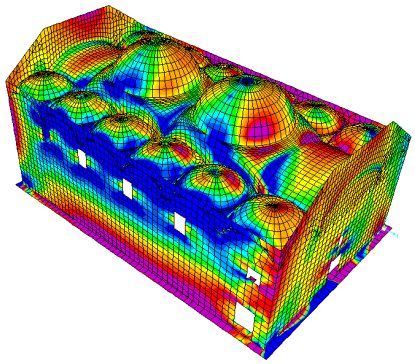
The 3-D numerical representation of the church, including the peripheral walls, the vaulting system of the superstructure and the wooden roof were subjected to load combinations of either 0.9G±1.4Ex or 0.9G±1.4Ey, where G is the gravitational loads and Ex, Ey the earthquake forces along the x-x axis (longitudinal East-West direction) or the y-y axis (transverse North-South direction, respectively.

This was done for both the non-deformable and the deformable foundation. Selected results of the obtained maximum stress response are shown in figures 4a to 4d. More results

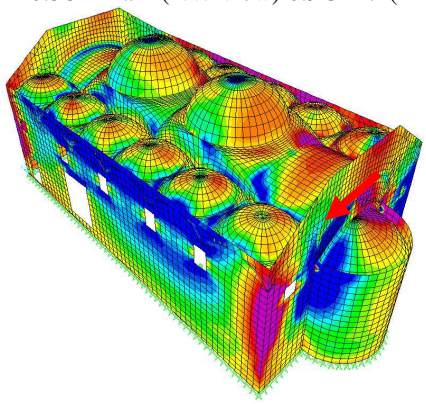
are given by Manos et al. ([7], [8]). The following summarize the most significant observations of this numerical study:



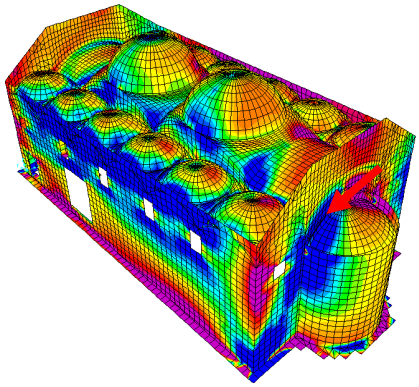
4a) **Non-deformable foundation**, $\boldsymbol{\sigma_{11}}$ top face, max $\boldsymbol{\sigma_{11}}$ = 0.38 MPa (NW view) 0.9G+1.4(+Ex)



4b) **Deformable Foundation,** $\boldsymbol{\sigma_{11}}$ top face, max σ_{11} = 0.53 MPa (NW view) 0.9G+1.4(+Ex)



4c) **Non-deformable foundation,** σ_{11} bottom face, max $\boldsymbol{\sigma_{11}}$ = 0.46 MPa (SE view)) 0.9G+1.4(-Ex)



4d) **Deformable Foundation,** σ_{11} bottom face, max $\boldsymbol{\sigma_{11}}$ = 0.64 MPa (SE view) 0.9G+1.4(-Ex)

- The foundation deformability due to layers of soft-soil deposits at the North-Eastern part of the foundation, as was approximated numerically, increased both the fundamental translational modes eigen-periods and the corresponding modal mass participation factors.
- This foundation deformability, as was approximated numerically, also increased the maximum predicted vertical and horizontal displacement values. This increase was threefold for the horizontal displacements and ten-fold for the vertical displacements.
- This foundation deformability, as was approximated numerically, also increased the maximum predicted axial stress values parallel to the bed-joint. This increase was of the order of 20% up to 40%.
- Due to this increase of the predicted maximum axial stress values parallel to the bed-joint, arising from the foundation deformability, the assumed corresponding tensile strength is exceeded in all the locations where actual damage was observed.
- Despite the simplicity of the adopted numerical modeling as well as of the assumed failure criteria in the direction parallel to the bed-joint, this simple failure criterion and the predicted relevant maximum stress values can explain the observed damaged in all the locations.
- Further research is necessary in order to establish stone masonry strength values and failure criteria that are based on tests representative of the stone masonry that is investigated.
- The capabilities of more refined numerical modeling should also be investigated.

3 THE CHURCH OF PROFITIS ILIAS AT SIATISTA – KOZANI.

This is also a Post-Byzantine three nave Basilica built in 1701 A.D. on the top of a hill in the town of Siatista of the prefecture of Kozani. It also has a wooden roof without the vaulting system of the Basilica church described in section 2. The horizontal dimensions of this church are 23.25m in length and 16.60m in width. The top of the roof lies at 7.1m from the floor level of the interior of this church. The naves are formed by 4-column colonnades built with stone masonry. The lower part of the key of each arch of these colonnades lies at 5.25m from the floor level of the interior of this church. All the exterior walls are made of stone masonry. Apart from the main church a narthex was built at the North side at a later stage; this is of a relatively lower height than the main church. The West part of the church is allocated to the women's quarters that is separated from the rest of the interior by a mid-transverse wall. The South longitudinal wall is supported by a system of wooden beams. These were installed after the Kozani-1995 earthquake sequence. Additional wooden supports are also placed at the mid-transverse wall as well as at the mid-span of a longitudinal beam that spans the women's quarters from East to West. According to past records, the structural system of this church showed signs of distress from soil-settlement sometime before the occurrence of this particular earthquake sequence. The records do not give information of any countermeasures being taken in the past up to the point of the earthquake occurrence. The main structural damage, as recorded after this earthquake sequence, is described below. Inclination of the South longitudinal wall outwards that is accompanied by extensive cracking at its joints with the East and West exterior masonry walls as well as with the mid-transverse wall. Cracking is evident at the arches of the colonnades. Recently, almost 20 years after this earthquake damage, a number of counter measures were introduced towards repairing the masonry walls as well as introducing a relatively shallow reinforced concrete beam at the foundation level from the exterior of the West, South and East peripheral walls.

The numerical investigation of this church included the following ([9], [10], 11]):

a) Simulation of the behaviour assuming non-deformable supports at the foundation level.
b) Simulation of the behaviour assuming deformable supports at the foundation level, introducing at this level elastic springs with properties reflecting the actual soil deformability that was found from in-situ sampling.

The soil consists of clay in its upper layers. For quantifying the stiffness of these soil layers use was made of the data from three bore-holes drilled in the vicinity of the church relevant to the constitution of the soil deposits at a depth up to 15m. All the numerical simulations assumed elastic behaviour with relatively low-values of the modulus of elasticity for the stone masonry equal to E=1660MPa. In the case of Basilica churches damaged in Kefalonia Greece by the 2014 earthquake sequence in-situ measurements of the dynamic response of a bell-tower were utilized in order to define indirectly the soil-foundation deformability ([12], 14]). The system of the wooden roof was modeled as well as all the wooden elements that connect the longitudinal and transverse walls with the interior colonnades and the mid-transverse wall. A small number of mortar samples were taken from the church. The natural stone used in the masonry elements is a type of slate with a compressive strength equal to 24MPa, as given in the literature survey.

Next, the procedure outlined by Manos et al. ([9], [10], [11], [12]) was followed for evaluating the performance of this church. This is based:

a) On the numerical predictions of the state of stress of the masonry walls as obtained from the dynamic analysis of this elastic numerical simulation being subjected to a combination of dead load and seismic forces and
b) On the values of the strength over demand ratios at the most critical locations of the masonry walls and vaults. In doing so, strength values were assumed for in-plane shear and flexure as well as out-of-plane flexure for relatively weak unreinforced stone masonry ([9], [10], [11], [12]).

The ratio of the in-plane shear or tensile strength value over the corresponding demand is signified by $\boldsymbol{R\sigma}$ or $R\tau$ whereas $\boldsymbol{R_M}$ denotes the ratio of the out-of-plane tensile strength value over the corresponding demand. Ratio values smaller than one ($\boldsymbol{R\sigma}$, $\boldsymbol{R\tau}$,$\boldsymbol{R_M}$ <1) predict a corresponding limit state condition ([9], [10, [11], [12], [15]).

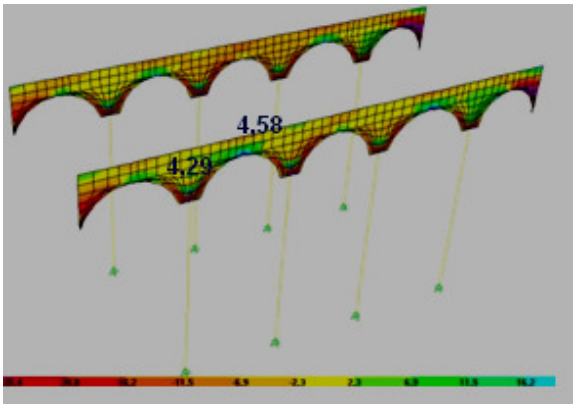


Figure 5a. G+0.3Q. Non-Deformable soil $\boldsymbol{R_\sigma}$ Ratio of in-plane strength / demand **F11** parallel to bed joint

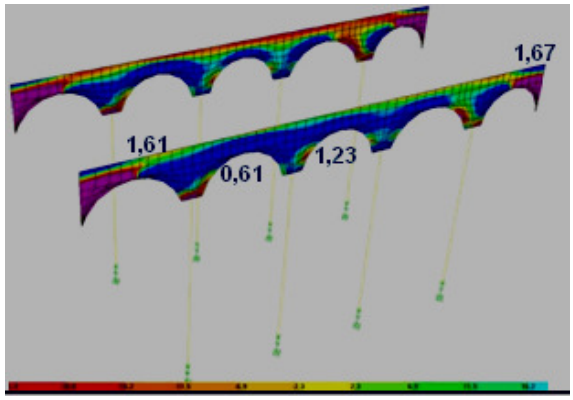

Figure 5b. G+0.3Q. Deformable soil $\boldsymbol{R_\sigma}$ Ratio of in-plane strength / demand **F11** parallel to bed joint

Figures 5a and 5b depict $\boldsymbol{R\sigma}$ ratio values for the masonry arches above the internal colonnades. These $\boldsymbol{R\sigma}$ ratio values of in-plane strength / demand were found by applying the limit tensile strength scenario parallel to bed-joint (F11). The demands in these figures were obtained for the load combination G+0.3Q. As can be seen from the above figures, the $\boldsymbol{R\sigma}$ ratio values are smaller for the deformable than the non-deformable foundation, which demonstrates the detrimental effect of the foundation deformability for this church even only for the gravitational forces. For the load combination 1.3G+1.5Q, that dictates the design for the gravitational forces under current code provisions, the above ratio values will become even smaller, which signifies that the colonnades cannot withstand the maximum gravitational forces. This is verified by the observed damage which is quite evident for these structural elements in this church having been supported for quite sometime after the earthquake event of 1995 by temporary wooden shoring internally as well as externally.

From the evaluation of the demands obtained from this numerical simulation as compared with the limit strength values adopted for the stone masonry of this church it can be concluded that the deformability of the foundation results in strength / demand ratio values smaller than the corresponding ratio values for the non-deformable foundation. This signifies critical regions of the masonry structural elements that cannot withstand the forces, as prescribed by the current code provisions. Moreover, such an evaluation can also explain, up to a point, the development of the existing current state of structural damage. Gaining such confidence in the employed methodology the designer gains also the advantage in evaluating with the same methodology the effectiveness of a potential retrofitting scheme.

In order for such a retrofitting scheme to be effective the resulting strength / demand ratios should attain values larger than the corresponding values without this retrofitting scheme and, if possible, larger than 1 (10], [11], [15]). Such an evaluation has been performed for the most vulnerable structural elements of this church; that is the internal colonnades, the South peripheral wall and the East peripheral wall with the apses. The existing or potential damage is predicted by the numerical analysis results when the strength / demand ratio values are well below 1. This is shown in figure 6 for the internal colonnade. In almost all structural elements the out-of-plane tensile behaviour results in strength / demand ratios with values well below one ($\boldsymbol{R_M}$ <1). The internal colonnade has visible signs of out-of-plane displacements and extensive cracking that are in agreement with the distress predicted by the followed methodology.

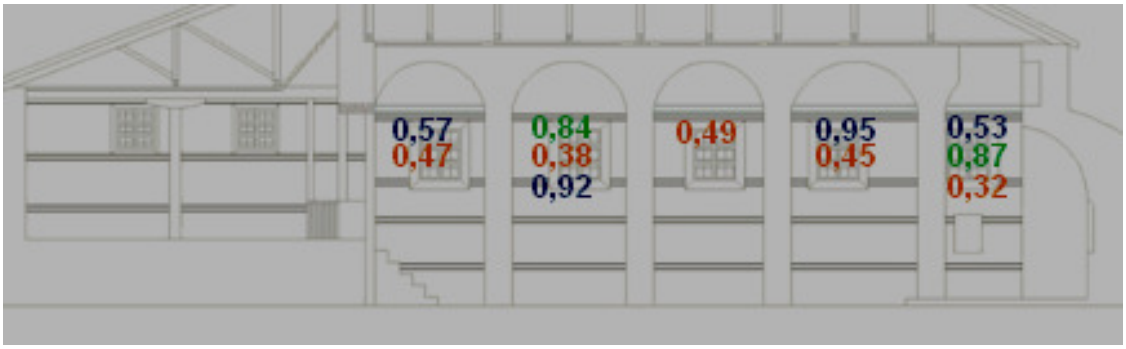

Figure 6. Internal colonnade. Regions with small values of the strength / demand $\mathbf{R_M}$ out-of-plane tensile behaviour (orange color), $\mathbf{R_\tau}$ in-plane shear behaviour (green color), $\mathbf{R_\sigma}$ in-plane tensile behaviour (blue color)

4 THE CHURCH OF ACHIROPOIITOS, AT THESSALONIKI

This church is a three nave Basilica located at the center of Thessaloniki, Greece. It is one of the oldest Greek Christian churches dating from the middle of the 5th century A.D. The interior is shaped by the peripheral (longitudinal and transverse) masonry walls and two series of colonnades formed by twelve columns each. The masonry is built with the old Christian construction technique whereby horizontal zones of brick masonry are succeeded by horizontal zones of stone masonry along the height of the peripheral walls.

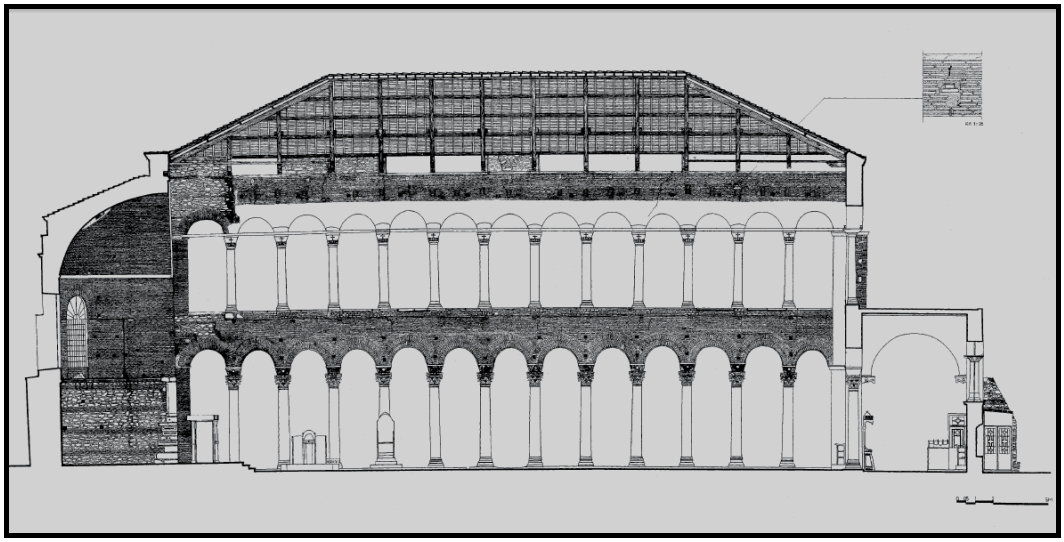

Figure 7. Longitudinal (East-West) cross section of the church of Achiropoiitos

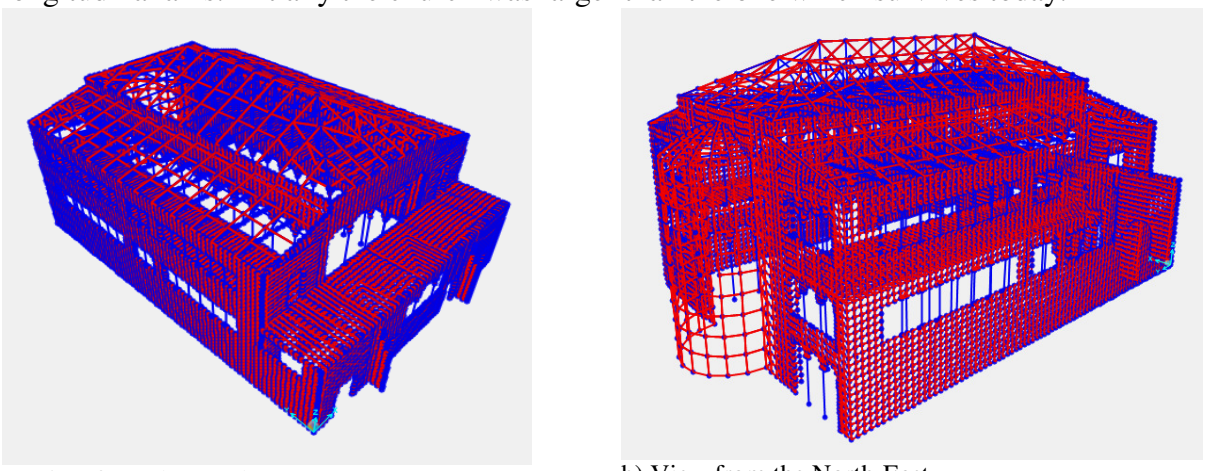
The overall external dimensions are 51.9m in the longitudinal East-West direction and 30.80m in the transverse North-South direction and a height of 14.0m for the peripheral masonry walls. The clear width of the central nave is 14.20m whereas the North and South nave width is 6.20m and 6.30m, respectively. At the East end the central nave extends further than the North and South naves by an extension that is partly formed with an apse. The whole structure is covered by a wooden roof that rises from the ground level 22.0m at the central longitudinal axis. Initially the church was larger than the one which survives today.



a) View from the North-West b) View from the North-East

Figure 8. Numerical simulation of the church of Achiropoiitos

Figure 7 depicts a longitudinal East-West cross section whereas figures 8a and 8b depict the numerical simulation of this church. As was done for the churches of the Assumption of Virgin Mary and for Profitis Ilias the foundation deformability was also examined for this church. This was done by assuming a) rigid soil-foundation conditions (pinned), b) deformable rather stiff soil-foundation and c) deformable rather flexible foundation condition. The soil-foundation deformability was introduced in the numerical simulation with a series of link elements at the soil-foundation interface.

Cumulative Modal participation mass ratios						
Eigen-Modes	Rigid Foundation (Pinned)		Stiff - Deformable Foundation		Flexible Deformable Foundation	
	$SumU_X$	$SumU_Y$	$SumU_X$	$SumU_Y$	$SumU_X$	$SumU_Y$
1st main translational transverse x-x (North-South, Transverse)	**30.5%**	0 %	**51. %1**	0 %	**68.8%**	0.1%
2nd	30.7%	0.6%	51.2%	1.7%	68.9%	16.7%
3rd	67.9%	0.7%	67.9%	14.1%	68.9%	70.6%
4th main translational longitudinal y-y (West – East, Longitudinal)	68.0%	**70.2%**	72.1%	**72.6%**	73.2%	**71.5%**
5th	70.2%	70.5%	73.8%	72.6%	73.3%	71.8%

Table 1. Cumulative Modal participation mass ratios of the church of Achiropoiitos

Table 1 lists the values of the cumulative mass participation ratios of the most significant eigen-modes (1st to 5th), whereas in table 2 the values of the corresponding eigen-periods are listed. As can be seen from table 1 the most significant eigen-modes are the 1st x-x translational eigen-mode in the transverse (North-South) direction and the 4th y-y translational longitudinal (East-West) direction. As can be seen in table 1, the increase in the flexibility of the soil-foundation results in a 1st x-x translational eigen-mode that mobilizes a larger modal

mass than for the case of the rigid foundation. Moreover, this increase in the flexibility of the foundation results, as expected, in the lengthening of the corresponding eigen-period values, as was also discussed for the previously examined churches of the Assumption of the Virgin Mary and for Profitis Ilias.

Eigen-period values (sec)			
Eigen-Modes	Rigid Foundation (Pinned)	Stiff - Deformable Foundation	Flexible Deformable Foundation
1st main translational transverse x-x (North-South, Transverse)	**0.5877**	**0.6111**	**0.6704**
2nd	0.5724	0.5740	0.5781
3rd	0.4974	0.5241	0.5617
4th main translational longitudinal y-y (West – East, Longitudinal)	**0.4734**	**0.5189**	**0.5439**
5th	0.3663	0.3688	0.3801

Table 2. Eigen-period values (sec) of the church of Achiropoiitos

As was done before, the loading conditions examined were a) G+E_x, b) G-E_x, c) G+E_y, and d) G-E_y, where G is the gravitational loads and Ex, Ey the earthquake forces ([1], [16], [17], [18]) along the x-x axis (transverse North-South direction) or the y-y axis (longitudinal East-West direction), respectively. The amplitude of these earthquake forces was obtained by utilizing the recorded ground acceleration during 1978 Thessaloniki earthquake at a close distance from the site of this church. In figures 9a to 9d the values of the ratio of shear strength value over the corresponding shear demand signified $R\tau$ is plotted for the case of rigid foundation and for the case of flexible foundation. In figures 9a and 9b this is done for the North peripheral wall and for the load combination G+Ey for the case of rigid and flexible foundation, respectively. In figures 9c and 9d this is done for the West peripheral wall and for the load combination G+Ex for the case of rigid and flexible foundation, respectively.

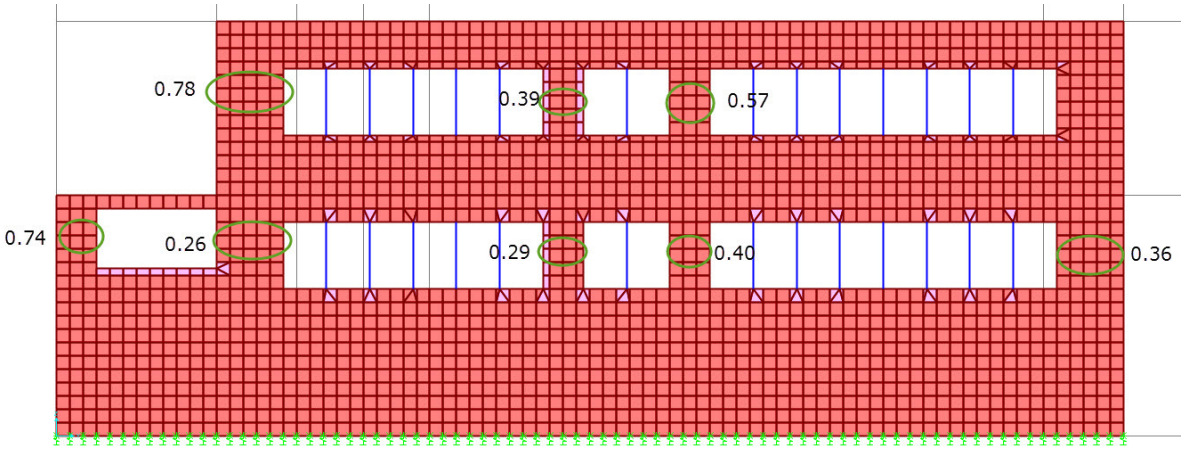


Figure 9a. Values of the ratio **Rτ** towards assessing the performance of the North peripheral wall against in-plane shear for load condition G+Ey . Case of rigid foundation

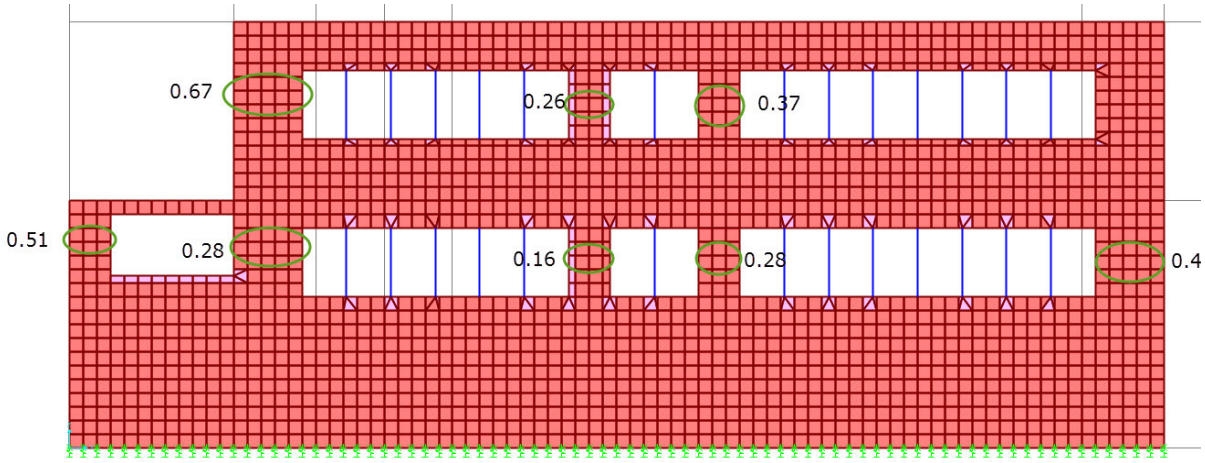

Figure 9b. Values of the ratio **Rτ** towards assessing the performance of the North peripheral wall against in-plane shear for load condition G+Ey . Case of flexible foundation

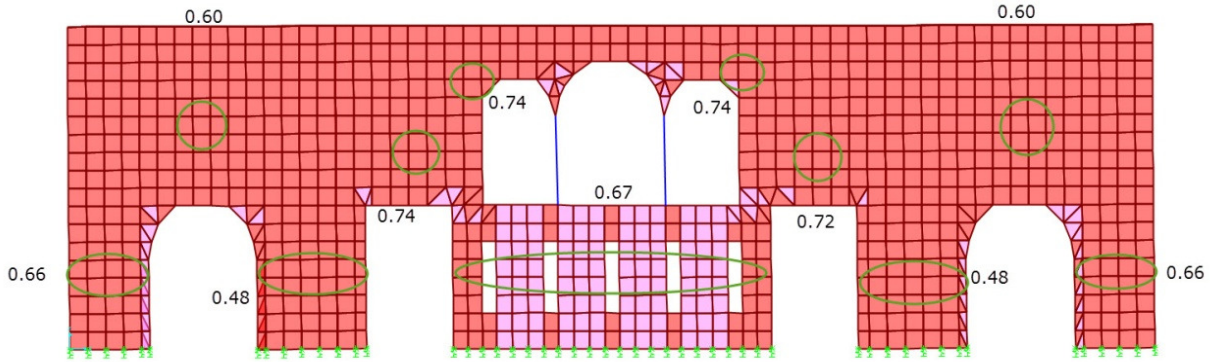

Figure 9c. Values of the ratio **Rτ** towards assessing the performance of the West peripheral wall against in-plane shear for load condition G+Ex . Case of rigid foundation

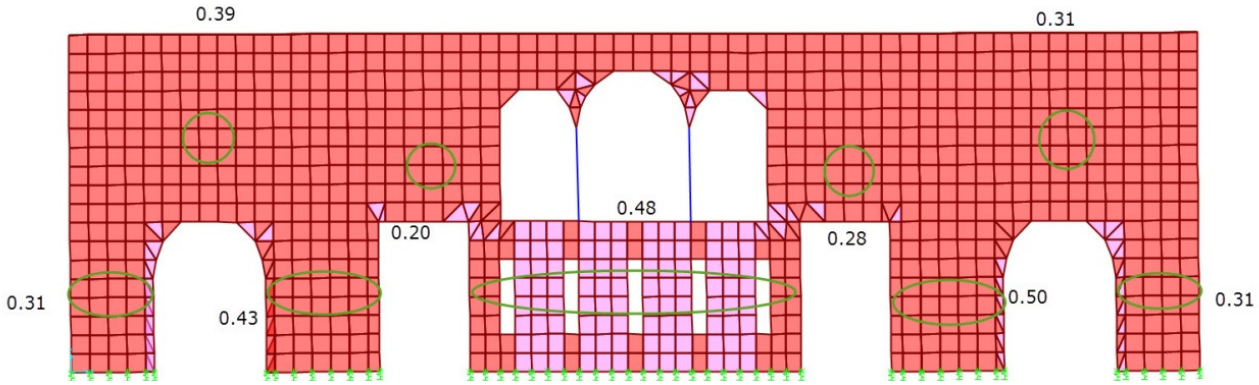

Figure 9d. Values of the ratio **Rτ** towards assessing the performance of the West peripheral wall against in-plane shear for load condition G+Ex . Case of flexible foundation

As can be seen in these figures 9a to 9d there are many locations in both the North and the West peripheral walls where these shear strength over shear demand ratio values are smaller

than 1, which signifies the appearance of shear mode of failure. This observation is in line with the damage that the masonry walls of this church sustained during the 1978 Thessaloniki earthquake sequence. Moreover, as can be seen by comparing the shear strength over shear demand $R\tau$ ratio values for the same location of these two peripheral walls (North wall, figures 9a and 9b or West wall, figures 9c and 9d) between the two cases of rigid and flexible foundation it can be seen that the flexibility of the foundation results in $R\tau$ values noticeably smaller than the case of flexible foundation. This observation supports the partial conclusion that the soil-foundation flexibility was an additional factor contributing to the observed earthquake damage.

5 CONCLUSIONS

- 1. The dynamic behaviour and earthquake performance of churches is a very wide subject. This paper attempts to address the earthquake performance of Basilica churches in parts of Greece during the last 30 years. Towards this objective use is made of in-situ observations together with relatively simple numerical tools. The numerical study includes soil-foundation deformability. The earthquake performance of three specific stone masonry Basilica churches is investigated. The second and third of these churches are simply covered by a wooden roof whereas the first has also a stone masonry vaulted superstructure under its wooden roof. All three churches developed significant structural damage typical of churches of this Basilica typology as was observed in Greece during the last 30 years.
- 2. The eigen-periods, eigen-modes and the deformation patterns to horizontal earthquake actions of the examined churches were predicted numerically. These numerical simulations resulted in large out-of-plane displacements at the top of the longitudinal peripheral walls for all examined churches. The presence of stone masonry vaulting systems increases the stiffening effect at the top of the peripheral wall level; however, such vaulting systems also add considerable masses at a high level that generate large seismic forces.
- 3. The predicted regions most vulnerable to damage are near the door and window openings for the in-plane behaviour; this agrees reasonably well qualitatively with observed damage, although the numerical simulation is based on elastic behaviour. For a superstructure consisting of vaults and domes, large seismic forces are generated leading to stress concentration at the bases of the domes and vaults and at the keys of the arches. Further investigation is needed to establish appropriate limit-state criteria for these stone masonry elements.
- 4. The foundation deformability was investigated introducing linear deformable springs at the foundation level. The results of such a numerical approximation combined with the followed methodology of limit state criteria of strength / demands ratio values ($R\tau$, $R\sigma$, R_M) demonstrate in all the examined cases that the foundation deformability, when combined with the gravitational forces and seismic actions, leads to $R\tau$, $R\sigma$, *and* R_M ratio values that are considerably smaller than for the case of non-deformable foundation thus verifying the detrimental effect of the foundation deformability in all the examined cases.

- 5. Retrofitting counter measures that aim at improving the earthquake performance of such structures must employ comprehensive means for improving the soil-foundation deformability and the interaction with the masonry walls resting on such foundation. This problem is also amplified by the presence of underground water pressures during certain time of the year with substantial rain fall or snow melting. Unfortunately, in many cases these counter measures of improving the soil-foundation-structure interaction are rather superficial.

Abstract. *This paper gives the results of a series of tests carried out on brick columns and panels reinforced with Fibre Reinforced Cementitious Materials. Steel and glass fibres were used, and cement and lime mortars were employed as the matrices. The issue of durability of reinforced masonry structures, that is the transformation from sole masonry structures to hybrid ones, was investigated. Six brickwork columns (three unreinforced and three reinforced) and eighteen solid brick panels were built and tested (two unreinforced, 16 reinforced with steel cords or glass fibre). Tests were carried out in laboratory, and the results enabled the determination of the compression strength of the masonry before and after the application of the reinforcement, and before and after environmental effects. The main goal of the durability testing was to verify whether the artificial ageing process hinders the resistance. At the end of the cycles, a first visual observation was performed in order to evaluate if superficial alterations took place, such as efflorescence or micro cracking due to the immersion in the sodium chloride (NaCl) solution. The aged reinforced specimens appear to have a losses that range from 4% to 25% of the ultimate load, depending on the type of reinforcement and mortar used, although scattering of results confirm the need of more extensive testing.*

1 INTRODUCTION

Structural enhancement of masonry elements, built with natural stones or clay bricks, is frequently necessary; in particular, compressed members, as columns, are prone to brittle failure under seismic forces or static overloads. Recent earthquakes in Molise (2002), Umbria

(2009), Abruzzo (2009) and Emilia-Romagna (2012) have shown that masonry structures are extremely susceptible to the forces imposed during such events [1-2]. Thus, there is an urgent need to upgrade these deficient masonry elements to meet the current design standards in seismic regions. Steel jacketing and reinforced concrete (RC) have been extensively used in Europe, particularly Italy, to retrofit masonry columns and have proved to be effective, but have some drawbacks [3-4]. Such techniques are in fact often non-reversible, expensive and add mass to the structure. Such issues have led researchers to investigate new retrofit solutions using innovative materials such as Fibre Reinforced Polymers (FRP) [5-9] or Steel fibre-Reinforced Polymers (SRP) [10-12] composites in the form of bonded surface reinforcements. Wrapping with FRP or SRP reinforcement offers the designer an outstanding combination of properties, including ease of handling, speed of installation and high strength-to-weight ratio [13-15].

On the other hand, some considerations advise against the use of such techniques. In fact, frequently natural masonry blocks are subjected to moisture entrapment from the ground, released through the external surface during their service life; for that reason it is not always recommendable to apply continuous epoxy-bonded jacketing, inhibiting the material transpiration. As a result of such considerations, beside the "traditional" FRP/SRP wrapping this paper presents the results of a second experimental investigation in a series dealing with the possibility of application of Fibre Reinforced Cementitious Matrices (FRCM). This gives a promising technique that may represent a new opportunity in the field of restoration, since it is reversible, aimed at integrating the masonry rather than transforming it and compatible with the preservation of the building materials.

In this paper, the structural validity of FRCM materials has been analysed by doing compression tests on FRCM-confined columns. Subsequent experimental work focused on the durability of FRCM reinforced elements. After an initial period of durability testing solely on the fibres, with and without their polymeric matrix, attention turned to research that would prove whether the degradation of the FRP system when applied to structural support would increase damage or simply result in not providing the structural reinforcement it had been designed to give. There were cases in which the degradation which started in the FRP system caused mould or other aggressive attacks to the underlying structural system, provoking more damage than if the FRP had not been present [16]. From the data analysed in previous experimental campaigns [17], the more aggressive durability testing performed on FRCM specimens consisted in wet/dry cycles in a 5% sodium chloride solution. Therefore this type of cycle was chosen for the durability on an FRCM reinforced structural element, in the attempt to verify whether the artificial ageing registered in the second experimental campaign described above had the same detrimental effects when the FRCM system was applied to masonry structures. Different schemes of reinforcement were here investigated, the difference consisting in the type of fibres, glass or steel, and the type of matrix, cement mortar or lime mortar.

2 MATERIALS

Small brick columns and panels were assembled, subjected to both compression loads and wet/dry durability cycles and tested in laboratory.

Compression tests were first conducted on FRCM reinforced columns. The results of compression tests show an interesting increase of load bearing capacity with respect to unreinforced columns and give useful indications on the correct application of the reinforcement. The columns were built using solid bricks and reinforced with different types of steel wires. The brick columns were 50 cm in height, were made of 8 courses of bricks and had two different cross sections: octagonal and square.

For wet/dry durability cycles, each panel was composed of five bricks (dimensions: 200x100x50 mm). Total panel's dimensions were 290x100x200 mm (Fig. 1). The test matrix is reported in Table 1.

Number of Specimens	Type of cementitious matrix for Reinforcement	Type of Reinforcement	N° of wet/dry cycles	
8	Lime	Steel (4)	0 (2)	75 (2)
		Glass (4)	0 (2)	75 (2)
8	Cement	Steel (4)	0 (2)	75 (2)
		Glass (4)	0 (2)	75 (2)
2	None	Unreinforced (2)	0 (2)	

Table 1: Test matrix. In parenthesis the number of specimens per type.

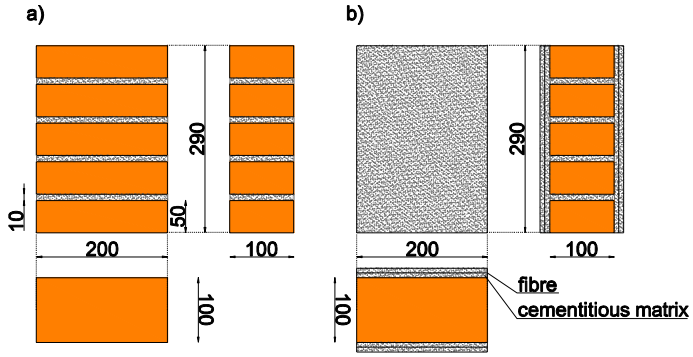

Figure 1: Graphic scheme (dimensions in mm) of the brick masonry panels, plan and elevation, a) unreinforced panel, b) reinforced panel.

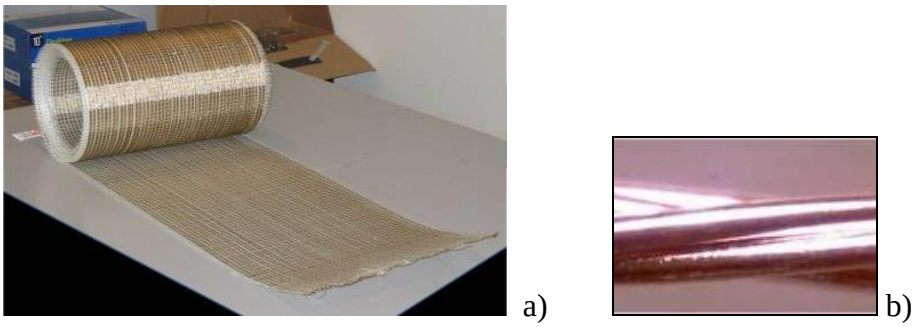

Figure 2: UHTSS steel fibres: a) the coil, b) detail of a single cord.

Two panels from a total of 18 remained unreinforced, as control specimens. All other panels, 16 in total, were reinforced though steel or glass fibres placed on the wide faces of the panels (200x290 mm) with either lime or cement-based mortar, in the manner of reinforced plaster. The mechanical properties of the steel and glass fibres used in the investigation are illustrated in Table 2.

The steel fibres are made of UHTSS (Ultra High Tensile Strength Steel) cords, which are provided from coils available on the market (with the commercial denomination 3X2), pro-

duced by Hardwire llc. They are either brass coated or galvanized with zinc, for increased protection against corrosion. When lime-based mortar is utilized for repointing, it is best to use cords protected by zinc galvanizing The coils used for the steel cords are about 30 cm wide and variable in length, and consist of a series of cords laid out parallel to each other and held together by a polyester mesh (Fig. 2). The most interesting property of the cords used in the proposed system consists in the high bonding and compatibility between the cords and the mortar surrounding them, due to their small size (their average diameter is 1 mm) and shape. In fact, the cords are made by twisting five individual filaments together (three straight filaments wrapped by two filaments at a high twist angle). The specifications of the single cord are shown in Table 2. The mechanical properties of the metal cords were verified by tensile tests carried out on 8 samples. The results substantially confirmed the values given by the manufacturer on the technical sheet, with small variations of the failure load (1539 N) and of the deformation at failure (2.1%) .

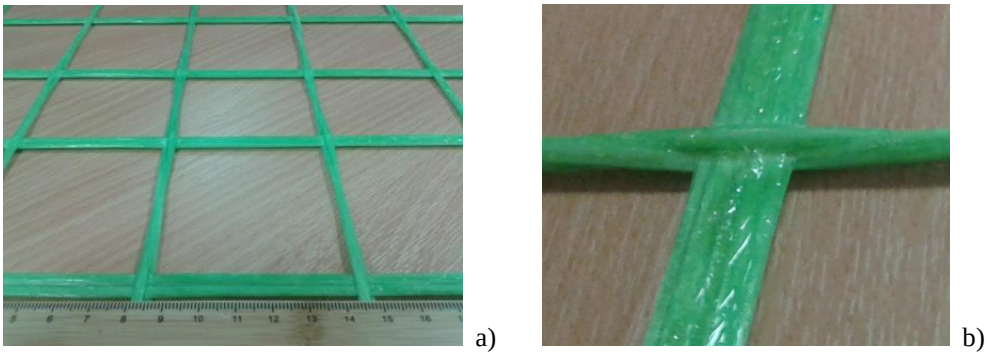
Cord diameter (mm)	0.89
Sample size	10
Tensile failure load (N)	1539
Cross section area (mm^2)	0.62
Young's modulus (GPa)	206.8 (16.4)
Tensile strength (MPa)	2479 (127)
Strain to failure (%)	2.1

Table 2: Mechanical properties of the steel fibres. Standard deviation in ( ).

Nominal dry section (mm^2)	3.8
Sample size	7
Tensile failure load (kN)	3.679
Tensile strength (MPa)	968.2 (85.93)
Young's modulus (GPa)	74.2 (3.4)
Strain to failure (%)	1.3

Table 3: Mechanical properties of the GFRP grid. Standard deviation in ( ).

The fiberglass grid (Glass Fiber Reinforced Polymer: GFRP) used in this research program was manufactured using AR-glass (Alkali-Resistant) fibers and a polyester resin. Specimens extracted from the composite mesh have been measured with a tensile modulus ranging from 71.1 to 79.8 GPa. The mesh has a nominal cross section dry fibre-area of 3.8 mm^2 both in the vertical (weft) and horizontal (warp) direction and has an opening of 66 mm in both directions (Fig. 3). The main mechanical characteristics of GFRP material measured via tensile tests, are shown in Table 3.



a) b)

Figure 3: GFRP grid: a) the grid, b) detail of the joint.

The lime and cement mortar used as cementitious matrices for the FRCM system are described in Table 4. The mortar used in the assembly of the panels was a cement mortar, hand

mixed (lime, cement 32.5 MPa, sand) with proportions in weight 1:1:6 (PCement, Tab. 4). This mortar was used solely in the building of the panels, and not in their reinforcement. Small cubic specimens of bricks, 5.5x5.5x5.5 cm in size, were tested in compression (Tab. 5).

Once the panels were assembled with the cement mortar described above, they were left to cure for 60 days in a humidity free environment at room temperature (circa 19°). Once curing was completed, the panels were reinforced, in number and type of reinforcement as described in Table 1. A layer of cementitious matrix was applied to the surface of the panel, covering the entire façade evenly. The reinforcement was then applied and pressed to ensure attachment to the applied layer of mortar. A second layer of mortar was applied, thus covering the fibre. The reinforced panels were left to cure again for another 60 days and in order to ensure complete curing, in order to avoid that this process could occur during the artificial ageing cycles.

Mortar Type	Average Flexural Strength (MPa)	Average Compressive Strength (MPa)
Lime	0.17	0.52
Cement	0.42	4.05
PCement	0.25	0.62

Table 4: Average values of flexural and compression strength obtained through testing on mortar specimens.

	Average maximum compression load (kN)	Average compressive strength (MPa)
Clay bricks	142.15	47.04

Table 5: Average compressive strength found for solid clay bricks used to build the panels.

3 ARTIFICIAL AGEING METHOD

Once curing was complete, wet/dry cycles on eight reinforced panels commenced. The cycles consisted in a wet period, during which the specimens were immersed in a solution of sodium chloride (NaCl) at 5%, followed by a dry period, during which the specimens were placed in a ventilated oven at 35°C. These specimens required a period of 45 minutes for complete sorption to occur. This amount of time was determined through weighing the specimens dry, and then after having been immersed in the NaCl solution at intervals of 5 minutes. Once the registered weight was stable, thus indicating that sorption was at maximum values, the time elapsed was considered to be the necessary amount for a complete wet cycle. The panels were immerged with the 5% NaCl solution at a level which covered the specimens for at least 2.5 cm and then placed in the oven and left to dry for 24 hours. One cycle duration of 75 days was chosen for all aged specimens.

4 TEST METHOD

4.1 Columns

For compression testing, six brick columns were subjected to axial compression tests in order to determine the efficacy of the confinement with steel fibres in terms of load bearing increase, ductility and axial stiffness. Testing was conducted through an oil-hydraulic Metrocom type press with a 3000 kN load cell with load increases of 5-7 kN/sec. Figure 4 shows the two types of columns tested while Figure 5 gives the cross-section dimension. The steel cords were glued by using a cement-based mortar. Reinforcement was executed in the following

steps: a) cleaning of the column surfaces of all inconsistent material to improve the adhesion between mortar and masonry; b) application of a first layer of mortar; c) application of a unidirectional FRCM sheet; d) application of a second layer of cementitious mortar. All specimens were wrapped with orientation perpendicular to their axis.

Figure 4: Brick columns: a) octagonal cross section, b) square cross section.

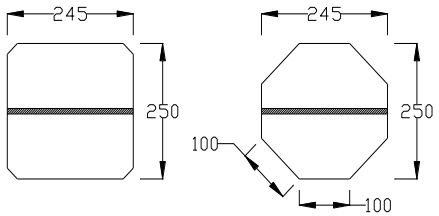

Figure 5: Column cross section (dimensions in mm).

4.2 Panels

Testing was carried out through eccentric compression loading. One of the objectives of this campaign was to study the behaviour of the fibres and the bonding, in an aged condition. By comparing the position of the central core of inertia with the compressive load, it was possible to verify that the compressive and tensile stresses were actively being applied to the brick panels. Loading was applied through a load cell (TCLP–10B Tokyo Sokki Kenkyujo Co, Ltd.) with a maximum capacity of 100 kN applying pressure on a steel cylinder positioned at 50 mm to the right of the central axis of the panel.

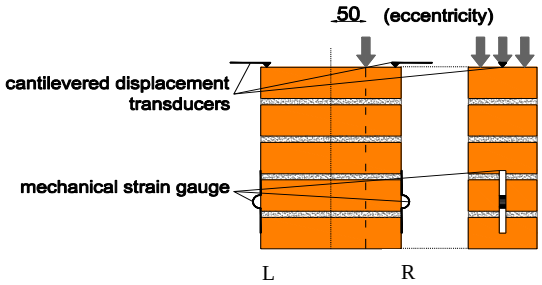

Figure 6: Graphic scheme of the positions of the mechanical strain gauges and transducers during testing (mm), with Left Hand (L) and Right Hand (R) sides indicated (dimension in mm).

Figure 7: Mechanical Strain Gauge.

The steel cylinder is the same width of the panel, ensuring that the load is applied only on the masonry structure and not on the FRCM reinforcement. Deformations were recorded through two mechanical strain gauges on the short sides of the panels and two cantilevered displacement transducers (CE-10 Tokyo Sokki Kenkyujo, Fig. 6). The two displacement transducers attached to the upper face of the panels measured the vertical displacement of the panel during loading. The second typology was applied for recording relative movements between the two extremities of the gauges. Omega-shaped (Fig. 7), the ends of these strain gauges are attached to the specimens and their hemispherical central part allows these ends to follow the displacements of the specimen.

5 RESULTS

5.1 Compression tests on columns

The specimens were subjected to axial monotonic load until failure occurs. The first three tests were conducted on unreinforced columns in order to obtain the average compressive strength of the columns, which resulted in 719 kN. Considering the area of the octagonal transversal section of the columns, 512 cm^2, the compressive strength is approx. 14 MPa. A similar value was measured for square cross section (14.8 MPa).

For octagonal cross-section columns confined by steel composites, the FRCM reinforcement (specimens 2&3) requires the application of a significant thickness of cementitious mortar, up to 5cm, which in some cases may be incompatible with the requirement of an unvaried transversal section. The compression testing on the reinforced columns show an increase of maximum load of 28% compared with unreinforced columns (Tab. 6).

Sample	Cross Section	Rinf.	Compression strength (MPa)	Failure load (kN)	Axial stiffness (MPa)
1	octagonal	no	14.0	719	2034
2	octagonal	steel	21.3	1089.8	2306
3	octagonal	steel	14.7	755.9	1462
4	square	steel	16.9	1020	2033
17	square	no	15.6	945	1745
18	square	no	14.0	847	2576

Table 6: Results of compression tests.

Figure 8: Compression test (reinforced column).

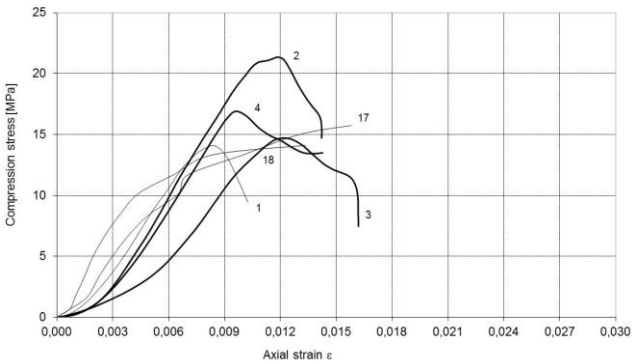

Figure 9: Stress vs. axial strain response.

For columns with a square cross-section, the effectiveness of the reinforcement is smaller (13.8%). This is mainly due to the stress-concertation near the columns corners. The flexural stiffness of the steel cords also prevent an adequate bonding of the fibres to the masonry surface and this partially compromises the confinement effect of the FRCM reinforcement.

The collapse mode of reinforced columns (Fig. 8) includes the cracking of the masonry underneath the fibres and the subsequent bulging of the columns around the midpoint. Total collapse of the columns occurs for the rupture of the fibres once the masonry is completely cracked internally. Significantly, the rupture of the FRCM reinforcement does not occur at the corners of the columns, a typical collapse mode in FRP reinforced columns, but at the midpoint of the specimens once the tensile strength of the fibres has been exceeded. Figure 9 shows the compression stress vs. axial strain response of reinforced and unreinforced columns.

5.2 Compression tests on small panels

Values for both reinforced and unreinforced specimens remain within values that range from 35 to 50 kN (Fig. 10). The small variation between reinforced and unreinforced specimens may be due to the fact that the FRCM system is simply bonded to the façades of the panels without mechanical anchoring systems. While the ultimate loads values do not vary greatly, the collapse mechanisms are different.

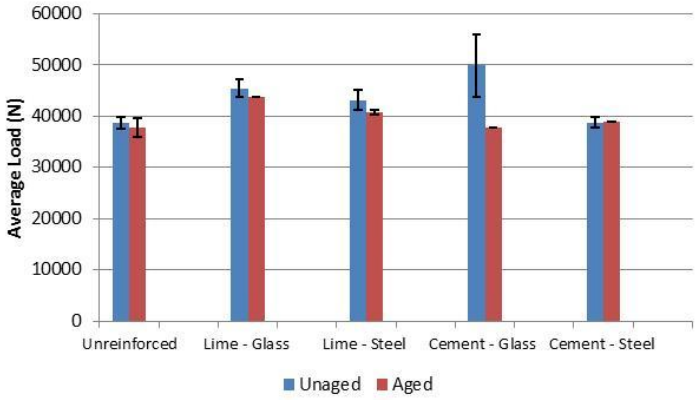

Figure 10: Average maximum loads for unaged and aged panels.

Unreinforced specimens fractured gradually. The average failure load of unaged specimen was 38.71 kN. The ageing process caused a negligible decrease of the panels' capacity of 2.3%. Cracks at first appear immediately below the point of load application, given by excessive compressive stress for a load of approx. 30 kN. At this point there is a drop in the load (Figs. 11-13). A secondary crack then appears at the bottom of the column opposite the loading point (Fig. 11a). This mechanism is not visible in the FRCM reinforced panels until the fibres detach completely from the side they are attached to, and even when detachment occurs it does not crack due to tensile strength; the rupture in reinforced specimens is abrupt and due to excessive compressive force as opposed to the gradual collapse verified in unreinforced specimens. The FRCM system does not prevent the masonry panel from cracking. The lateral shorter sides of the panels are free from reinforcement. Therefore when cracking of the bricks occurs, there may be a rotation of the elements shortly after the detachment of the fibres commences. This is the consequence of the eccentric compression, when the loads are outside the central core of inertia of the panel. The fact that the slate of FRCM detaches either completely or only partially makes little difference to the resistance of the panel; in fact, once the FRCM begins to detach, it is as if the fibre reinforcement is virtually non-existent.

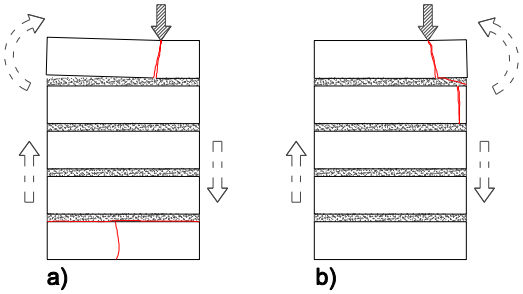

Figure 11: Graphic description of the cracks that occurred in unreinforced specimens; a) Specimen 1UR and b) Specimen 2UR.

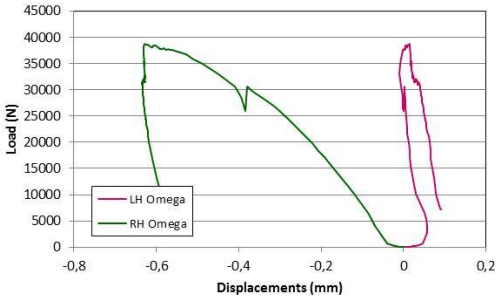
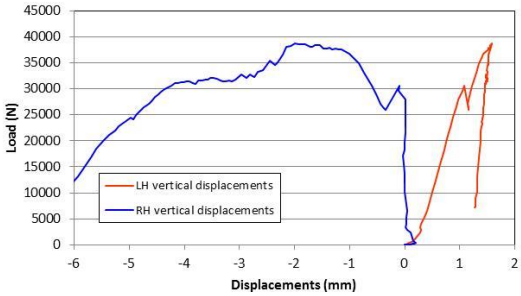
It is possible that strain gauges and transducers register concurrently opposing displacements. Due to the position of the instruments separated by two bricks which may rotate and move in directions other than those of the two bricks the gauges are glued to (Fig. 14), displacements may have opposing sign when referring to one side of the specimen. In the testing condition, the larger displacement has been recorded under the loading point. After collapse, vertical cracks appeared with elongations of the right side (Fig. 15).





Figures 12 and 13: Load - displacement diagrams for Unreinforced Specimen 1; values given by cantilevered vertical displacement transducers and Omega transducers.

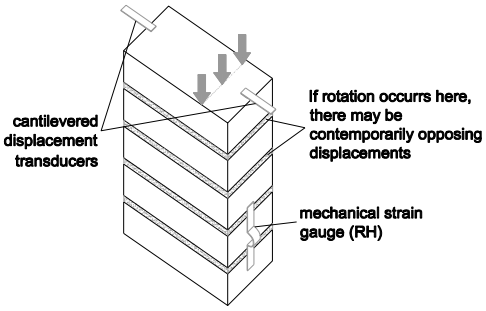


Figure 14: Axonometry of panels with strain gauges and displacement transducers. The mortar layers where possible rotations may lead to discording diagrams are highlighted.

The application of the FRCM reinforcement always caused an increase in the panel capacity. The application of the reinforcement is moderately able to absorb the tensile stresses and to partially prevent brickwork from cracking near the bed joints. The use of a cementitious mortar to bond the GFRP reinforcement increased the panel capacity of 29% compared to unreinforced specimens. The use of a lime-based mortar for both GFRP and steel reinforcements caused a limited increase of the panel capacity between 11.5 and 17%: this is probably due to the small tensile and shear strength of this mortar.

As for the differences in behaviour between aged and unaged specimens, none of the values of the aged specimens differed greatly from those of their unaged control specimens, as is clearly shown in Figure 10. However the ageing process caused a significant reduction of the panel capacity.

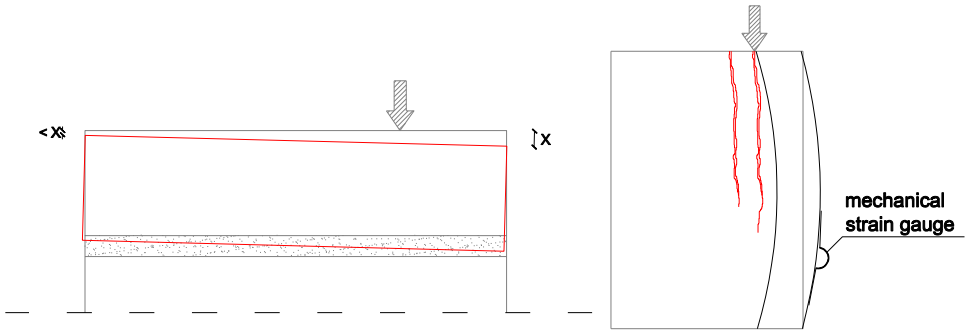

Figure 15: The upper section of the panel, showing larger displacements on the right side of the panels, and a graphic scheme of elongations that might occur in the right side of specimens.

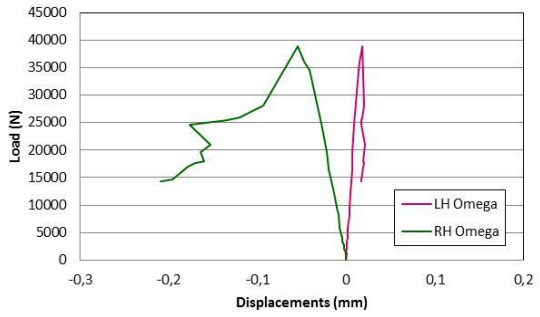
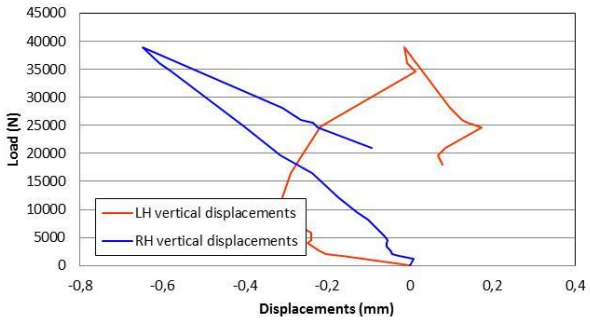
Again, the ageing process on panels reinforced using a lime-based mortar caused a limited decrease of the panel capacity (approx. 5%) and this demonstrated that both the steel and GFRP reinforcement can be used to reinforce wall panels without significant ageing problems. However the oxidation of the steel fibers is another aspect to consider, when steel fibre - Cement matrix are used to reinforce masonry members. However since the number of specimens tested was limited, results should be confirmed by a larger experimental programme. However, the emerging line seems quite correct. As may be inferred by the following graphs, all of the reinforced panels reach their ultimate load abruptly (Figs. 16-17), with no substantial differences between aged and unaged specimens.





Figures 16 and 17: Load - displacement diagrams for Steel Fibre - Cement Matrix Specimen 4 after 75 wet/dry cycles; values given by cantilevered vertical displacement transducers and Omega transducers.

Some other considerations can be made from the observation of the photographic survey conducted during testing which seem to be relevant to all unaged specimens. From physical observations of the aged specimens, the most evident effects of the ageing cycles is in the efflorescence of the saline solution on the surface of both the brick structure, visible at the sides of the panels, and the cementitious matrix covered faces of the panels. The glass fibres did not show any signs of degradation after the artificial ageing cycles were complete, while the steel fibre reinforced specimens began to show rust on the surface of the matrix used to cover them as soon as the 5th cycle. By the end of the 75 wet/dry cycles, the rust was heavily distributed throughout the matrix surface. However, rust was not detected on the surface of the masonry

once the reinforcement detached after testing, and no other kinds of spots or smears were detected; the formation of mould, which could eventually cause the fibre reinforcements to detach from their structural supports, did not appear in the aged specimens.

6 CONCLUSIONS

The main inquiry of the present experimental campaign was aimed towards determining whether FRCM reinforced masonry panels are severely affected by artificial ageing, achieved in this particular case through wet/dry cycles in a 5% NaCl solution.

Sheet of steel or glass fibres (GFRP) can be easily applied as masonry strengthening. Preliminary compression tests demonstrated that it is possible to increase the compression capacity of brickwork columns by wrapping with FRCM systems using steel fibres. Increase in capacity up to 30% have been measured compared to unreinforced columns. However the shape of the cross-section could influence the effectiveness of the FRCM reinforcement.

It may be also noted that the FRCM system does not appear to be affected by the wet/dry cycles. While no substantial differences were found between the two types of specimens, due to the lack of anchorage of the reinforcement to the masonry substrate, the reinforced ones presented abrupt ruptures due to detachment of reinforcement, while the unreinforced ones collapsed in a more gradual manner. The degradation caused by the 5% NaCl solution appears only in saline efflorescence in all aged specimens, while in the steel fibre reinforced specimens rust was apparent from as soon as the 5th wet cycle. When the FRCM system was removed from the surface of the masonry panels after testing, no mould formations were detected. Regarding the resistance of the FRCM system to the tensile strength to which the panels were subjected as a consequence of eccentric compression, cracks caused by tensile stress did not appear in reinforced specimens, leading to the conclusion that the fibres successfully absorbed such stresses.

From the results of testing in the present campaign and the observations conducted throughout the cycles, it can be stated that FRCM reinforced panels are not affected by wet/dry cycles as regards the ultimate load carrying capacity. However, the superficial degradation of the specimens, in particular of those reinforced with steel fibre, must be addressed in order to avoid the detachment of the FRCM.

Keywords: Masonry vaults, Limit analysis, NURBS, Genetic Algorithm.

Abstract. *In the present contribution, a novel Genetic Algorithm NURBS-based approach for the limit analysis of FRP reinforced masonry vaults based on an upper bound formulation is developed.Vaults geometry can be described by a NURBS representation of their mid-surface, which can be generated within any commercial free form modeler, together with information about the local thickness at each point of the surface. By exploiting the properties of NURBS functions, a mesh of the given surface, which still provides an accurate representation of the vaulted surface, can be obtained. Each element of the mesh is a NURBS surface itself and is idealized as a rigid body. Starting from the obtained rigid bodies assembly, an upper bound limit analysis problem with very few optimization variables can be devised and in which dissipation is allowed along element edges only. A possible dissipation at the interfaces between FRP and masonry is also considered in order to take into account, in an approximate but effective way, the possible delamination of the strips from the supports. Due to the very limited number of rigid elements used, the quality of the collapse load so found depends on the shape and position of the interfaces, where dissipation is allowed. Mesh adjustments are therefore needed which is carried out by adopting a simple meta-heuristic (like a standard Genetic Algorithm GA) approach of mesh adjustment. The strength of the proposed GA-NURBS method lies in the fact that even by using a mesh made of very few elements (which therefore require a negligible computational time to have an estimate of collapse loads), it is possible to obtain accurate load multipliers and failure mechanisms, thus exhibiting an edge over existing methods for the collapse analysis of masonry vaults in terms of computational efficiency.*

1 INTRODUCTION

Masonry vaults represent one of the most widespread structural typologies in the historical buildings of both Eastern and Western architecture. Therefore, the interest for their preservation is growing over time along with the need for developing new efficient tools to analyze and evaluate their load-bearing capacity.

As pointed out in [1, 2], it can be affirmed that the modern theory of limit analysis of masonry structures, which has been developed mainly by Heyman [3], is the most reliable tool to assess the ultimate load bearing capacity of masonry vaults. According to Heyman [3], limit theorems of plasticity, i.e. static (lower bound) theorem and kinematic (upper bound) theorem, can be applied to masonry structures provided that the following conditions are verified: i) the compressive strength of the material is infinite; ii) sliding between parts is prevented; iii) tensile strength of masonry is negligible.

Let us observe that for structures made of clay bricks and mortar, collapse generally occurs at small overall displacements. Moreover, in some cases sliding is possible though with a relatively high friction coefficient [4] and shear failure at the joints can be treated within the framework of non-associate plasticity [5]. Finally, although clay bricks masonry exhibits an almost zero tensile strength and a good compressive strength, the infinite compressive strength hypothesis is questionable and, as shown in [3], it is possible to include finite compressive strength within a limit analysis formulation. Nevertheless, material crushing play a minor role in the collapse behavior of masonry structures, except for very shallow segmental arches, pillars, towers and massive vertical structures.

Limit analysis can be also extended to the case of FRP (fibro-reinforced polymers) reinforced masonry structures [6].

Other essential aspects concerning actual masonry vaults should be considered, such as the effects due to material heterogeneity, the importance of the overall geometry for achieving the equilibrium, the importance of properly taking into account the infill and the presence of existing cracks [7].

The recently developed computational methods for masonry vaults, simple or reinforced, can be classified into two broad categories: the Finite Element methods developed both for nonlinear incremental analysis [8] and for limit analysis [9], and the thrust network methods [10-11] directly based on a lower bound formulation [12]. Practical application of these methods requires skilled users and, in the case of thrust network methods, the definition of an equilibrium surface for the vault, which is a priori unknown.

The present paper proposes a new NURBS-based approach [13] for the limit analysis of masonry vaults based on an upper bound formulation also allowing for the presence of FRP reinforcements, developing an idea proposed in [14] for masonry arches. NURBS (i.e. Non-Rational Uniform Bi-Spline) are special approximating base functions widely used in the field of 3D modeling [15]. A given masonry vault geometry can be represented by a NURBS parametric surface, which can be generated within any commercial free form modeler. By exploiting the properties of NURBS functions, a mesh of the given surface, which still provides an exact representation of the vaulted surface, can be obtained. Each element of the mesh is a NURBS surface itself and can be idealized as a rigid body.

Starting from the obtained rigid bodies assembly, an upper bound limit analysis formulation can be devised, which takes into account the main aspects of masonry material (i.e. negligible tensile strength and good compressive strength) and in which dissipation is allowed along element edges only. Furthermore, a meta-heuristic approach based on the implementation of a Genetic Algorithm allows adjusting the initial NURBS mesh until a good estimate of the collapse load multiplier is obtained. This happens when element edges describes the actual

failure mechanism. The strength of the proposed method lies in the fact that even by using a mesh made of very few elements, it is possible to obtain an accurate estimate of the load multiplier, thus exhibiting an edge over existing methods for the collapse analysis of masonry vaults in terms of computational efficiency,

The paper is organized as follows: in Section 2 a synthetic survey is given about how the geometric shape of a masonry vault can be described by a NURBS surface representation and a NURBS mesh can be defined on it. In Section 3, an upper bound limit analysis formulation is proposed, based on the NURBS geometric representation of the masonry vault, which allows to compute the collapse load for a set of given failure mechanisms. Section 4 outlines a Genetic Algorithm, which is capable of selecting the correct failure mechanism, by adequately adjusting the initial mesh. Finally, Section 5 is devoted to presenting several simple numerical results obtained by the proposed procedure.

2 NURBS GEOMETRIC DESCRIPTION

Description and computation of geometries in commercial CAD packages are based on B-Splines and NURBS approximating functions. More precisely, NURBS basis functions are built on B-splines basis functions, which are piecewise polynomial functions defined by a sequence of coordinates $\Xi = \{\xi_1, \xi_2, ..., \xi_{n+p+1}\}$, also known as the knot vector, where the so-called knots, $\xi_i \in [0,1]$, are points in a parametric domain, in which *p* and *n* denote the polynomial order and the total number of basis functions, respectively. Once the order of the basis function and the knot vector are known, the *i*-th B-spline basis function, $N_{i,p}$, can be computed by means of the Cox-de Boor recursion formula [15]. Given a set of weights, $w_i \in \mathbb{R}$, the NURBS basis functions, $R_{i,p}$, read

$$R_{i,p}(\xi) = \frac{N_{i,p}(\xi) w_i}{\sum_{i=1}^{n} N_{i,p}(\xi) w_i}. \tag{1}$$

NURBS share many properties with B-spline basis functions [13]. Among these, they are all nonnegative, they have a compact support, and build a partition of unity (PoU), that is

$$\sum_{i=1}^{n} N_{i,p}(\xi) = \sum_{i=1}^{n} R_{i,p}(\xi) = 1 \tag{2}$$

for each $\xi \in [0,1]$ [13]. Hence, according to Eqs. (1) and (2) B-spline basis functions can be thought of as NURBS basis functions when all weights w_i are equal to one. However, NURBS basis functions have the great advantage of representing exactly the geometry of a wide set of curves such as circles, ellipses, and parabolas [15], and of the surfaces that can be generated by these curves. Geometries that can be generated with B-spline and NURBS are obtained as linear combinations of basis functions [13]. If one considers a set of NURBS basis functions $R_{i,p}$, a NURBS curve of degree *p* is a parametric curve in the three-dimensional Euclidean space defined as

$$\mathbf{C}(u) = \sum_{i=1}^{n} R_{i,p}(\xi) \mathbf{B}_i \tag{3}$$

where coefficients $\mathbf{B}_i \in \mathbb{R}^3$ are known as control points. Unlike standard Lagrange and Hermite approximations, NURBS geometries do not usually interpolate these points. The conti-

nuity of the curve follows from that of the adopted basis functions [15], which is generally C^{p-1} throughout the domain. However, if a knot has multiplicity, *m*, the continuity decreases *m* times at that point [15]. Analogously, a NURBS surface of degree *p* in the *u*-direction and *q* in the *v*-direction is a parametric surface in the three-dimensional Euclidean space defined as

$$\mathbf{S}(u,v)=\sum_{i=0}^{n}\sum_{j=0}^{m}R_{i,j}(u,v)\mathbf{B}_{i,j} \tag{4}$$

where $\{\mathbf{B}_{ij}\}$ form a bidirectional net of control points. A set of weights $\{w_{i,j}\}$ and two separate knot vectors in both *u* and *v* directions must be defined. Given a NURBS surface $\mathbf{S}(u,v)$, isoparametric curves on the surface can be defined by fixing one parameter in the parameter space and letting the other vary. By fixing $u=u_0$ the isoparametric curve $\mathbf{S}(u_0,v)$ is defined on the surface $\mathbf{S}$, whereas by fixing $v=v_0$ the isoparametric curve $\mathbf{S}(u,v_0)$ is obtained.

Many commercial free form surface modelers, such as Rhinoceros® [16], utilize NURBS representation and its properties to generate and manipulate surfaces in the three-dimensional space. In what follows, simple vault geometries have been generated within Rhinoceros and the resulting NURBS structure have been imported within a MATLAB® environment through the IGES (Initial Graphics Exchange Specification) standard [17]. Once the NURBS structure has been transferred to the MATLAB® environment, it is possible to manipulate it by exploiting NURBS properties in order to define a NURBS mesh on the given surface, i.e. a mesh in which each element is a NURBS surface itself. When working with simple surfaces like the one considered in the present contribution, the easiest way to generate a NURBS mesh on the given surface is to define a subdivision of the two-dimensional parameters space *u*-*v*, which follows from subdividing the knot vectors in both *u* and *v* directions into equal intervals. The resulting mesh is formed by isoparametric curves on the surface in the three-dimensional Euclidean space. Each element is a NURBS surface and its edges are branches of isoparametric curves belonging to the initial surface. More precisely, the counter-image of each element of the mesh is a rectangle $S_{ij}=[u_i,u_{i+1}]\times[v_j,v_{j+1}]\in\mathbb{R}^2$ defined in the parameters space. For each element (which can be denoted by E_{ij}), the area of the surface can be computed through the following relation:

$$A_{ij}=\int_{S_{ij}}dS=\int_{u_i}^{u_{i+1}}\int_{v_j}^{v_{j+1}}\left\|\mathbf{S}_u\times\mathbf{S}_v\right\|du\,dv \tag{5}$$

where $\mathbf{S}_u$ and $\mathbf{S}_v$ are partial derivatives of the parametric surface $\mathbf{S}(u,v)$ in the *u* and *v* directions. Analogously, the center of mass of each element may be computed with the following relation:

$$\mathbf{c}=\frac{1}{A_{ij}}\int_{S_{ij}}\mathbf{x}\,dS=\frac{1}{A_{ij}}\int_{u_i}^{u_{i+1}}\int_{v_j}^{v_{j+1}}\mathbf{S}(u,v)\left\|\mathbf{S}_u\times\mathbf{S}_v\right\|du\,dv \tag{6}$$

Computations can be numerically carried out using a standard Gauss quadrature method.

3 KINEMATIC LIMIT ANALYSIS

Limit analysis is a powerful tool to assess the structural safety level of a masonry construction. As already discussed, given the NURBS geometric representation of the vaulted surface, a NURBS mesh can be defined on the same surface. Each element of the mesh, which is a NURBS surface itself, can be regarded as a rigid body. Starting from the geometrical proper-

ties of each element, an upper bound formulation can be outlined and implemented through a linear programming algorithm in order to assess the ultimate load bearing capacity of a given masonry vault. This paragraph summarizes the proposed upper bound formulation.

Be N_E the number of elements composing the NURBS mesh, which geometrically represents the vaulted surface. Each element is considered as a rigid element. Thus, the kinematics of each element is determined by the six (three translational and three rotational) generalized velocity components $\{u_x^i, u_y^i, u_z^i, \Phi_x^i, \Phi_y^i, \Phi_z^i\}$ of its center of mass G_i, expressed in a global reference system $Oxyz$. On the structure, dead loads $\mathbf{F}_0$ and live loads $\mathbf{\Gamma}$ are acting. Internal dissipation is assumed to occur only along element interfaces. Indicating by N_I the number of interfaces, total internal dissipation power D_{int} is equal to the sum of the power dissipated along each interface P_{int}^i, which is defined in Section . Furthermore, total internal dissipation power D_{int} is equal to the sum of the powers of live ($\mathbf{1} \cdot \Gamma$) and dead ($\mathbf{F_0}$) loads, indicated as $P_{\mathbf{\Gamma}}$ and $P_{\mathbf{F_0}}$ respectively:

$$D_{\text{int}} = \sum_{i=1}^{N_I} P_{\text{int}}^i = P_{\mathbf{\Gamma}} + P_{\mathbf{F_0}} \tag{7}$$

Γ is a load multiplier. The linear programming problem related to the kinematic formulation of limit analysis consists in an appropriate minimization of the load multiplier Γ under the action of suitable constraints, which are described in the following Subsections. The vector of unknowns of the linear programming problem, $\mathbf{X}$, contains the six generalized velocity components for each element and a number of plastic multipliers along each interface which will be defined in Subsection 3.2.

3.1 Geometric constraints

Vertex belonging to element free edges, which do not constitute an element interface, can be subjected to external kinematic constraints, by imposing an assigned value for translational and/or rotational velocities at these points. For each of such vertex V_j, kinematic constraints can be expressed in terms of generalized velocities of the center of mass of the *i*-th element they belong. For example, in case only translational velocities of a given vertex V_j, belonging to element *i*, are constrained to zero, the following relation holds as a geometric constraint:

$$\mathbf{u}_{V_j} = \mathbf{u}^i + \mathbf{R}\left[\mathbf{x}_{V_j} - \mathbf{x}_{G_i}\right] = \mathbf{0} \tag{8}$$

where $\mathbf{u}_{V_j} = [u_x^{V_j}, u_y^{V_j}, u_z^{V_j}]^T$ are the three translational velocity components of the vertex V_j, $\mathbf{u}^i = [u_x^i, u_y^i, u_z^i]^T$ are the three (unknown) translational velocity components of the center of mass of element *i* to whom vertex V_j belongs, and $\mathbf{R}$ is a rotation matrix whose elements are the (unknown) generalized rotational velocities of the center of mass of element *i*. In general, all linear geometric constraints can be re-written in the following standard form:

$$\mathbf{A}_{eq,geom}\mathbf{X} = \mathbf{b}_{eq,geom} \tag{9}$$

where $\mathbf{A}_{eq,geom}$ is the matrix of geometric constraints and $\mathbf{b}_{eq,geom}$ the corresponding vector of coefficients.

3.2 Compatibility constraints

In order to enforce plastic compatibility along interfaces and correctly evaluate dissipation power, intrados and extrados edges of each interface have been subdivided into an assigned number $(N_{sd}+1)$ of points P_i. On each point P_i, a local reference system $(\mathbf{n},\mathbf{s},\mathbf{t})$ have been defined, where $\mathbf{n}$ is the unit vector normal to the interface, $\mathbf{s}$ is the tangential unit vector in the longitudinal direction and $\mathbf{t}$ is the tangential unit vector in the transversal direction.

On each point P_i of each interface, which separates the two elements E' and E'', the following compatibility equation must hold:

$$\Delta\tilde{\mathbf{u}} = \dot{\boldsymbol{\lambda}}\frac{\partial f}{\partial \boldsymbol{\sigma}} \tag{10}$$

where $\boldsymbol{\sigma}=[\sigma_{nn},\sigma_{ns},\sigma_{nt}]$ is the stress vector acting on P_i in the three local reference directions, $f(\boldsymbol{\sigma})$ is a suitable yield function and $\dot{\boldsymbol{\lambda}}$ is an unknown plastic multiplier vector. In Eq. (10), $\Delta\tilde{\mathbf{u}}$ is the representation in the local reference system of the quantity $\Delta\mathbf{u}$ in the global reference system which is defined as:

$$\Delta\mathbf{u} = \mathbf{u}'_{P_i} - \mathbf{u}''_{P_i} \tag{11}$$

where $\mathbf{u}'_{P_i}$ is the vector composed by the three translational velocity components of the point P_i seen as belonging to element E' and $\mathbf{u}''_{P_i}$. $\Delta\mathbf{u}$ is related to $\Delta\tilde{\mathbf{u}}$ through the following relation:

$$\Delta\tilde{\mathbf{u}} = \tilde{\mathbf{R}}\Delta\mathbf{u} \tag{12}$$

where $\tilde{\mathbf{R}}$ is a suitable 3×3 rotation matrix whose rows are respectively the components of the three local vectors $(\mathbf{n},\mathbf{s},\mathbf{t})$ expressed in the global reference system.

For the sake of simplicity, the yield surface $f(\boldsymbol{\sigma})$ have been defined in the stress-space as the parallelepiped defined by the inequalities $-f_c \le \sigma_{nn} \le f_t$, $-\tau_{0,ns} \le \sigma_{ns} \le \tau_{0,ns}$, $-\tau_{0,nt} \le \sigma_{nt} \le \tau_{0,nt}$ where f_c, f_t, $\tau_{0,ns}$, $\tau_{0,nt}$ are material parameters corresponding respectively to compression strength, tensile strength, shear strength in the direction tangential to the interface midline and shear strength in the direction orthogonal to the interface midline. If the interface is reinforced by FRP strips at intrados or extrados f_t is replaced by the delamination stress f_d computed according to [18] in order to take into account dissipation due to FRP delamination.

With the assigned yield surface, Eq. (10) simplifies and must hold for each point P_i of each interface. On each point P_i, six unknown plastic multipliers $\dot{\lambda}^+_{nn},\dot{\lambda}^-_{nn},\dot{\lambda}^+_{ns},\dot{\lambda}^-_{ns},\dot{\lambda}^+_{nt},\dot{\lambda}^-_{nt}$ are defined. Therefore, the total number of unknown plastic multipliers is equal to $6\cdot(N_{sd}+1)\cdot 2N_I$.

3.3 Non-negativity of plastic multipliers

An additional constraint which must be included into the linear programming problem is the non-negativity of each plastic multiplier:

$$\dot{\lambda}_{ij} \geq 0. \tag{13}$$

3.4 Normality condition

The last condition to be applied is the so-called normality condition which requires that the external power dissipated by the live load $\mathbf{1} \cdot \Gamma$ set equal to one, is itself equal to one, i.e.:

$$P_{\Gamma=1} = 1 \tag{14}$$

This condition allows to rewrite Eq. (7) in the following way:

$$\Gamma = \sum_{i=1}^{N_I} P_{\text{int}}^i - P_{F_0} \tag{15}$$

3.5 Internal dissipated power and linear programming problem

On each interface i, covering the surface S_i, the internal dissipated power is defined as the integral:

$$P_{\text{int}}^i = \int_{S_i} \boldsymbol{\sigma} \cdot \Delta\tilde{\mathbf{u}} \, dS \tag{16}$$

in the local reference system, where both $\boldsymbol{\sigma}$ and $\Delta\tilde{\mathbf{u}}$ have been defined in Subsection 3.2. Therefore, remembering Eq. (15) and following the kinematic theorem of limit analysis, the related linear programming problem can be stated as follows:

$$\min \left\{ \sum_{i=1}^{N_I} P_{\text{int}}^i - P_{\mathbf{F_0}} \right\} \tag{17}$$

under geometric constraints (9), compatibility constraints (10), non-negativity of plastic multipliers constraints (13) and the normality condition (14). The unknowns of the linear programming problem are the $6 \cdot N_E$ generalized velocity components of the center of mass of each element and the $6 \cdot (N_{sd} + 1) \cdot 2N_I$ plastic multipliers at each point of each interface.

4 GENETIC ALGORITHM

A genetic algorithm is used to progressively modify the mesh in order to find the minimum collapse multiplier among all possible configurations and therefore to determine the actual collapse mechanism. A genetic algorithm is a method for solving both constrained and unconstrained optimization problems based on a natural selection process that mimics biological evolution. The algorithm repeatedly modifies a population of individual solutions. At each step, the genetic algorithm randomly selects individuals from the current population and uses them as parents to produce the children for the next generation. Over successive generations, the population "evolves" toward an optimal solution.

A NURBS mesh of a vaulted surface, is determined by a given number N_{par} of real parameters $p_1, p_2, ..., p_{Npar}$, that depend on the type of collapse mechanism which must be detected. A given NURBS mesh is regarded as an individual and each individual (or chromosome), is written as an array with $1 \times N_{par}$ elements:

$$individual = [p_1, p_2, ..., p_{Npar}] \tag{18}$$

Each individual has a cost, found by evaluating the cost function *f* at the parameters $p_1, p_2, ..., p_{Npar}$. The cost function *f* is defined as a function which outputs the collapse load multiplier λ_c for every assigned individual (i.e. an assigned mesh on the surface) through the implementation of the limit analysis procedure described in Section 3:

$$\lambda_c = f(individual) = f(p_1, p_2, ..., p_{Npar}) \tag{19}$$

To begin the genetic algorithm, we define an initial population of N_{ipop} individuals. A matrix represents the population with each row in the matrix being a $1 \times N_{par}$ array (individual) of continuous parameters values. Given an initial population of N_{ipop} individuals, the full matrix of $N_{ipop} \times N_{par}$ random values is generated by

$$IPOP = (hi - lo) \times \mathbf{random}\{N_{ipop}, N_{par}\} + lo \tag{20}$$

where $\mathbf{random}\{N_{ipop}, N_{par}\}$ is a function that generates an $N_{ipop} \times N_{par}$ matrix of uniform random numbers, *hi* and *lo* are the highest and lowest number in the parameter range.

Individuals are not all "create equal": each one's worth is assessed by the cost function. In order to decide which chromosomes in the initial population of individuals are fit enough to survive and reproduce offspring in the next generation the N_{ipop} costs and associated individuals are ranked from lowest cost to highest cost. We retain the best N_{pop} members of the population for the next iteration of the algorithm and the rest die off. This process is called natural selection and from this point on, the size of the population at each generation is N_{pop}. An equal number of mothers and fathers is selected within the N_{pop} individuals, which pair in some random fashion. There are various reasonable ways to pair individuals [19]. In this paper, a weighted cost selection with assigned probabilities is used [19]. Each pair produces two offspring that contain traits from each parent. Mating is carried out by choosing one or more points in the chromosome to mark as the crossover points and the, parameters between these points are merely swapped between the two parents.

Finally, if care is not taken, the genetic algorithm converges too quickly into one region of the cost surface and this may be not good if the problem we are modeling has several local minima, in which the solution may get trapped. To avoid this problem of overly fast convergence, we force the routine to explore other areas of the cost surface by randomly introducing changes, or mutations, in some of the parameters. A mutation rate of 15% is chosen.

5 NUMERICAL EXAMPLES

In this Section, two numerical examples of NURBS based kinematic limit analyses of both reinforced and unreinforced masonry vaults are synthetically described. For each example, the mid-surface of the vault have been modeled with the 3D free form modeler Rhinoceros® and the corresponding NURBS structure have been imported within a MATLAB® environment using the IGES protocol. The limit analysis procedure described in Section 3 have been implemented and the collapse mechanism is determined by suitably adjusting the mesh through the genetic algorithm described in Section 4.

5.1 Unreinforced skew barrel vault

The proposed GA-NURBS approach is applied to the skew circular arch experimentally tested in [20]. The arch, named *Skew 2* in [20], has a clear square span of 3000 mm, a rise of 750 mm and a skew of 45 degrees. The width of the barrel was approximately 670 mm and the average thickness 215 mm. The arch was constructed using Class A engineering bricks were on two reinforced concrete abutments representing rigid supports. The geometry of the arch is reported in Fig. In the test, a concentrated load *P* was applied under force control at the three quarter span mid-width of the arch barrel. The load was monotonically increased up to 17.4kN when collapse occurred because of the formation of cracks extending in the mortar joints through the whole width of the arch, giving rise to a 3D failure mode typical of skewed masonry arches. An average brickwork compression strength f_c of 2.4 MPa and a tensile strength f_t of 0.2 MPa were measured, whereas a shear strength τ of 0.1 MPa is assumed. Average specific weight of brickwork is $22\,kN/m^3$. The initial NURBS mesh of the vaulted surface is formed by three quadrangular elements. A single centered vertical live load of $\lambda \cdot 1kN$ is applied at 1/4L.

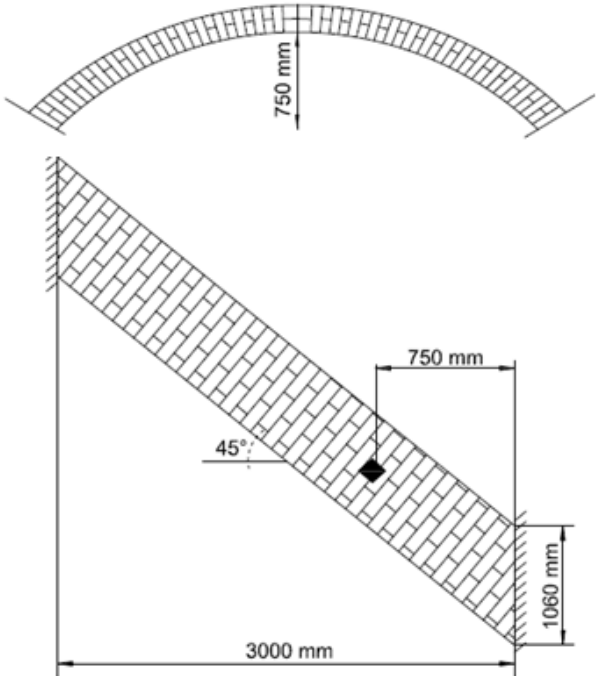

Figure 1: Skew arch geometry in the test configuration described in [20].

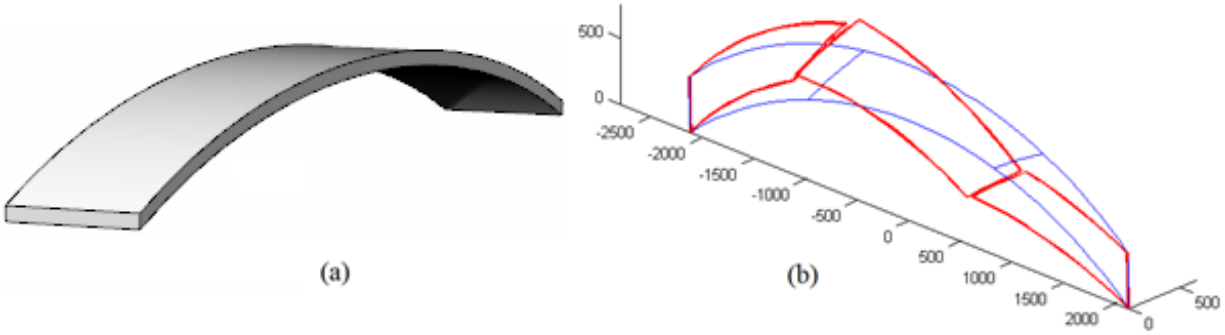

Figure 2: (a) 3D NURBS model of the skew arch experimentally tested in [20] generated with Rhinoceros®. (b) Three-element NURBS mesh (blue) and collapse mechanism from kinematic limit analysis (red).

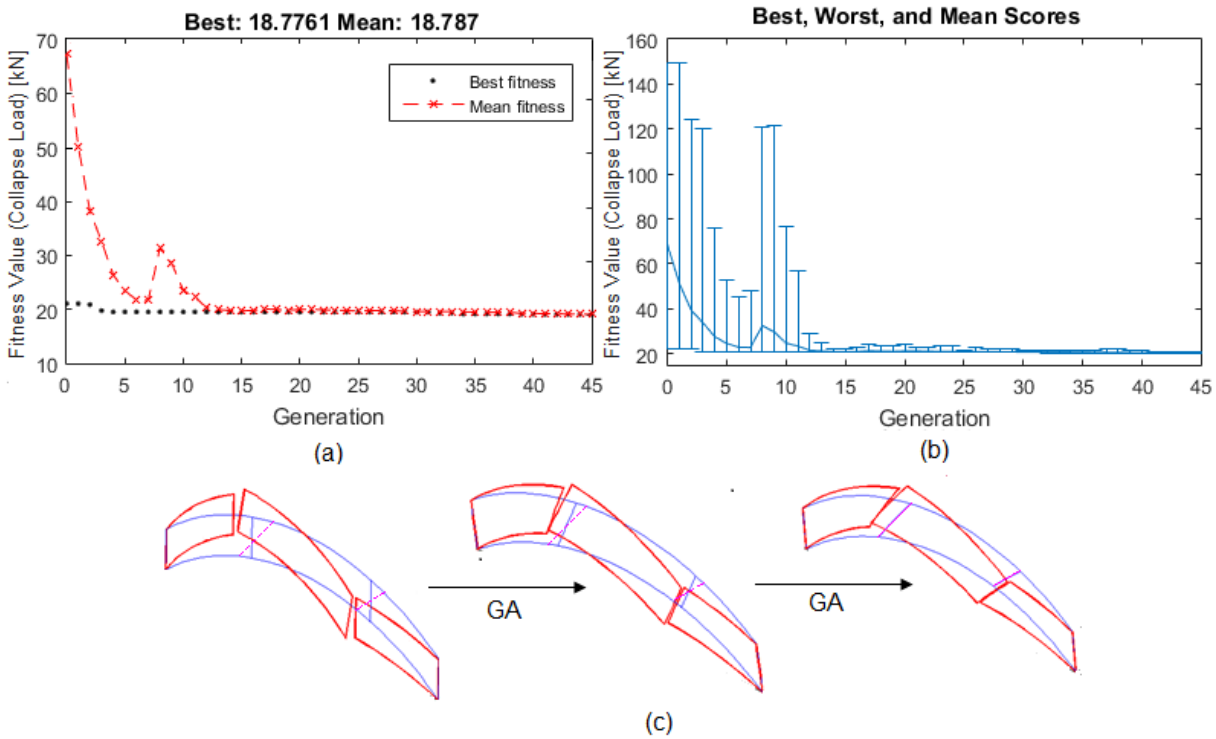

Figure 3: Skew arch: convergence of the genetic algorithm towards the optimal solution in terms of best fitness and mean value (a) and in terms of best, worst and mean scores (b) at each generation; evolution of the free interfaces towards the optimal solution (c).

The genetic algorithm allows evaluating the optimal position of the two active interfaces, in order to minimize the collapse load multiplier and therefore obtaining the actual collapse mechanism. Due to the point load presence, the position of the active interfaces is governed by three parameters: two parameters fix the extremes of the unloaded interface, whereas a third parameter fixes the position of the loaded interface (since this interface is bound to pass though the load application point). In the genetic algorithm an initial population of 40 individuals have been chosen, each individual being a 1x3 vector.

A collapse load multiplier $\lambda = 18.78$ have been obtained. Fig.2(a) shows the 3D NURBS model of the vault generated within Rhinoceros® and Fig.2(b) depicts the computed collapse mechanism, which proves to be equal to the one observed in [20].

As shown in Fig. 3(a-b), the algorithm presents a fast convergence towards the optimal solution and the final best fitness value is obtained after the first four generations. Fig. 3(c) represents the evolution of the mesh towards the optimal solution.

5.2 FRP reinforced square barrel vault

At first, a comparison with the experimental tests presented in [21] and later analyzed in [9, 14] for the unreinforced square barrel vault is carried out. In [21] the ultimate strength of a segmental masonry arch was tested, with a clear span of 3 m, an inner radius of 2.5 m and a sagitta of 0.5 m. The arch is a one-head brick structure with depth equal to 0.10 m and width equal to 1.25 m. The test-arch had 51 layers and was built with Rijswaard soft mud bricks and 1:2:9 mortar. Brick compressive strength was 27 MPa and mortar compressive strength was 2.5 MPa. The test-arch was loaded with four concentrated loads, applied by four hydraulic jacks 600 mm centre to centre. In Fig. 5a the geometry of the test-arch and its loading conditions are reported. Only the second concentrated load from the left was increased until failure, whereas the remaining loads were maintained constant at the values of 5.9, 9.1 and 9.1 kN

respectively. At failure, a four hinges collapse mechanism was observed in [21], which is depicted in Fig. 6a and measured a collapse load equal to 40.7 kN at the second jack. An average brickwork compression strength f_c of 2.4 MPa, a tensile strength f_t of 0.1 MPa and a shear strength τ of 0.1 MPa are assumed. Average specific weight of brickwork is $20\,kN/m^3$.

The described test-arch has been modeled within Rhino and its 3D model is reported in Fig. 5b. The initial NURBS mesh of the vaulted surface is formed by four quadrangular elements.

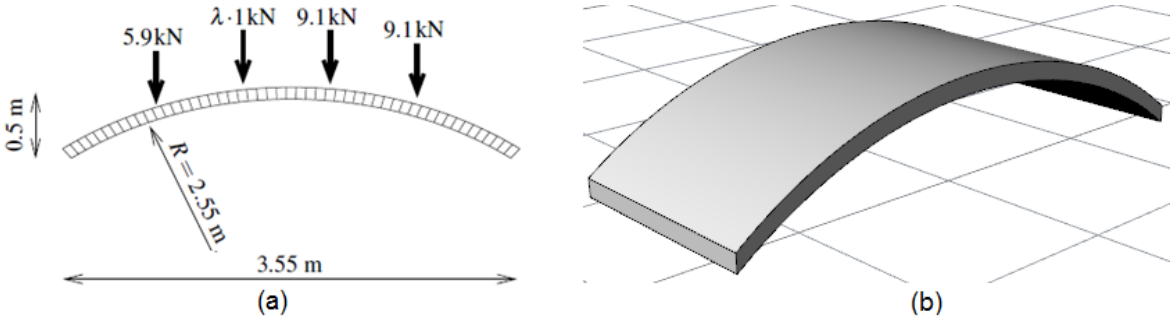

Figure 5: (a) Schematic representation of the segmental masonry test-arch used in [21]: geometry and loading conditions. (b) 3D NURBS model of the arch experimentally tested in [21] generated with Rhinoceros®.

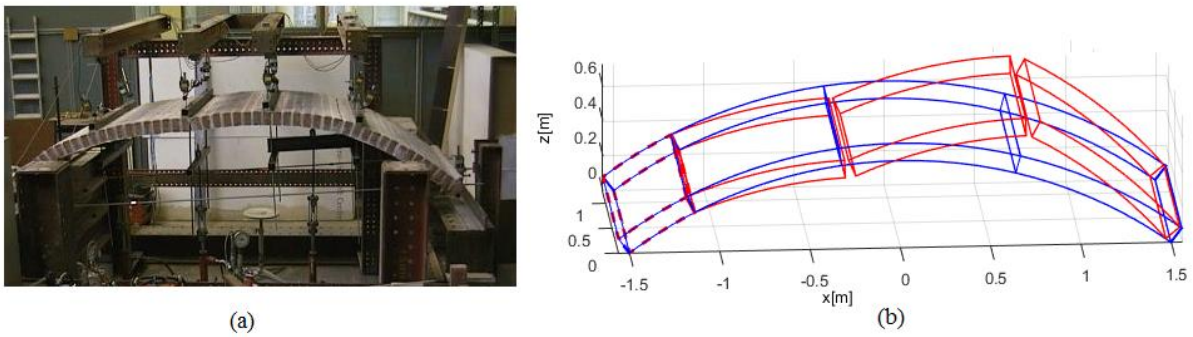

Figure 6: (a) Experimental failure mechanism obtained in [21]. (b) Failure mechanism computed through the GA-NURBS approach.

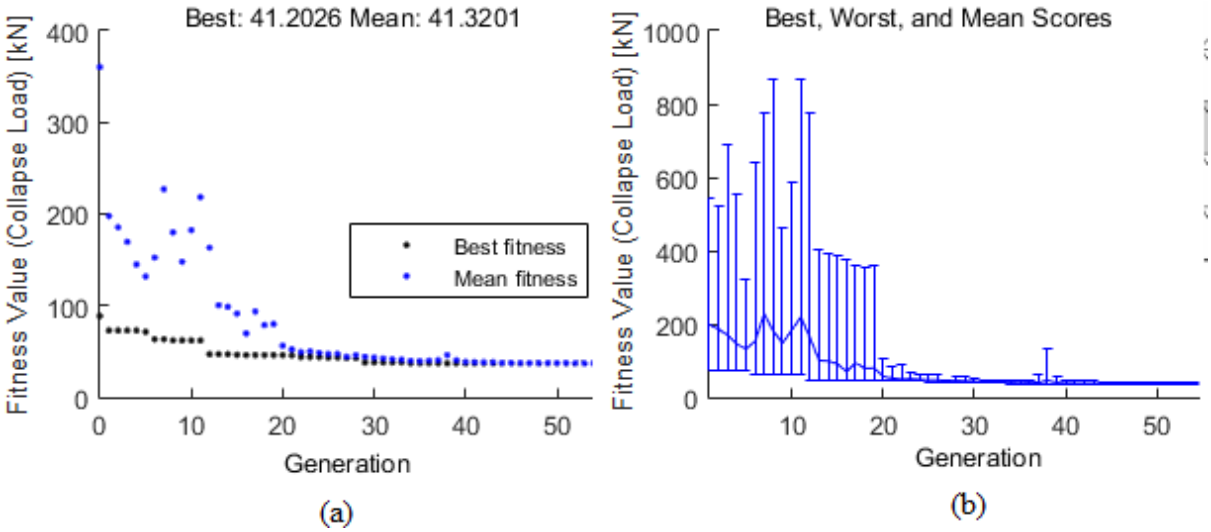

Figure 7: Square barrel vault: convergence of the genetic algorithm towards the optimal solution in terms of best fitness and mean value (a) and in terms of best, worst and mean scores (b) at each generation.

The genetic algorithm allows evaluating the optimal position of the active interfaces, in order to minimize the collapse load multiplier and therefore obtain the actual collapse mechanism. Only the second point load from the left have been marked as a live load. Collapse will occur after formation of four plastic hinges. Thus, the position of the active interfaces is governed by four parameters. In the genetic algorithm an initial population of 20 individuals have been chosen, each individual being a 1x4 vector. A collapse load multiplier $\lambda = 41.2$ have been obtained. Fig.6(b) depicts the computed collapse mechanism, which proves to be equal to the one observed in [21] and depicted in Fig. 6(a). As shown in Fig. 7, the algorithm presents a fast convergence towards the optimal solution.

Finally, the same vault was analyzed by assuming FRP reinforcement set on the extrados (Fig. 8). In order to prevent the formation of the plastic hinges indicated in Fig. 6(b), we suppose to strengthen the arch by means of two sets of FRP strips (width 100mm). The first set of strips is disposed at the extrados of the arch, whereas the second is applied at the intrados. The reinforcement tissue has thickness of 0.2 mm, Young's elastic modulus is assumed equal to 164 GPa (for tensile stress only) and an ultimate strain of 2% is adopted. FRP delamination stress f_d has been calculated by following the Italian FRP Design Guidelines [18]. Masonry strength parameters have been assumed the same of the unreinforced arch. The NURBS model is kept unchanged and so is the number of parameters governing the problem.

Again, the genetic algorithm allows evaluating the optimal position of the active interfaces, in order to minimize the collapse load multiplier and therefore obtaining the actual collapse mechanism.

The GA-NURBS approach allows to compute a collapse load multiplier $\lambda = 86.3$ of the FRP reinforced arch, which is in agreement with the results presented in [6].

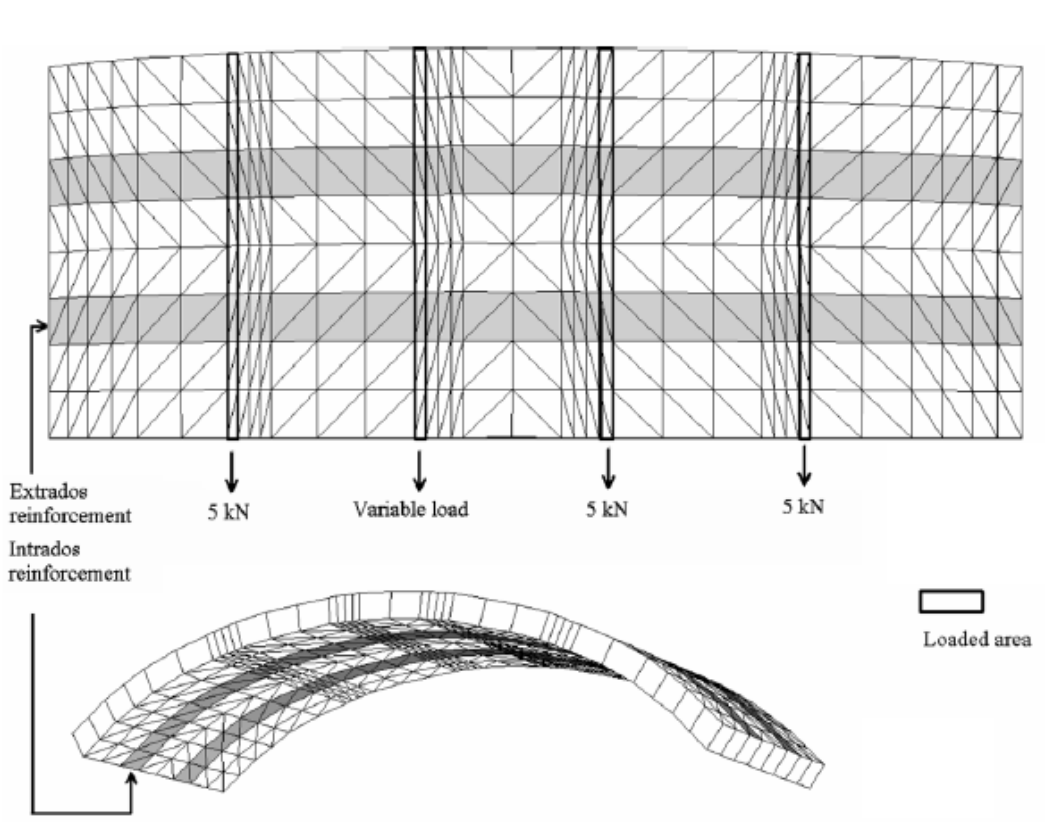

Figure 8: Reinforced parabolic arch. FRP strips dimensions and disposition.

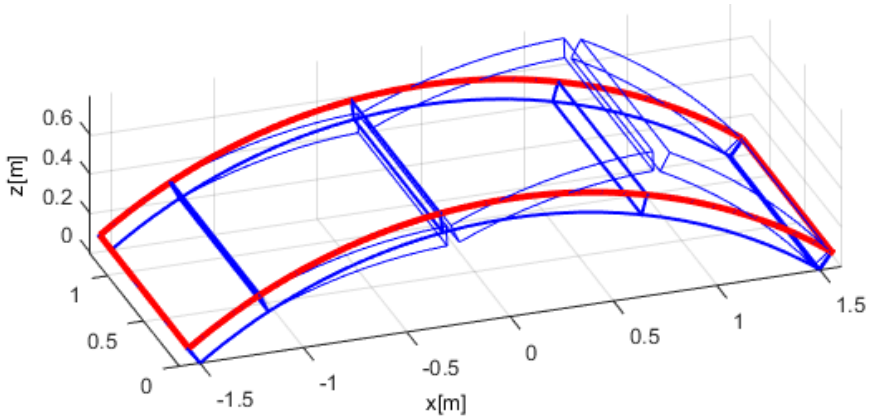

Figure 9: Square barrel vault: convergence of the genetic algorithm towards the optimal solution in terms of best fitness and mean value (a) and in terms of best, worst and mean scores (b).

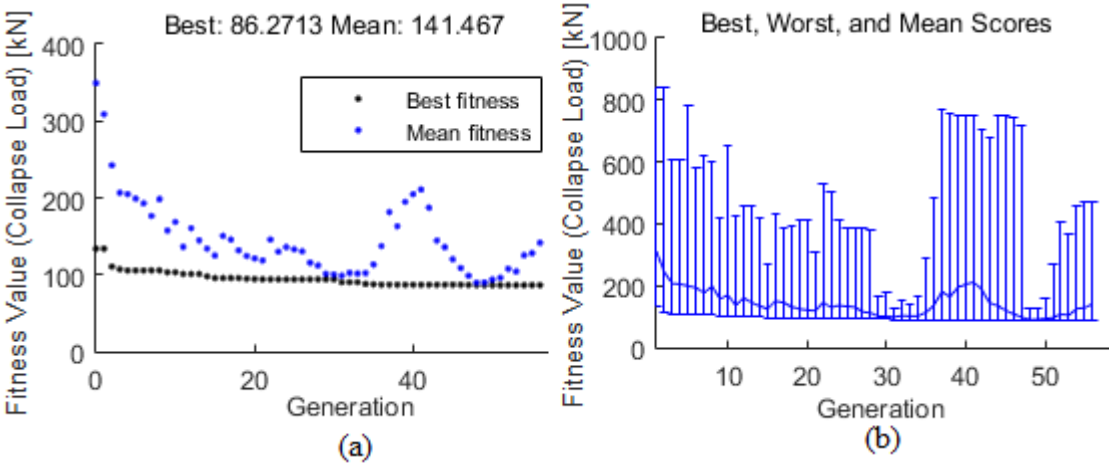

Figure 10: Square barrel vault: convergence of the genetic algorithm towards the optimal solution in terms of best fitness and mean value (a) and in terms of best, worst and mean scores (b).

In Figure 9 the four hinges collapse mechanism is shown: in this case the mechanism develops only after FRP delamination has occurred at the extrados hinges. The thick red line represents the outline of the FRP reinforcement.

As shown in Fig. 10, the algorithm presents a fast convergence towards the optimal solution and the final best fitness value is obtained after few generations.

Abstract. *Monuments and historical buildings are degraded as time passes due to natural ageing, environmental factors, as well as natural phenomena such as earthquakes. Their conservation and restoration thus becomes crucial in order to preserve our cultural heritage. Repointing of monuments and historical buildings is perhaps the most usual conservation action, as it restores and ensures masonry continuity in a reversible manner. However, this is accomplished only if the restoration mortar applied fulfills compatibility and serviceability criteria. In the current study, the characterization of the historical mortars of the Kaisariani monastery was undertaken and six restoration mortars were selected from literature and examined in order to assess their compatibility with the historical structure of the Kaisariani Monastery in Greece. The restoration mortars were assessed regarding their compatibility with the structural materials of the Kaisariani Monastery, as well as their impact on the earthquake resistance of the structure. A new stochastic computational framework for earthquake resistant design of masonry structural systems, based on fragility analysis and artificial neural networks was applied for the assessment of the seismic vulnerability of the Kaisariani Monastery, for three different repairing scenarios, utilizing the results of the examined restoration mortars. The results showed that a variety of restoration mortar characteristics can be achieved, an important feature, which coupled with the results of the fragility analysis for the repairing scenarios, can be utilized for the selection of the optimum restoration mortar in terms of compatibility and serviceability.*

1. INTRODUCTION

Monuments and historical buildings are degraded as time passes due to natural ageing, environmental factors, as well as natural phenomena such as earthquakes [1]. Their conservation and restoration thus becomes crucial in order to preserve our cultural heritage. **Repointing** of monuments and historical buildings is perhaps the most usual conservation action, as it restores and ensures masonry continuity in a reversible manner. However, this is accomplished only if the restoration mortar applied fulfills **compatibility** and **serviceability** criteria.

The need for knowledge of the traditional mortars has recently arisen from an increased interest in the techniques and materials used in the past. Negative results in recently restored buildings due to the use of improper materials have created a growing demand for research into the field of the traditional ones. Traditional building materials, such as joint mortars, plasters, waterproofing mortars etc., have exhibited remarkable longevity throughout time, however their production technology has been lost, as traditional materials have been replaced due to the extensive use of common contemporary materials, like cement and polymers, materials highly incompatible with the authentic building materials, resulting in extensive and irreversible damage to many cultural heritage monuments [2, 3, 4].

A methodology which has proved helpful in this procedure is reverse engineering [1, 5, 6]. Thus, by discovering the ancient technology employed for the production of the original mortars, new, compatible restoration mortars can be designed. The researcher however cannot rely solely on the results of the analysis of the historical mortar; one must examine the other building materials as well, such as stones and bricks, in order to assess whether the new restoration mortar is compatible with these materials as well. Furthermore, one must always take into consideration the specific environment of the monument, as environmental factors, such as excessive humidity or atmosphere pollution also affect the longevity of the materials [7, 8]. The most important steps that must be followed, are i) sampling of representative mortar samples, selecting the mortars that exhibit the least possible decay (environmental, physical, mechanical), ii) characterization of the historical mortar through various techniques, classification in order to determine the range of acceptability values, as well as analysis of specific considerations, deriving from the in situ analysis of the structure, the restrictions accompanying the other building materials and the study of the materials decay and iii) production of proper restoration mortars or selection of restoration mortars available in literature and compatibility and serviceability assessment [6].

In the current study a number of historical samples deriving from the Kaisariani monastery masonries were studied through *Fiber Optic Microscopy (FOM), Sieve analysis, Differential Thermal and Thermo-Gravimetric Analysis (DTA-TG), Mercury Intrusion Porosimetry (MIP)* and *Total Soluble Salts Measurements.* Several compatibility and serveacability criteria were set during this process, in order to then evaluate the selected restoration mortars and concretes. Six restoration mortars were selected from existing literature and the results of their analysis were examined in order to assess their compatibility with the historical structure of the Kaisariani Monastery in Greece. The restoration mortars examined were two lime-metakaolin mortars and one hydraulic lime mortar, and two lime-metakaolin concretes and one hydraulic lime concrete (thick joint mortars) [9, 10]. The concretes were designed with the addition of crushed bricks, in order to simulate historical mortars of byzantine monuments that have shown excellent performance in earthquakes [11]. The restoration mortars were examined by DTA/TG, in order to assess their

physicochemical characteristics and MIP in order to study their microstructural characteristics. These results were crucial in the assessment of compatibility. Finally, the mechanical strength of the restoration mortars was examined. Thus, the restoration mortars were assessed regarding their compatibility with the structural materials of the Kaisariani Monastery, as well as their impact on the earthquake resistance of the structure through the use of fragility analysis for different repairing scenarios, thus accomplishing the selection of the optimum restoration mortar in terms of compatibility and serviceability.

The Catholicon of the Kaisariani Monastery is a typical mid-byzantine Athenian church structure (11th or 12th century), its main building elements consisting of carved stones, bricks and mortars. The monastery has a rich history, and subsequently many construction phases throughout the centuries. The original building was a complex cross-in-square four-column domed church, without a narthex; the domed narthex was added to the west of the original structure in the early 17th century, and the barrel-vaulted chapel dedicated to Aghios Antonios positioned at the southwest of the Catholicon was added in the late 17th century (Fig. 1), thus comprising the present structure. The monastery complex has undergone many conservation treatments, which are not fully documented; however two important reconstruction projects took place in the complex in the beginning and the middle of the 20th century [12-14].

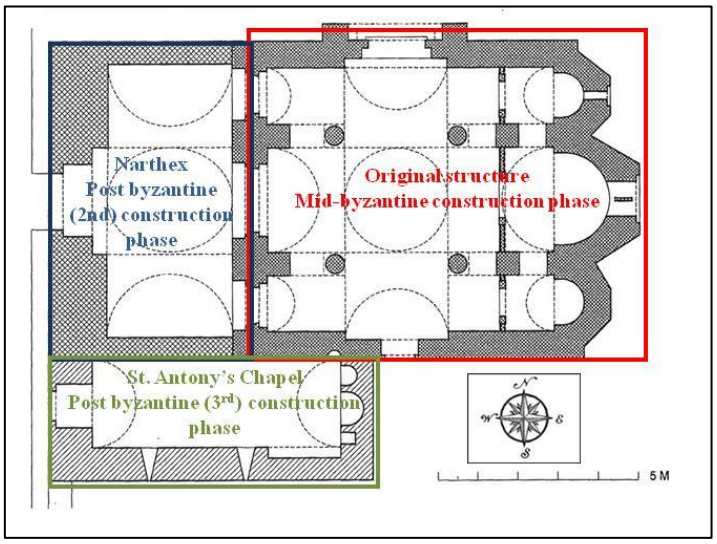

Figure 1: Ground plan of the church [15], with probable construction phases

2. SAMPLING

A number of historical mortar samples deriving from the historic masonry of the original Catholicon structure were examined (Table 1, Figure 2), as well as two brick samples. The samples were obtained internally and externally of the main temple, from different sides and depths of the walls.

Sample Code	Sampling Location	Sample Description
MK1	East wall of the Catholicon, in depth of the exterior masonry leaf. Position from ground level 1.4 m	Whitish mortar with the addition of straw, aggregates not discernible
MK2	East wall of the Catholicon, in depth of the exterior masonry leaf. Position from ground level 1.4 m	Mortar with evident lime lumps and the addition of straw, presence of dark-colored aggregates

MK2b	East wall of the Catholicon, exterior. Position from ground level 1.4 m	Whitish joint mortar, deriving from the joint of the cloisonné, presence of straw in matrix. Very low cohesion between mortar constituents
BR3a	East wall of the Catholicon, exterior. Position from ground level 0.4 m	Detached ceramic, evident biodegradation
BR3b	East wall of the Catholicon, exterior. Position from ground level 0.4 m	Whole piece of ceramic brick deriving from the cloisonné masonry. Mortar with straw adhered on the surface
MK4	North wall of the Catholicon, masonry left of the entrance, in depth of the exterior masonry leaf. Position from ground level 3.1 m	Whitish mortar straw additives, presence of dark-colored aggregates
MK5	North wall of the Catholicon, masonry right of the entrance, exterior. Position from ground level 3.5 m	Mortar, deriving from the joint of the cloisonné. Two layers visible: Exterior layer is pink hued and appears as 1mm thick (MK5a). Interior layer is (MK5b).
MK6	North wall of the Catholicon, masonry left of the entrance, in depth of the interior masonry leaf. Position from ground level 3 m	Whitish mortar with the presence of discernible dark-colored and light grey colored aggregates
MK7	Interior west wall of the Catholicon, joining with the Narthex Position from ground level 2.1 m	Whitish mortar. Presence of lime lumps. Presence of dark-grey colored aggregates, presenting a wide grain size distribution.
MK8	South wall of the Catholicon, in depth of the exterior masonry leaf. Position from ground level 3.6 m	Whitish mortar with dark-colored aggregates.

Table 1 Description of samples

3. METHODS AND TECHNIQUES

Various lab techniques were applied in order to characterize and study the samples taken from the Catholicon. *Fiber Optic Microscopy (FOM)* was employed in order to examine the samples microscopically, using a PICO SCOPEMAN-MORITEX and x50 magnification. *Sieve analysis* was performed according to Normal 27/88 [16] in order to analyze the mortar aggregates grain size distribution and to calculate the binder aggregate ratio. The sieves used were according to ISO 565. *Differential Thermal and Thermo-Gravimetric Analysis (DTA-TG)* provides qualitative and quantitative information regarding the composition of the samples (Mettler Toledo 651e). The temperature range applied was 25-1000^{o}C and the heating rate was selected at 10^{o}C/min [17]. X-ray diffraction (XRD) provides information regarding the mineralogical composition of the materials (Advance D8 Diffractometer of Bruker Corporation) [16-18]. The microstructural characteristics of the samples were studied through the use of *Mercury Intrusion Porosimetry (MIP)* with the use of a Pascal 400 Thermo-Electronics-Corporation [16, 19]. Taking into consideration the high water content of the masonries as well as the efflorescence of salts on the interior walls of the church [20], *Total Soluble Salts Measurements* were conducted, in accordance to the guidelines of Normal 13/83 [21], as well as spot tests in order to identify the salts present [22]. Finally, Water Absorption by Capillarity test was conducted in accordance to Normal 11/85, in order to estimate the capillarity absorption coefficient of the brick sample [23].

The restoration mortars were selected through extensive research of available literature [9, 10]. The selected mortars were all designed for use in historical buildings through the reverse engineering methodology. Furthermore, it was a prerequisite that the restoration mortars were examined with the same techniques as the historical samples, in order to assist the examination of their compatibility. The compatibility of the selected mortars was examined through the evaluation of their physicochemical and mechanical characteristics in relation to the historic mortars of the original structure, as well as the criteria arising from the study of the materials decay and the environmental factors affecting the monument. Finally, the use of the restoration mortars is evaluated as far as serviceability through the use of fragility curves.

4. RESULTS AND DISCUSSION

4.1 Characterization and classification of historical mortars

Fiber Optic Microscopy (FOM) results indicated that all samples are in a bad state of preservation, presenting low adhesion between binder and aggregates. Lime lumps are present in all samples, except for MK5a (the final mortar layer of the cloisonné). The presence of straw additives is detected in samples MK1, MK2, MK2b and MK4, whereas no straw is detected in samples MK5b, MK6, MK7, MK8. Furthermore, extensive biodeterioration is evident on the surface of brick sample BR3a (Fig. 2).

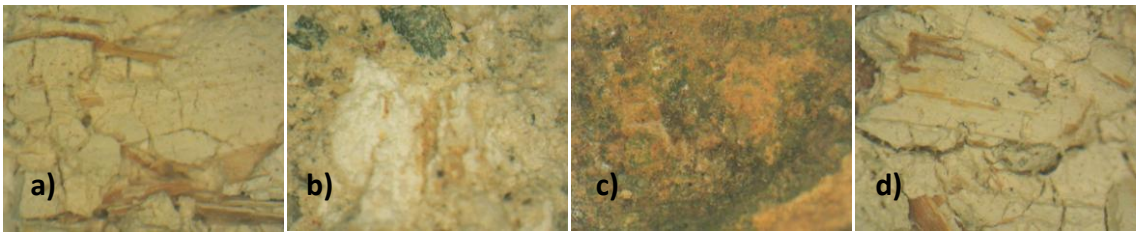

Figure 2: Selected FOM images of samples, a) MK2 – evident straw addition, b) MK2b – evident lime lumps, c) BR3a – Evident bio deterioration, d) Mortar attached on BR3b – evident straw hay addition

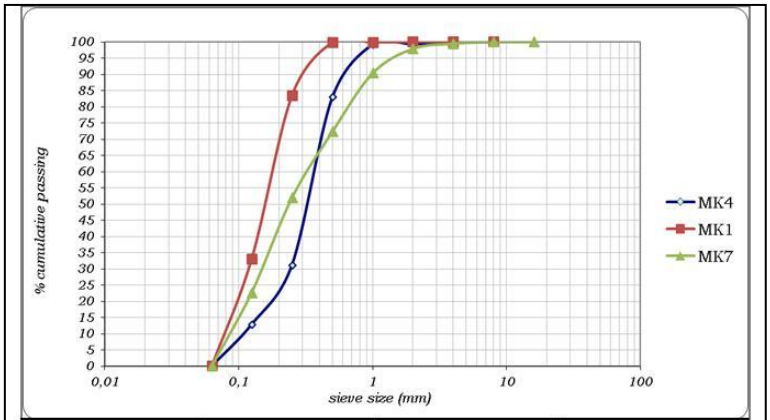
The grain size distribution analysis showed a good sorting of aggregates. MK1 and MK4, deriving from the exterior wall of the Catholicon present a greater similarity in comparison to sample MK7, the mortar of the interior wall joining the main temple and the Narthex (Fig. 3). The binder to aggregate ratio differs between samples.



Sample Code	MK1	MK4	MK7
B/A ratio	0,41	0,65	0,22

Figure 3: Grain size distribution analysis results

The results from the historical mortar sieve analysis act as a guide for the selection of the aggregates for the restoration mortar. Taking into consideration that the gradation curves of the historical mortars are only indicative of the original aggregates' gradation curve, as after many centuries the material has deteriorated and altered, the gradation curve of the restoration mortar aggregates must be as close as possible to that of the historical mortars, thus fulfilling compatibility criteria, but at the same time it must present a normal distribution, in order to fulfill serviceability criteria.

Thermal analysis was conducted on all mortar samples, as well as on the binder parts of the mortars separated through sieve analysis. The results show two types of mortars. The first type (samples MK1, MK2, MK2b, MK6) presents a curve as seen in Figure 4a, and the second type (samples MK4, MK5a, MK5b, MK7 and MK8), which presents an exothermal peak at 420-480^{o}C, corresponds to a curve as seen in Fig. 4b. The values of physically bound water, which is connected to weight loss observed in the temperature range <120 ^{o}C, are very low, corresponding to lime mortars [1]. In the temperature 120-200 ^{o}C weight loss is attributed to the dehydration of hydrated salts. The weight loss in the temperature range 200-600^{o}C is attributed to the dehydration of water chemically bound to hydraulic compounds, however in the case of samples MK4, MK5a, MK5b, MK7 and MK8 the exact amount cannot be calculated, as an exothermal peak connected to the presence of organic matter, probably due to the addition of plant-based natural fibers, is also observed within this range (420-480^{o}C). Therefore the reversed hydraulicity index cannot be calculated for the aforementioned samples. The endothermal peak at 580^{o} C, not accompanied by any mass loss, is attributed to the transition of quartz-a to quartz-b. The high values of CO_2 loss (>600 ^{o}C), corresponding to the decomposition of calcium carbonate, in combination to the high reverse hydraulicity index calculated in the cases where no decomposition of organic matter was noticed, further confirms the classification of the mortars as lime mortars (Table 2, Fig.5) [24]. Furthermore, the mortar aggregates are solely calcitic in the case of samples MK1, MK2,MK2b, MK4, whereas in the rest of the samples, aggregates are a mix of calcitic and silicate nature. Thermal analysis results can be utilized to correlate physicochemical values to mortar tensile strength (Fig.6) [1].

Sample	**Mass loss for each temperature range (%)**				**$CO_2/H_2O_{ch.b}$**	**$CaCO_3$**

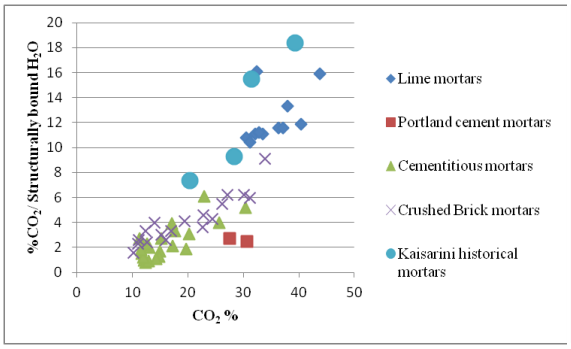

Figure 5: Grouping of the Kaisariani mortars according to thermal analysis results

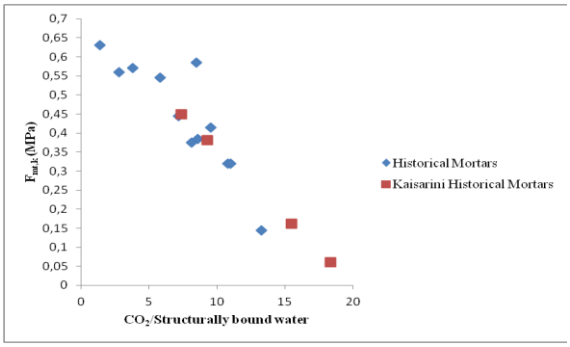

Figure 6: Correlation of tensile strength and inverse hydraulicity index

Thermal analysis results can be further utilized in the selection of the proper restoration mortars, as the restoration mortar selected must be compatible with the historical mortars, regarding its physicochemical characteristics, and in particular in terms of reverse hydraulicity index and CO_2 % loss.

X-ray diffraction analysis of mortar samples, showed the mineralogical compositions (Table 3 and Fig. 7). The principal mineralogical phase of all examined mortars is calcite. Quartz is detected in all samples, muscovite is detected in almost all samples.

X-ray diffraction results	
Sample	**Mineralogical Composition**
MK1	Calcite, quartz
MK2	Calcite, muscovite, quartz, albite, chlinochlore
MK2b	Calcite, quartz, muscovite, chlinochlore
MK4	Calcite, quartz
MK5a	Calcite, quartz, muscovite, hornblende, chlinochlore
MK5b	Calcite, muscovite, quartz
MK6	Calcite, quartz, muscovite, albite, chlinochlore, vaterite
MK7	Calcite, quartz, muscovite, chlinochlore, albite
MK8	Calcite, quartz, muscovite, albite, chlinochlore

The microstructural characteristics of selected samples were examined through mercury intrusion porosimetry (Table 4, Fig.8). The brick samples present characteristics similar to handmade byzantine bricks, as found in literature [25, 26]. The mortars examined through MIP were MK6 deriving from the north wall and selected from the interior, MK7, from the interior west wall of the Catholicon, in joint with the Narthex wall and MK8, selected from the South Wall of the Catholicon. All samples present relatively high total cumulative volume values (MK7 total cumulative value is much higher than the other two). MK7 also presents a very low bulk density value, whereas MK6 and MK8 present similar values. MK6 and MK8 present similar average pore radius, total porosity and specific surface area values, whereas MK7 presents a much higher total porosity, as well as a lower average pore radius and higher specific area. The examination of the mortars microstructure confirms them as lime mortars [27].

Sample	***Total Cumulative Volume (mm^3/g)***	***Bulk Density (g/cm^3)***	***Total Porosity(%)***	***Average pore radius (μm)***	***Specific Surface Area (m^2/g)***
BR3a	131,24	1,89	24,85	0,81	5,82
BR3b	167,68	1,82	30,54	0,85	1,03
MK6	233,75	1,61	37,70	0,44	3,27

The microstructural characteristics of the historical mortars, serve as a tool in the selection of the optimum restoration mortar, as it must present compatibility regarding microstructural characteristics. A study by Moropoulou & Bakolas 1998 assists in this task as it states the acceptability limits for restoration mortars for different mortar categories [27].

The presence of soluble salts in the church masonries was then assessed through the examination of the samples with Total Soluble Salts Measurements. The percentage of soluble salts is calculated through the following equation:

$$SST\% = (C \times 6{,}88) / M, \quad (1)$$

where C is the measured conductivity in μS and M is the mass of the sample undergoing the measurement. Following the Total Soluble Salts Measurements, the results of which are presented below, spot tests were conducted in order to identify the salts present. The detection of chloride (Cl^-), sulphate (SO_4^{-2}) and nitrate (NO_2^{--}) salts was possible through the use of $AgNO_3$, $BaCI_2$ and diphenylamine respectively.

Sample	Conductivity	TSS	Cl^-	SO_4^{3-}	NO^{2--}
MK1	72,2	4,84	-	-	+
MK2	83,3	5,54	-	-	+
MK2b	65,7	4,38	-	+	-
BR3b	53,8	3,57	-	-	-
MK4	97,1	6,53	+	-	++
MK5	122,1	8,28	-	-	+++
MK6	48,3	3,2	-	-	-
MK7	61,4	4,09	+	-	-
MK8	87,7	5,91	-	-	+

*Very high content (+++++), high content (++++), medium content (+++), low content (++), extremely low content (+), traces (tr).

Table 5: Total Soluble Salts measurements results and spot test results

All examined samples present high soluble salts contents, above the limit of 3%. A very high content of nitrates was detected in the mortar samples of the North wall, attributed to the more intense biodeterioration on this side, the transportation of fertilizers through rising damp into the masonries, as well as the presence of an underground ossuary at close proximity to the north wall of the church. The high amount of soluble salts must be taken into account when selecting the proper restoration mortars, as the presence of salts, as well as the movement of salts through water transportation phenomena, creates various problems to masonries.

Finally, the capillary rise coefficient of the brick sample (BR3b) was estimated through the Water Absorption by Capillarity test. The experiment was conducted at 15 ^oC and 70% RH. The capillary rise coefficient (C.R.C.) is calculated as:

$$C.R.C. = \Delta B/(S*t^{1/2}) \quad (2)$$

Where, S is the surface of the sample in contact with the water and ΔB is the amount of water absorbed at a chosen time t(s). The above results where then designed in the following diagram, selecting the experimental results up to the time of $\sqrt{t}$ = 30 which corresponds to the linear part of the experimental curve, in order to estimate the trend line, and calculate the coefficient which is equal to the trend line slope. The trend line shows a very good R-squared value of 0.9948. The capillary rise coefficient value was thus calculated as $C.R.C._{MK3b}$=16.5 mg/($cm^2 \cdot s^{1/2}$) (Fig.9). The restoration mortars must present a capillary rise coefficient equal or higher than this value in order to avoid moisture concentration in the brick elements.

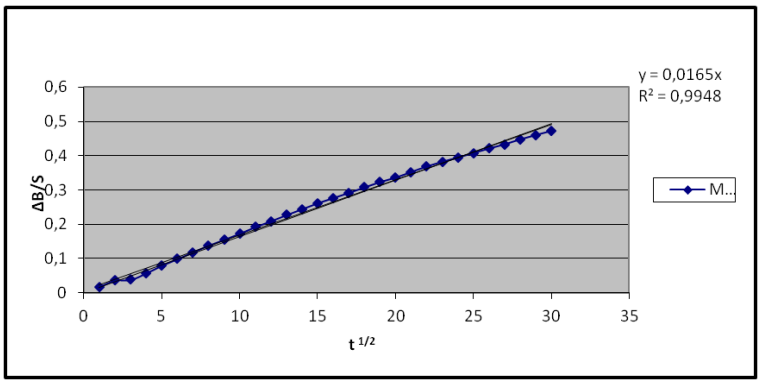

Figure 9: Plot of selected water absorption by capillary test results in order to estimate the capillary rise coefficient

4.2 Determination of decay factors, restriction arising from other building materials and earthquake behavior

An important degradation factor of the structure is the high water content of the structure, as revealed by non-destructive techniques in a previous study [20]. The high humidity content of the structural materials is attributed to rising damp, low sun radiation on all sides except for the south, as well as intense vegetation at a close proximity to the masonries of the structure and is further aggravated by problems in the roof system. The restoration mortars must be hydraulic in order to harden in high humidity conditions, as well as to serve adequately in this environment.

Furthermore, the detection of soluble salts above the acceptable limit of 3% for building materials dictates the use of a hydraulic mortar, either lime-pozzolan, either natural hydraulic lime, either a lime crushed brick restoration mortar, as these mortars exhibit a better behavior in the presence of soluble salts [8].

Although no stone samples were permitted, a previous study managed to categorize the building stones of the historical masonries of the Kaisariani Monastery and to estimate the compressive strength of the most common stone (fossiliferous) appearing in the structure. The compressive strength of the fossiliferous stone was estimated through a Schmidt hammer rebound test and the average value was estimated at 8.2 MPa with a standard deviation of 1.72 [20]. As the fossiliferous stone is the weakest building stone in the masonry, this values must act as a limit as far as the restoration mortar compressive strength is concerned, in order to avoid compatibility problems.

As the region of Greece is in constant danger from a potential earthquake, it is important to examine the structural system in earthquake stresses. Due to the thickness of the joint mortar in the Catholicon masonries, the restoration mortar is an important element contributing to the mechanical properties of the structure; the restoration mortar will inevitably affect the behavior of the structure to earthquake stresses. Therefore an important serviceability criterion must be the results of the fragility analysis for different repairing scenarios; the fragility analysis results can be utilized for the selection of the optimum restoration mortar.

Another important factor is the use of the monument; if a monument is in use or even only accessible to visitors as a cultural site, it is important that the restoration mortars used present high values of early strength. Therefore another serviceability criteria arises, namely the restoration mortar must present adequate early strength values.

4.3 Evaluation of selected restoration mortars

The goal in selecting the optimum restoration mortar is the compromise between all compatibility and serviceability requirements. The restoration mortars selected exhibit adequate hydraulicity, so as to ensure hardening in high humidity conditions and resilience in the presence of salts. Specifically, two lime-metakaolin and one hydraulic lime mortar, and two lime-metakaolin and one hydraulic lime concrete were selected (Table 6). The concretes were designed with the addition of crushed bricks, in order to simulate historical mortars of byzantine monuments that have shown excellent performance in earthquakes [11]. The raw materials used fulfilled all criteria in order to be acceptable for use in a historical masonry [6]. The selected aggregates presented a good agreement with the historical mortars' gradation curve, as well as a good sorting and normal distribution.

Sample Code	Lime powder	Meta kaolin	NHL3,5	Silicate Sand (0-2 mm)	Silicate Sand (0-6 mm)	Crushed brick (0-16 mm)
LM_1	27,5	2,5	-	70	-	-
LM_5	25	5	-	70	-	-
NHL	-	-	25	-	75	-
$LM_{C5.}$	27,5	2,5	-	-	35	35
NHL_{C10}	-	-	30	-	35	35
LM_{C15}	20	10	-	-	35	35

Table 6: Synthesis of selected restoration mortars [9, 10]

The thermal analysis results are stated for all selected restoration mortars (Table 7, 8). Furthermore, the resulting data is compared with the historical mortars thermal analysis results in order to assess compatibility (Fig.10); it is clear that they fulfill compatibility requirements, especially the lime-metakaolin mortars.

Restoration mortar	Curing time (months)	$(H)_{t.ch.b.}$	H-CH	CH	$(CH)_{react.}$ (%)	CO_2	$CaCO_3$	$CO_2/(H)_{t.ch.b.}$

Table 8 Mass loss percentages for restoration mortars in relation to curing time [9]

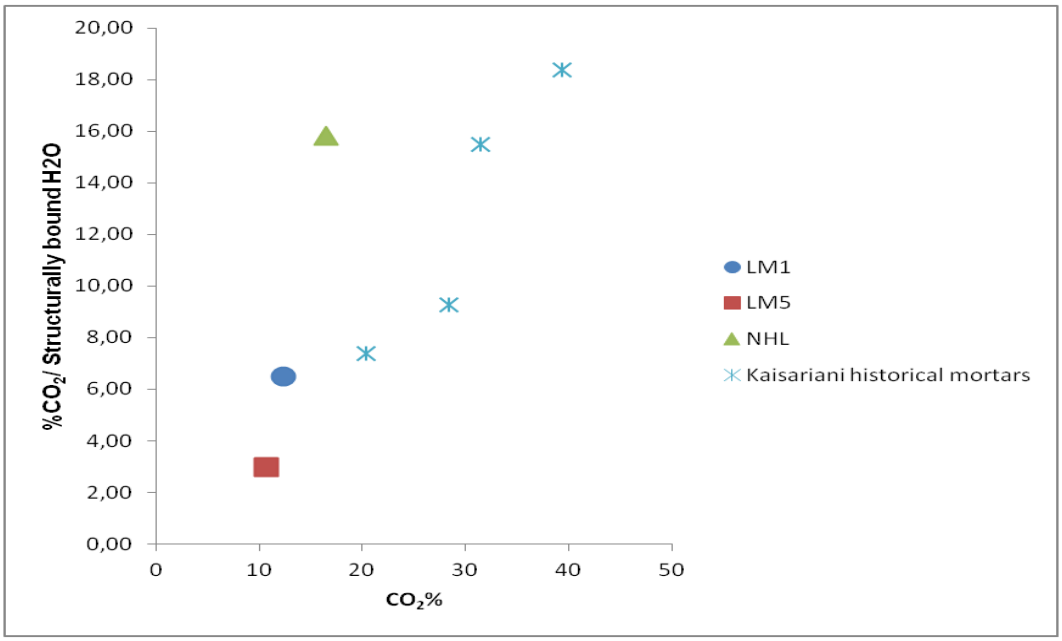

Figure 10: Correlation of $\%CO_2$ loss with inverse hydraulicity index

The microstructural characteristics of the selected mortars are presented in the following table. The concretes, due to the large size of the aggregates were only analyzed regarding their apparent density.

Sample code	T.C.V. (mm^3/g)	S.S.A. (m^2/g)	Por. Rad. Av. (μm)	d_{bulk} (g/cm^3)	$d_{corr.}$ (g/cm^3)	Total Porosity (%)
LM_1	198,78	4,15	0,32	1,73	2,63	34,30
LM_5	191,63	5,56	0,29	1,75	2,64	33,57
NHL	151,1	4,24	0,28	1,90	2,67	28,7
LM_{C5}	-	-	-	1,62	-	-
NHL_{C10}	-	-	-	1,85	-	-
LM_{C15}	-	-	-	1,69	-	-

**T.C.V.: Total Cumulative Volume, S.S.A.: Specific Surface Area, Por.Rad.Av.: Average Pore Radius, d_{bulk}: apparent density, $d_{corr.}$: corrected density, Total Porosity (%)*

Table 9 MIP results – Hardened restoration mortar characteristics [9, 10]

Regarding the thermal analysis results, at the end of twelve months the entire $Ca(OH)_2$ has reacted, except for concretes LM_{C5} and NHL_{C10}, where a very small amount remains. Regarding the microstructural characteristics of the selected mortars, all lime-metakaolin mortars, as well as the lime-metakaolin concretes, are within the range of acceptability limits [27]. Therefore, regarding physicochemical and microstructure compatibility, LM_1, LM_5, LM_{C5} and LM_{C15} are all deemed as acceptable and exhibit adequate hydraulicity, thus fulfilling serviceability criteria.

The average values of flexural and compressive strength measured for the examined mortars is listed in Table 10. The flexural strength values result as the average of the value measured for three different prismatic samples for each mortar mix, while the compressive strength values result as the average of the value measured for six different cubic samples for each mortar mix.

Sample Code	Curing time	F_f (MPa)	St.Dev.	F_c (MPa)	St.Dev.	Ed (MPa)
LM_1	**12 months**	1,59	0,34	3,92	1,40	6532
LM_5	**12 months**	1,51	0,46	5,88	0,88	6641
NHL	**12 months**	1,00	-	4,50	-	-
LM_{C5}	**12 months**	1,50	0,25	8,4	0,36	6981
NHL_{C10}	**12 months**	2,22	0,27	18,7	0,50	18547
LM_{C15}	**12 months**	2,40	0,35	21,4	1,26	13334

**Ff: Flexural strength (MPa), Fc: Compressive strength (MPa), St.Dev.: standard deviation, Ed:Dynamic elasticity modulus*

Table 10 Flexural and Compressive strength values for examined mortar and concrete mixes – Dynamic elasticity modulus [9, 10]

In the case of the lime-metakaolin mortar mixes, LM_1 και LM_5, it is concluded that the early acquirement in compressive strength noticed is enhanced due to the use of metakaolin (Fig.11). Furthermore, the results show that by increasing the percentage of metakaolin in relation to the lime powder, the compressive strength also increases. Regarding the gain in flexural strength with hardening, it is concluded that both lime-metakaolin mortar mixes present similar final values, however not the same trend in the progression of hardening in time. In the case of the hydraulic lime mortar, the highest compressive strength value is measured at 6 months of curing, while it has already acquired 66% of its final mechanical strength values already from the first month of hardening. The final compressive strength value measured for the hydraulic lime mortar is between the compressive strength values of LM_1 and LM_5. The flexural strength of the hydraulic mortar is relatively lower than the lime-metakaolin mortar mixes. The concretes examined present a large range of compressive and flexural strength values (Table 10). As expected the concretes mixes examined presented much higher modulus of elasticity values in comparison to the mortar mixes. Amongst the concretes, the lowest values of dynamic elasticity modulus are exhibited by concrete LM_{C5}, which also presented the lowest values of flexural and compressive strength; the highest dynamic modulus of elasticity values by far is exhibited by the hydraulic lime concrete, although it exhibited lower compressive and flexural strength values than LM_{C15}. The mortar containing the highest amount of metakaolin p.w., presented the highest compressive strength values, and also the highest modulus of elasticity value, however near the value exhibited by LM_1.

In Fig.11 compressive strength values are presented in relation to curing time. The results show that a large range of mechanical properties can be achieved with small variations to the mortar mixes and furthermore the use of the selected mortars fulfills the serviceability criteria set, namely the early acquirement of compressive strength.

The optimum selection in order to ensure a good behavior under seismic action is the compromise of a high compressive strength and low dynamic elasticity modulus. In Fig.12 these values are correlated for the selected restoration syntheses.

The selected lime-metakaolin mortars present C.R.C. values between 17-25 $mm^3/g.s^{1/2}$, and are therefore compatible with the original brisk elements of the historical masonry [9].

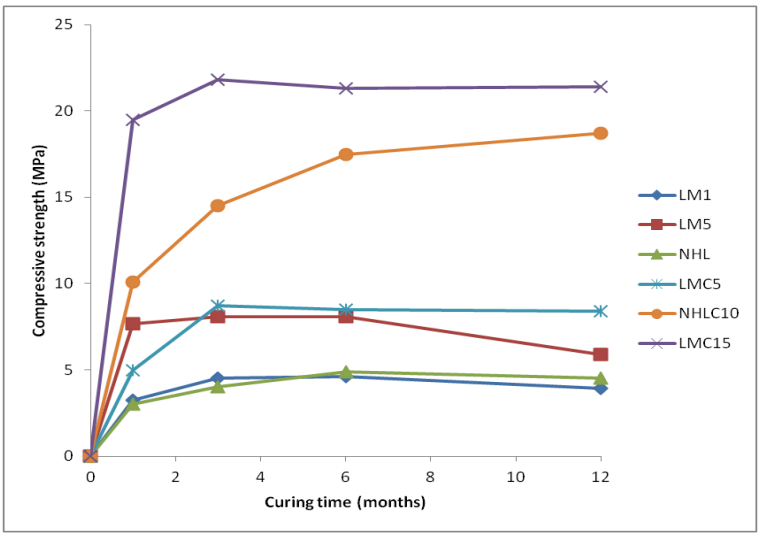

Figure 11: Compressive strength values (MPa) in relation to curing time (months)

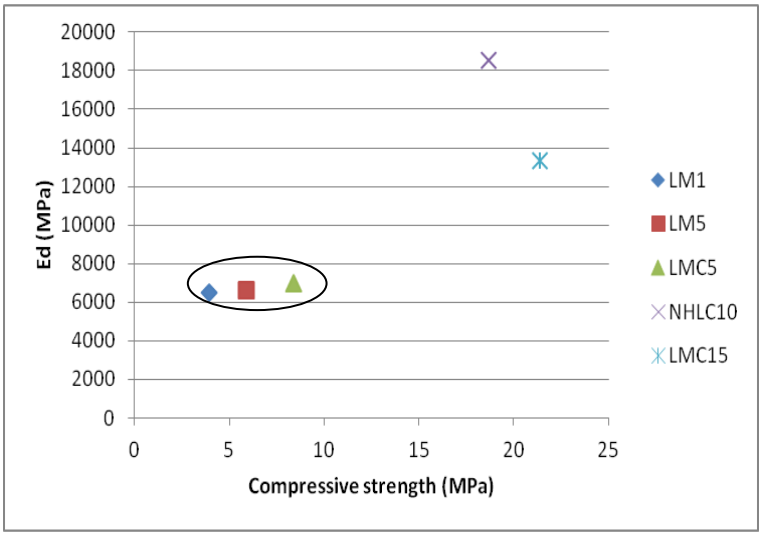

Figure 12: Correlation of compressive strength and dynamic elasticity modulus for selected restoration mortars and concretes

Fragility analysis was conducted for the case of the Catholicon of the Kaisariani monastery, for different repairing scenarios, in accordance to the analysis of the selected restoration mortars [28-36]. The entry values selected for the original materials was an average values of 12 MPa compressive strength for the building stones, taking available literature into account, and 1 MPa for the original mortars, as correlated through the analysis of the physic-chemical properties [20]. Specifically, the probability of damage occurring under the effect of different ground accelerations was estimated for a) the original structural materials, b) repointing of joints with restoration mortar exhibiting 5 MPa compressive strength, c) repointing of joints with restoration mortar exhibiting 10 MPa compressive strength. The fragility analysis concerned the probability of appearance of insignificant, moderate and heavy damage (Fig.13-15) for the different repairing scenarios.

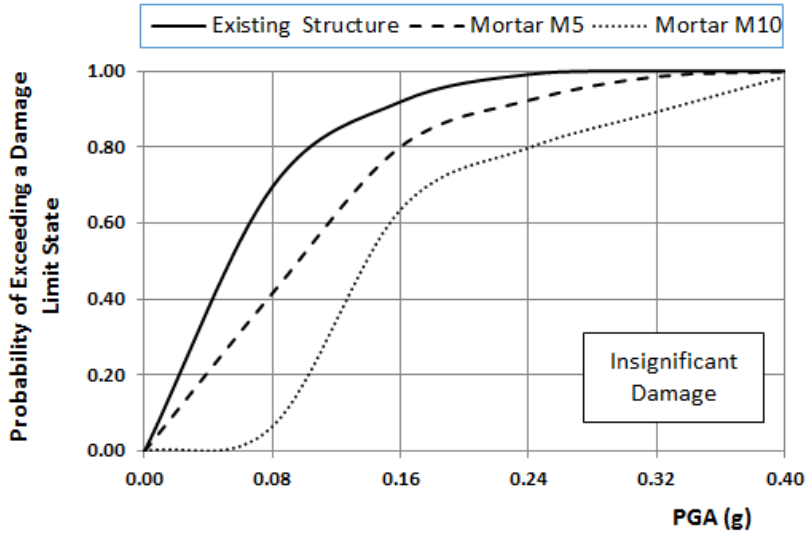

Figure 13: Probability of insignificant damages occurring for different ground accelerations

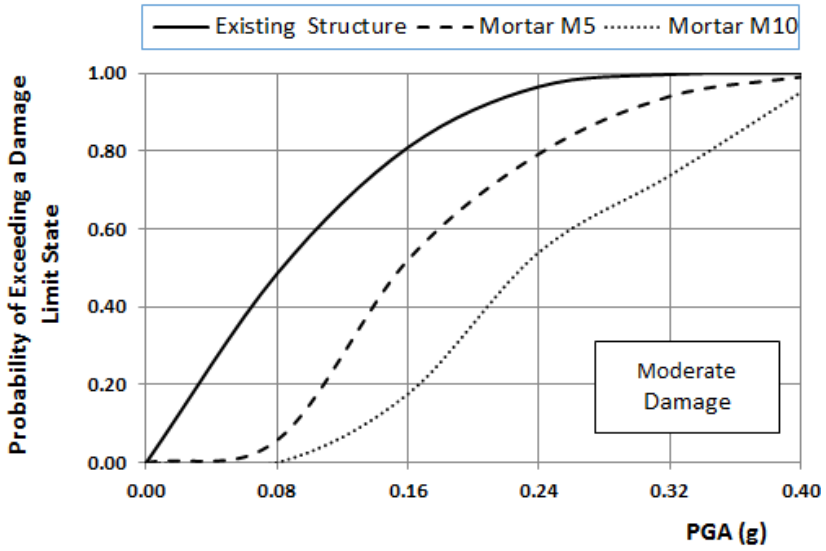

Figure 14: Probability of moderate damages occurring for different ground accelerations

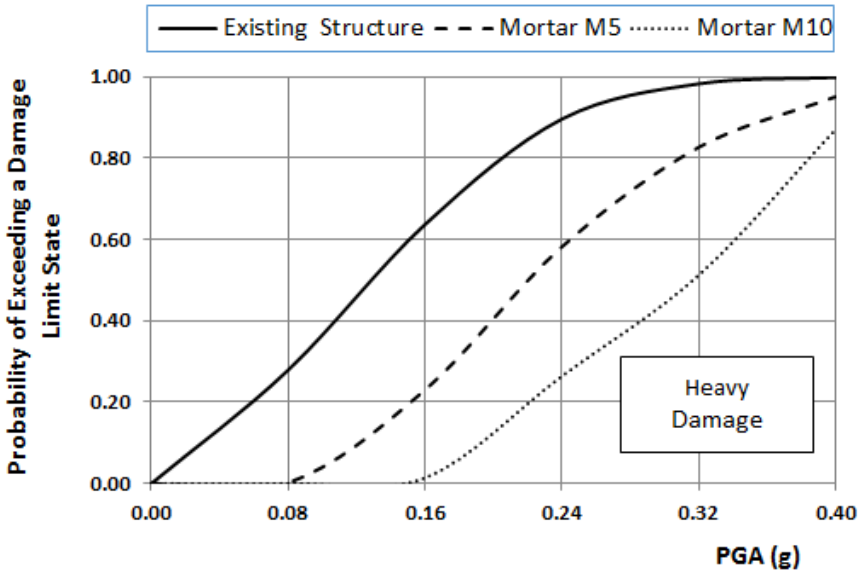

Figure 15: Probability of heavy damages occurring for different ground accelerations

The results show that even the use of a restoration mortar exhibiting compressive strength 5 MPa, can achieve an improvement in terms of damage in the case of an earthquake; the improvement is greater as the damage severity increases. At this point, the restriction deriving from the low compressive strength of the fossiliferous stone must be taken into consideration; NHL_{C10} and LM_{C15} are therefore rejected as possible restoration mortars, in order to ensure compatibility with the original structural materials. Thus, restoration mortar LM_5 and LM_{C5} can be selected in order to use according to the joint thickness, as these restoration mortars exhibit compatibility with the original structure and serviceability in the environment of the Kaisariani monastery, at the same time contributing to the mechanical performance of the structure under earthquake stresses.

5. CONCLUSIONS

- The mortars of the Kaisariani Monastery Catholicon are typical lime mortars mixed with calcite and aluminosilicate aggregates, with high porosity values and occasionally the addition of straw or fiber admixtures
- Tensile strength can be estimated for historical mortars, through correlation with physicochemical properties; this is only an estimation, but can be indicative and assist in the assessment of the seismic behavior of the masonry
- The microstructural characteristics of the examined bricks are typical for handmade bricks of the byzantine period
- By setting requirements during the characterization of the historical materials and the in situ investigation of the monument, the selection of the optimum mortar, complying with the set compatibility and serviceability requirements can be accomplished
- Lime-metakaolin mortars present similar physicochemical and microstructural characteristics with the examined historical mortars, at the same time contributing in a decisive manner to the behavior of the masonry under earthquake stress
- The role of restoration mortars is crucial in the earthquake protection of thick joint masonries
- Fragility analysis is a valuable tool that can be utilized for the selection of the optimum restoration mortar in terms of compatibility and serviceability amongst different repairing scenarios

ACKNOWLEDGEMENTS

Part of this investigation was performed within the research project “Seismic Protection of Monuments and Historic Structures - SEISMO” which is co-financed by the Greek Ministry of Education and Religions and the European Union under the action “Thales” within the context of the Operational Programme - Education and Lifelong Learning, NSRF 2007-2013. The authors would like to thank the employees of the 1st Ephorate of Byzantine Antiquities for their cooperation.

Keywords: Masonry dome, Historical construction, Structural health monitoring, FE model

Abstract. *This paper newly proposes the use of ambient vibration testing, vibration-based continuous dynamic monitoring and automated modal identification for structural assessment of monumental masonry domes. The final purpose of this research is the development of a general methodology for online structural health monitoring of large domes, enabling early detection of damages caused by low return period earthquakes, in a general framework of preventive conservation and heritage resilience. The case study considered here is the dome of the Basilica of Santa Maria degli Angeli in Assisi, recently added to the World Heritage List of Unesco. The basilica is located in the center of Italy and it was built between 1569 and 1679 on the design of the architect Galeazzo Alessi. It consists of a latin cross plan, with 126 m and 65 m dimensions, with a nave, two aisles and a semicircular apse. At the intersection between the transept and nave the building hosts the Porziuncola, a little ancient chapel, symbol of Franciscan spirituality and pilgrims destination since the construction of the basilica.*

In order to preliminary assess the structural behavior of the dome, several dynamic experimental investigations have been carried out and ended with the installation of a simple vibration-based monitoring system, based on the use of a few high sensitivity accelerometers, placed at the top and the base of the drum, as well as temperature and humidity sensors. This paper presents and discusses the first results of the vibration-based monitoring of the drum-dome system, demonstrating the potential for using similar approaches for the preservation of this special kind of historic structures.

Figure 1: Basilica of Santa Maria degli Angeli in Assisi.

1 INTRODUCTION

Monitoring the structural integrity of historical constructions is an important topic for the conservation of the architectural heritage [1], that has received a considerable interest both from researchers and practitioners in the last decades [2, 3, 4, 5, 6, 7]. Within this context, vibration-based dynamic monitoring can be considered as a quite novel approach, if applied to cultural heritage. In particular, while the use of Operational Modal Analysis (OMA) techniques is well-established for performing dynamic structural investigations and/or implementing continuous monitoring of relatively new slender structures [8, 9], their application in the context of heritage monumental buildings is far less common. A few documented applications of vibration-based monitoring to monumental buildings are however available, whereby some literature studies have proposed the use of OMA techniques for the dynamic identification of masonry civil and bell towers [10, 11, 12]. On the contrary, applications to different kinds of historic structures are quite rare and only a few studies have proposed to use OMA techniques in the context of continuous dynamic monitoring systems [13, 14]. This is mainly due to the low levels of vibration typically exhibited by massive masonry buildings, as well as to their complex structural behavior, that makes the development of vibration-based continuous monitoring systems for cultural heritage preservation a new and worthwhile scientific and technical challenge.

In this paper, the results of ambient vibration tests carried out on a masonry dome, which lead to the installation of a permanent dynamic monitoring system, are presented. The case study considered here is the dome of the Basilica of Santa Maria degli Angeli in Assisi, recently added to Unesco's World Heritage List, which represents one of the most important focal points of the franciscan spirituality (Figure 1). Field measurements of the dynamic response of the structure have been carried out by installing high sensitivity accelerometers both at the top and at the base of the drum. Data are first processed to preliminary assess the structural behavior and to attain a proper configuration of the sensors layout for the monitoring system. The same

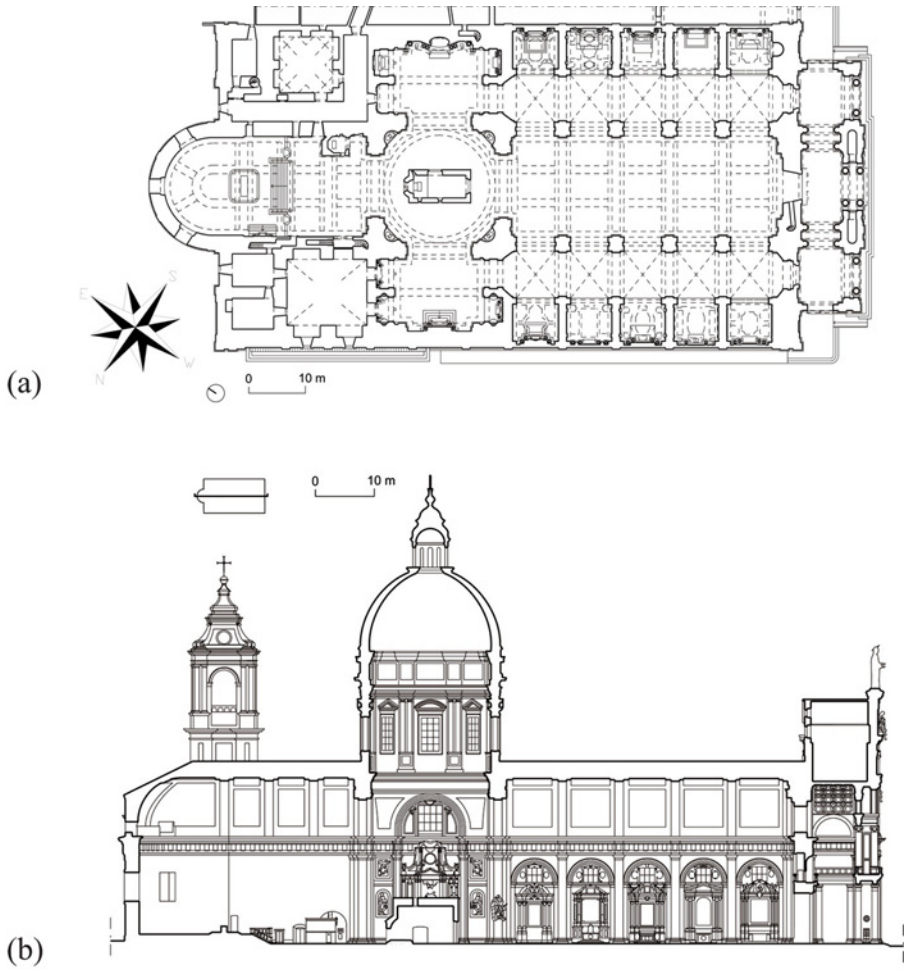

Figure 2: Basilica of Santa Maria degli Angeli in Assisi: (a) plan; (b) longitudinal section [15].

data are then continuously processed by using both classical Frequency Domain Decomposition (FDD) and Stochastic Subspace Identification (SSI) techniques. The results of the first months of monitoring are presented, providing an overall demonstration of the potential of this kind of measurements in the context of heritage preservation.

2 THE DOME OF THE BASILICA OF SANTA MARIA DEGLI ANGELI IN ASSISI

2.1 The architecture

The Basilica of Santa Maria degli Angeli in Assisi was built between the 16-th and the 17-th centuries, on the design of the architect Galeazzo Alessi. It consists of a latin cross plan, with 126 m and 65 m dimensions, with a nave, two aisles and a semicircular apse. The Basilica contains the Porziuncola, a little ancient chapel representing a symbol of Franciscan spirituality and an important pilgrims destination. This chapel is located at the intersection between the transept and nave. Figures 2(a) and 2(b) show the plan and the longitudinal section of the Basilica carried out after a recent architectural survey [15].

The presence of the Porziuncola inside the basilica, as well as the need to provide a visible sign for pilgrims coming from all over the world, have induced the architect to design an uncommonly high drum-dome system. In this way, the dome appears majestic and impressive owing to the singular slenderness and lightness of the drum. It is characterized by a single shell

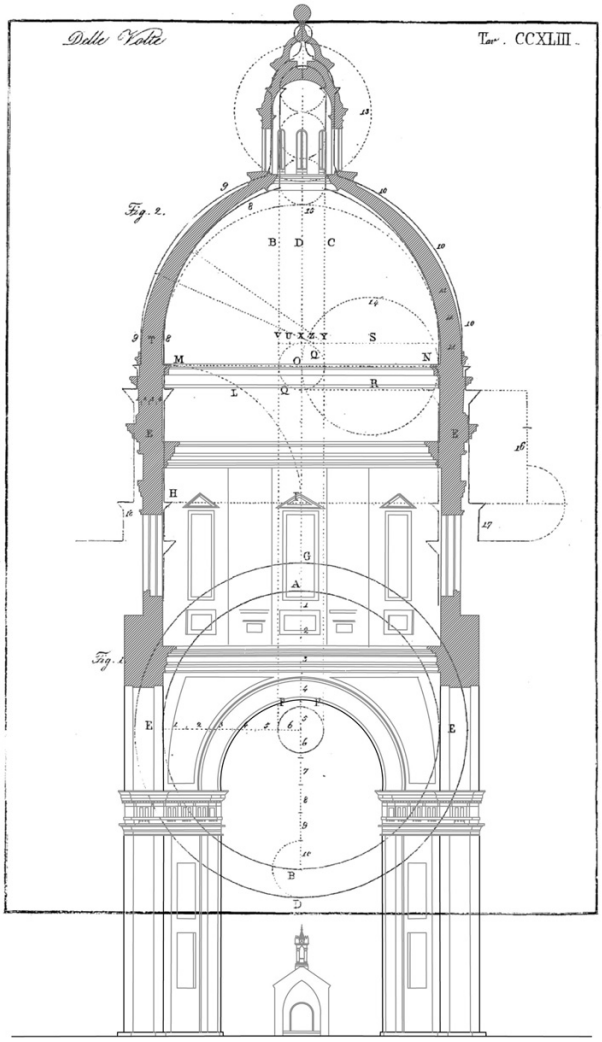

Figure 3: Superposition between Fontana's drawing and the dome section of the Basilica of Santa Maria degli Angeli [17].

and provided with an external staircase to climb up to the lantern. The inner diameter is of approximately 20 m and the variable thickness of the unique shell ranges from 1.80 m at the bottom, up to 0.90 m at the top. The inner perimeter of the drum is circular, while the outer one is octagonal; the coupled pilasters at the angles of the octagon become stiffening ribs over the dome's extrados, joining at the oculus, the base of the lantern, that gives to the architectural complex an overall height of approximately 75 m.

It should be noted that, if compared with the rules of construction illustrated in the most important architectural treatises, e.g. the work of Carlo Fontana [16], the drum appears to be very high. In particular, its height is more than twice the height that would correspond to the prescriptions proposed by Fontana, conferring to the structure a really unusual slenderness and unique architectural feature. This aspect is emphasized in Figure 3, where the section of the drum-dome system is superimposed to a drawing explaining the geometrical rules proposed by Fontana.

It is worth recalling that Fontana's graphical rules were developed for the design of some structural parts of the Vatican Temple, which made his treatise a fundamental reference for

Figure 4: Lineengraving of the basilica damage state after the 1832 earthquake. *Prospetto delle ruine del famoso Tempio di Santa Maria degli Angioli di Asisi*, by Cilleni Nepis.

architects of those times [19]. Nonetheless, the dome of the basilica of Santa Maria degli Angeli was a notable exception to those rules and differed from all other contemporary designs. This significant slenderness motivated the authors towards the implementation of a vibration-based monitoring system for the dome.

2.2 Evolution of the structural system

Throughout its history, the Basilica of Santa Maria degli Angeli was subjected to significant seismic events. The most important one was certainly the earthquake of 1832, which caused the collapse of the nave and of a portion of the left aisle (Figure 4). The drum-dome system was severely damaged, but did not collapse, conceivably because of its high flexibility and low natural periods of vibration. The strengthening of the drum with three orders of steel rings dates from this period. In the reconstruction phase, a particular attention was devoted to the cross section of the central vault and to the timber truss system of the roof designed by Poletti, in order to reduce the horizontal thrust acting on the lateral walls [20]. After the Umbria-Marche earthquake of 1997, the basilica was subjected to other phases of strengthening and restoration [21]. However, a pattern of cracks and micro-cracks, that can be attributed to seismic and static actions, is still evident both in the drum and the dome. The most significant through-wall cracks are located above the north-east side, for the presence of internal staircases and tunnels, and the west side of the drum.

3 ANALYSIS PROCEDURES AND MONITORING SYSTEM

3.1 Data processing

Field recorded vibration data have been processed using two different techniques. The first considered approach is the classic Frequency Domain Decomposition (FDD) based on the evaluation of the spectral matrix $\mathbf{G}(f)$ (i.e. the matrix of cross-spectral densities) of recorded accelerations, whose diagonal terms are the auto-spectral densities (ASD), while the out of diagonal are the cross-spectral densities (CSD). The time series are first resampled in order to estimate $\mathbf{G}(f)$ with a frequency resolution of 0.01 Hz. Subsequently, the contour plot of the first singu-

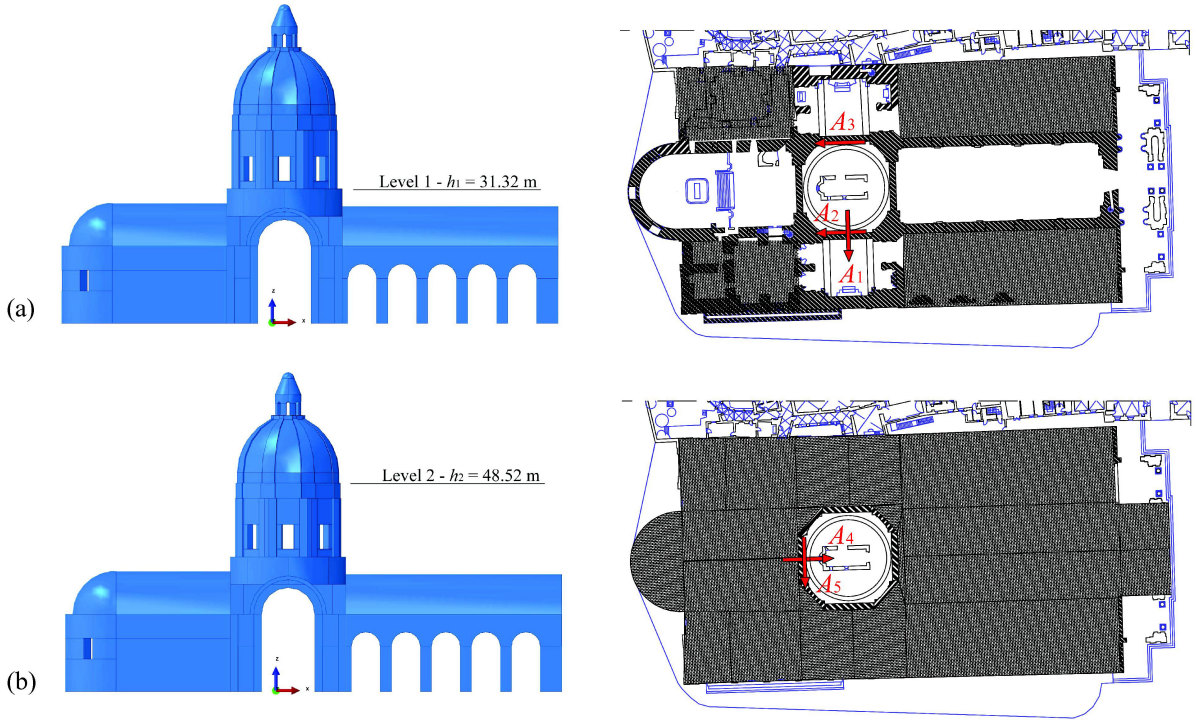

Figure 5: Structural monitoring system installed in the dome of the basilica.

lar value (SV) of the spectral matrix $\mathbf{G}(f)$ estimated in consecutive data sets has been obtained. This plot is commonly known as frequency spectrogram, which highlights resonant frequencies and their variation in time as local maxima of the SV contour plot and, consequently, of the energy content of the data, in the time-frequency domain.

The second considered approach is based on the Stochastic Subspace Identification (SSI) technique. This method has been used to identify the natural frequencies of the structure by a fully automated for step procedure [22, 23]: (i) run of SSI-data analysis, using the classic Canonical Variate Analysis (CVA) formulation, for different values of the order of the model and of the number of output block rows adopted to construct the block Hankel matrix of the data; (ii) elimination of noise modes on the basis of similarity checks between modal parameters estimates; (iii) clustering of remaining modes; (iv) extraction of mean values of modal parameters estimates with 95% confidence intervals, under variation of model's order and number of block rows of block Hankel matrix. Using the SSI technique to consecutive data sets it is possible to obtain a frequency time series of the lower structural natural modes.

3.2 Dynamic monitoring system

The monitoring system installed in the drum and the dome consists of five high-sensitivity (10V/g) uni-axial accelerometers placed at the base of the drum and at the base of the dome, as described in Figure 5. In particular, three accelerometers have been fixed on the easily accessible external side of the drum base (sensors A_1, A_2 and A_3 in Figures 6(a) and 6(b))). The sensors A_4 and A_5 have been placed in the only accessible part with highest location inside the dome shell (Figure 6(c)), at the top of the internal staircases which allow the access to the dome extrados. The data have been recorded by using a multi-channel system, carrier model cDAQ-9188 with NI 9234 data acquisition modules (24-bit resolution, 102 dB dynamic range and anti-aliasing filters), down-sampled at 100 Hz for storage purpose and stored in 30-minutes long

Figure 6: Images of the accelerometers installed at the base of the drum (a) and (b), and of the dome (c).

	ρ [t/m^3]	μ_E [MPa]	$\sigma_{ln,E}$	μ_G [MPa]	$\sigma_{ln,G}$
Brick	1.8	1500	0.2	500	0.2
Stone	2.2	2800	-	860	-

Table 1: Mechanical material properties: mass density (ρ); mean value (μ_E) and standard deviation of the logarithm ($\sigma_{ln,E}$) for the elastic modulus; mean value (μ_G) and standard deviation of the logarithm ($\sigma_{ln,G}$) for the shear modulus

time histories, representing the data sets. The monitoring system also includes humidity and temperature sensors, as well as displacement transducers monitoring the evolution of existing cracks. The related information is however not illustrated in this work and, therefore, these additional sensors are not considered.

4 ANALYSIS OF RESULTS

4.1 Preliminary numerical model

The Basilica of Santa Maria degli Angeli has been investigated focusing on both historical and structural aspects [17, 18]. As far as the structural analysis is concerned, a preliminary Finite Element numerical model has been developed in order to investigate the static and dynamic behavior of the structure, with a focus on the drum-dome system. The model details the central core of the basilica, i.e. the triumphal arches, the drum and the dome, while the remaining parts of the basilica are considered as lateral restraints. In this way, it has been sufficient to include a rough model of the nave, the transepts and the apse to reproduce a consistent lateral stiffness.

A peculiarity of the developed numerical model is the probabilistic approach for the estimation of the eigenfrequencies and eigenmodes starting from a stochastic model for the elastic moduli of the materials. The main constituent material is brickwork everywhere, except for the stone pillars of the nave. An homogeneous material with orthotropic elastic behaviour has been considered, in which the values of stiffness have been selected from the recent instructions proposed by the Italian National Research Council [24], with their lognormal distribution parameters (Table 1).

A set of 1000 samples have been generated for both the Young's modulus (E) and shear modulus (G) of the brickwork (Figure 7), and then multiplied by a coefficient $\alpha = 1.5$ which takes into account the good condition of the mortar.

Figure 8 shows the eigenproblem solutions of the first modes. For each mode the distribution of the corresponding frequencies for the 1000 samples of the elastic parameters is reported. It should be noted that all considered modes are flexural in x and y directions, with the only

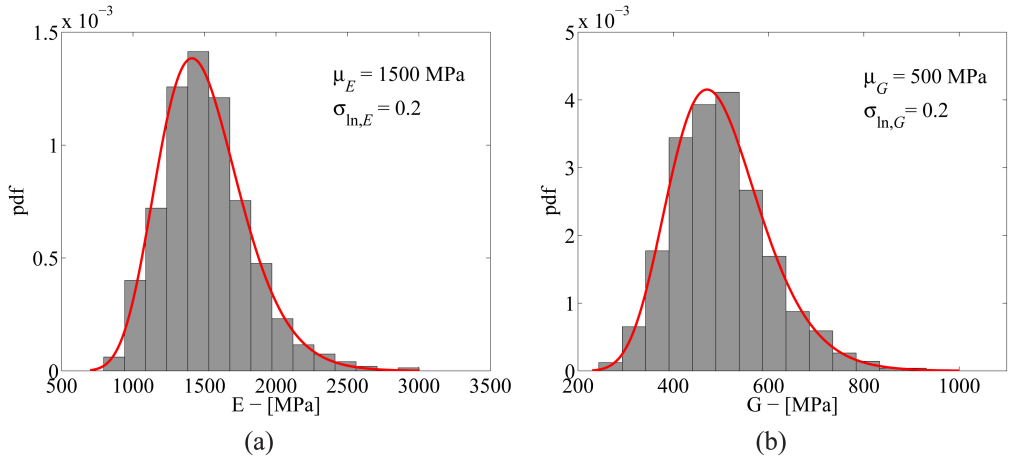

Figure 7: Generated values of Young's modulus (a) and shear modulus (b) from the statistical moments of the related distributions.

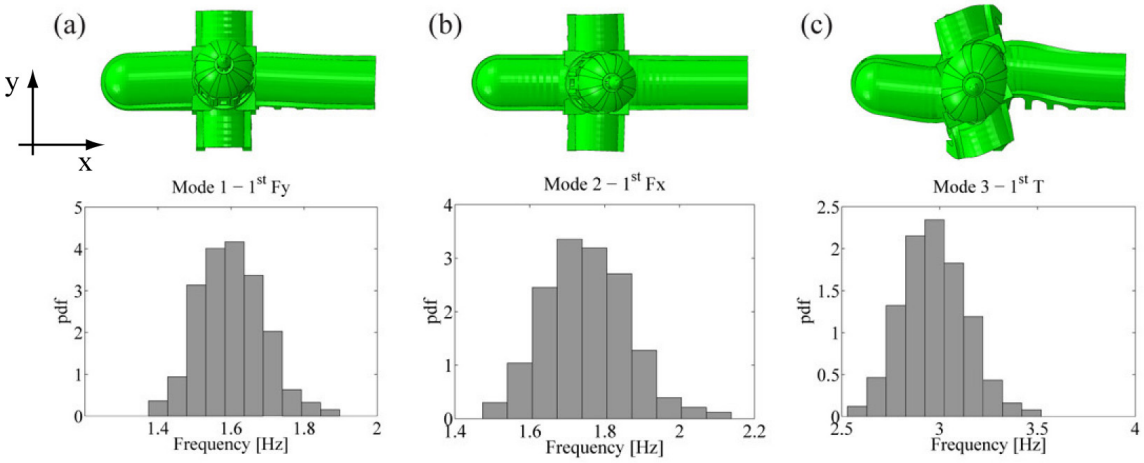

Figure 8: Modal shape and distribution of the related frequencies of the first seven modes derived by FE model by varying material stiffness [25].

exception of the third mode, which is a torsional mode. The x and y directions are defined according to the reference system of the numerical model (Figure 8).

4.2 Dynamic identification of the modal parameters and frequency tracking

The dynamic monitoring system has been started on October 16-th 2015. Figure 9 shows an example of acceleration time histories of a sample 30-minute data set, with excitation mainly given by micro-tremors due to road traffic around the Basilica and by wind loading. The very low levels of vibration in operational conditions are especially noteworthy, whereby peak accelerations are of the order of 0.2-0.3 mm/s^2. The different levels of noise in the signals can be conceivably due to the length of the cables connecting the sensors to the data acquisition unit.

The modal parameters of the structure have been estimated by means of the aforementioned SSI technique. In particular, the analysis has allowed to clearly identify the first five natural modes, where the first two modes are flexural in the y (Fy1) and x (Fx1) directions, respectively, the third mode is torsional (T1), and the last two modes are, again, flexural in the y (Fy2) and x (Fx2) directions, respectively. Figure 10 and Table 2 summarize the results of the modal parameters with their mean values and standard deviations identified from October 16th 2015

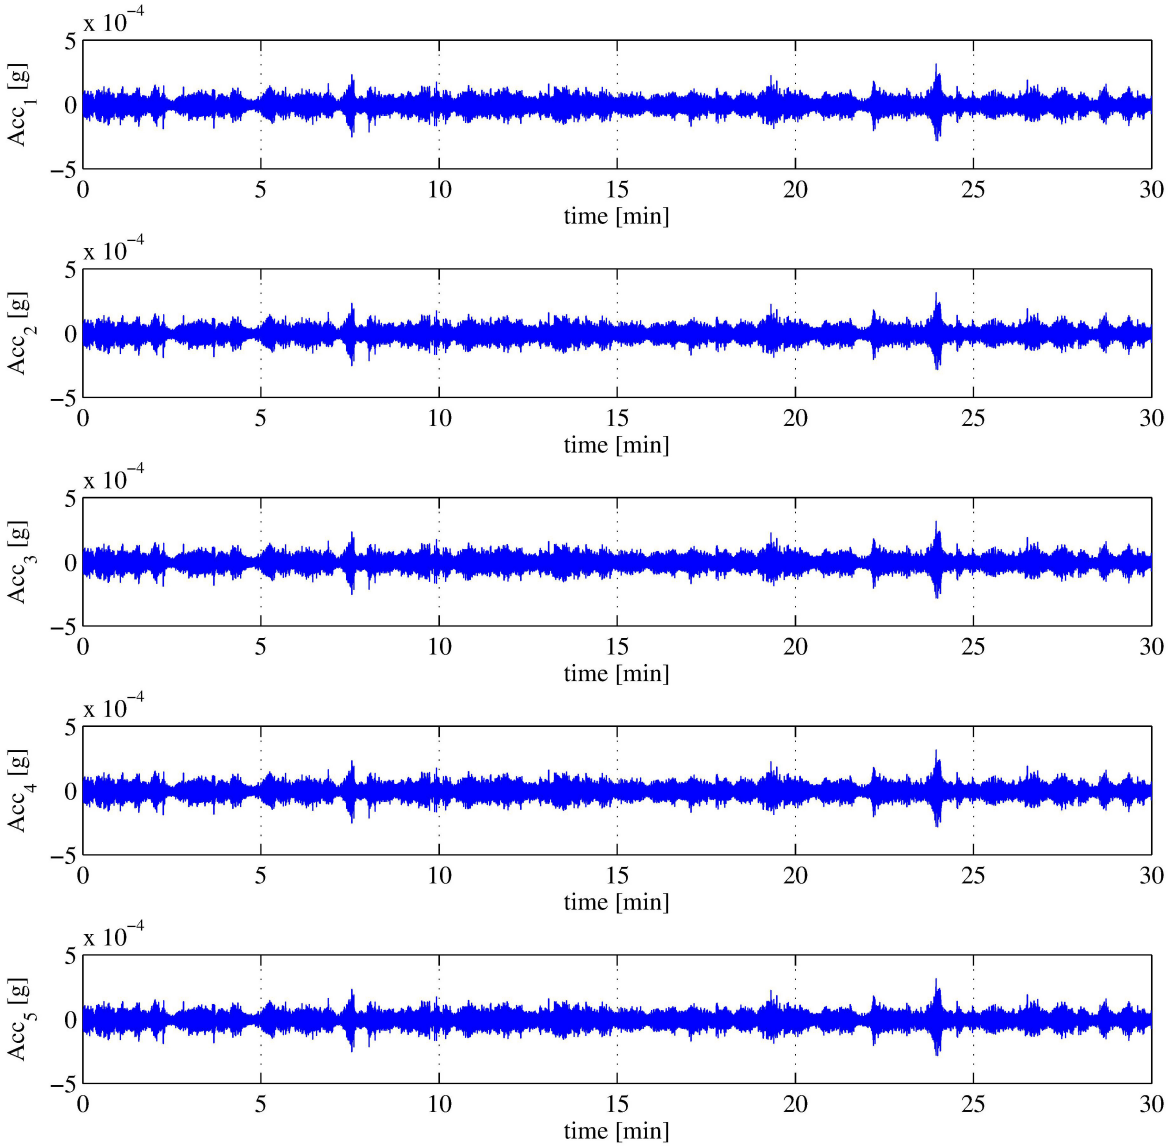

Figure 9: Sample of a 30-minutes recorded data.

Mode	Type	Frequency [Hz]	
		μ_f	σ_f
1	Fy1	1.77	9.25e-3
2	Fx1	1.81	1.10e-2
3	T1	3.08	1.01e-1
4	Fy2	3.51	4.78e-2
5	Fx2	4.40	5.57e-2

Table 2: Identified modal frequencies of the drum-dome system: mean values μ_f and standard deviations σ_f.

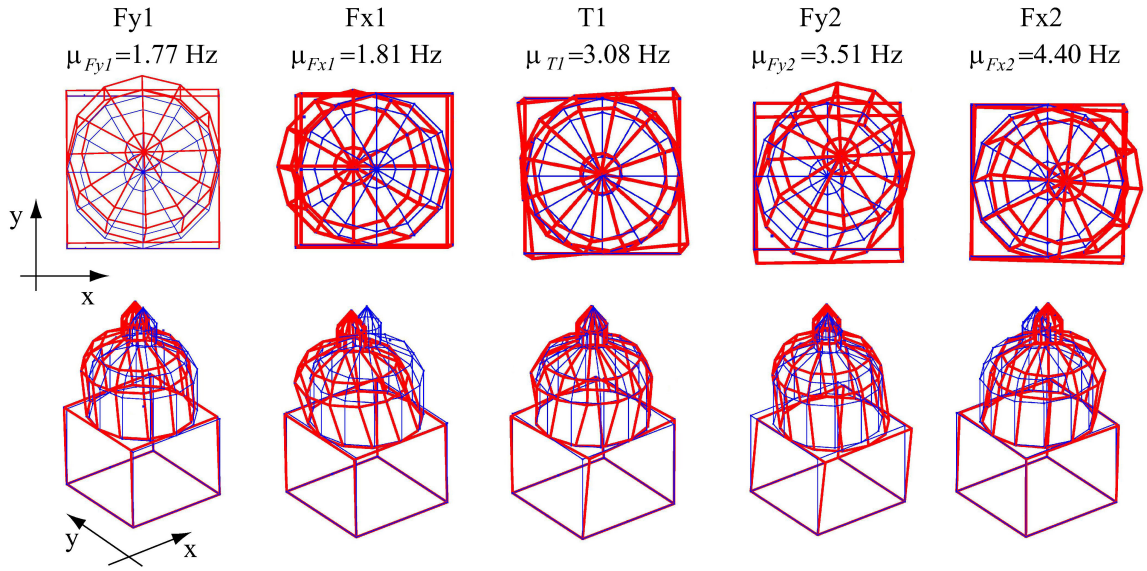

Figure 10: Representation of the identified modal shapes.

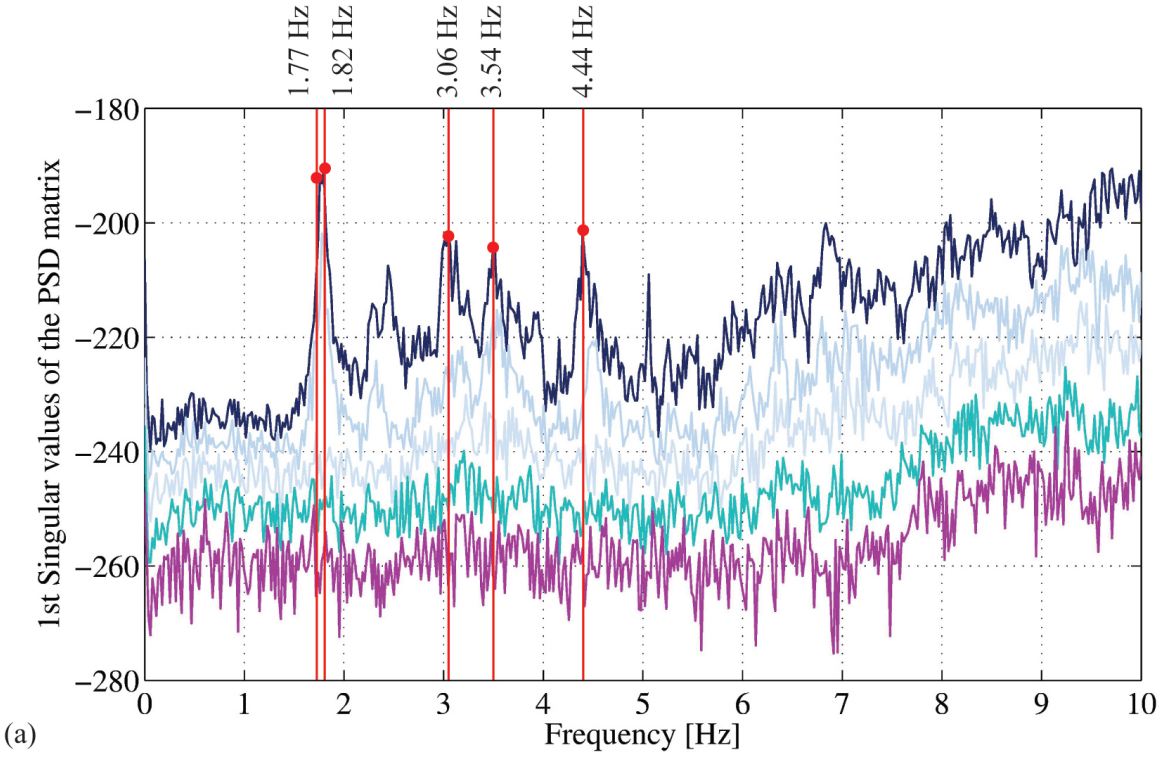
to January 4th 2016.

The application of the FDD technique has allowed to extract the first resonant frequencies through the peak-peking method. As an illustrative example, Figure 11(a) is a plot of the singular values of the power spectral density matrix of recorded accelerations as a function of frequency, for the sample data set in Figure 9. The first five resonant frequencies identified by SSI analysis can be clearly detected in the plot of Figure 11(a). Peaks associated to higher frequencies are also visible in this plot, which might conceivably correspond to higher order modes. A final decision about the nature of these peaks goes however beyond the purposes of the present investigation.

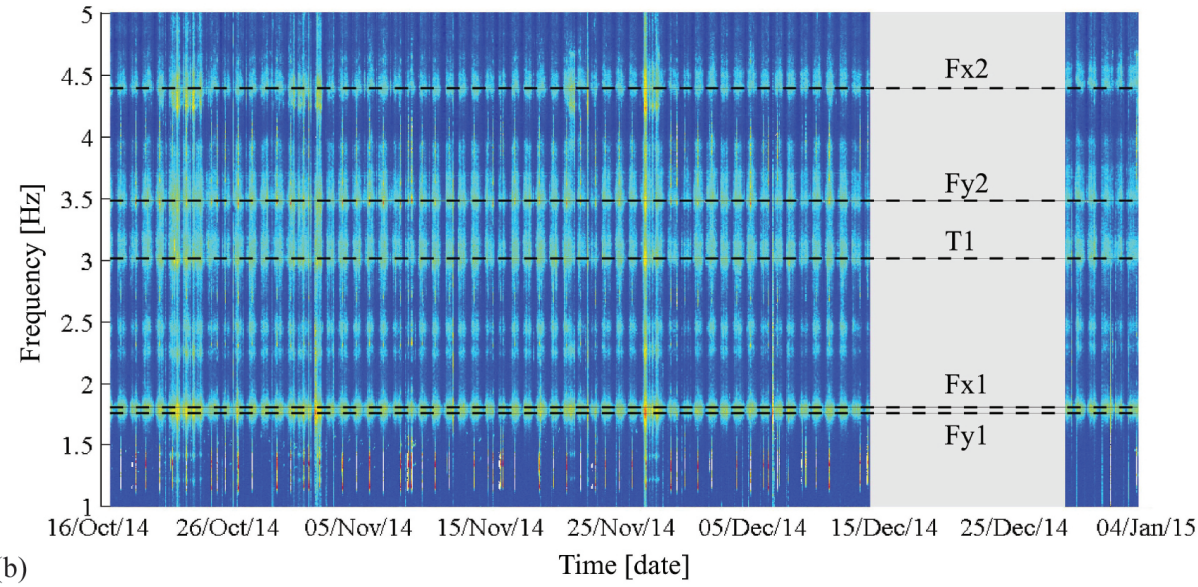
Figure 11(b) shows the spectrogram of the first singular value of the PSD matrix of the five acceleration records over the monitoring period. The traces of the first five modal frequencies are clearly visible in this plot and are indicated through dashed lines. By a closer inspection of the analysis results, it could be verified that these modes corresponds to those identified by FDD in a single data set, as discussed above. Another remark on the plot of figure Figure 11(b), is the presence of daily vertical lines that are associated with an increase in vibration energy during day-time and a decrease during night-time. This periodicity is conceivably associated to the periodicity of traffic intensity around the basilica.

Figure 12 shows the identified natural frequencies versus time, as obtained by the application of the aforementioned fully automated SSI technique on the data sets recorded over the monitoring period. The presented results are in perfect agreement with those obtained by spectral analysis of accelerations, as presented above. In particular, a quite clear tracking of the frequencies of the first five modes is achieved. Daily and long-term fluctuations of such frequencies are also clearly visible in this plot and conceivably attributable to changing environmental conditions, primarily ambient temperature. Also, natural frequencies are almost systematically identified during the day-time, while some frequencies are missing during night-time, due to a comparatively lower level of excitation.

From the results presented above, some comments on the agreement between experimentally identified and numerically predicted natural frequencies are mandatory. This comparison reveals that the frequencies of the second and the third numerical modes are in a good agreement



(a)



(b)

Figure 11: (a) Singular values of the power spectral density matrix and identification of the first resonant frequencies. (b) Spectrogram of the natural frequencies obtained by the FDD technique.

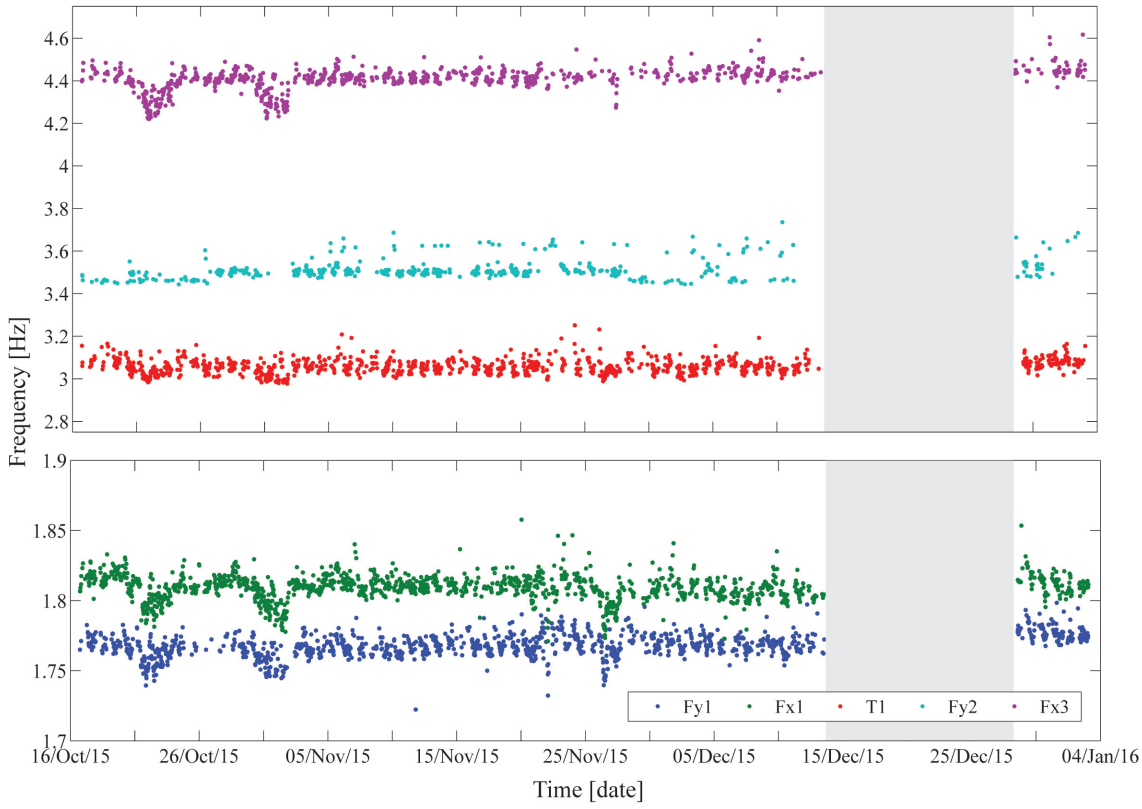


Figure 12: Frequency tracking of drum-dome system obtained by SSI technique.

with experimental results. The comparison with the higher modes requires further investigations which have not been carried out in this work. A final remark concerns some resonant frequencies in the range around $2.3 \div 2.5$ Hz which are often observed (e.g. Figure 11(a)). These phenomena are probably to be ascribed to the lateral restraint effect of the surrounding basilica. The numerical model is not able to describe these effects since, at this preliminary stage, the lateral structural elements are not fully reproduced. However, it can be concluded that the agreement between the preliminary developed finite element model and the identified natural frequencies is acceptable.

5 CONCLUSIONS

In this paper the first results obtained by a vibration-based monitoring system installed in the dome of the Basilica of Santa Maria degli Angeli in Assisi have been presented. The structural modal parameters and, in particular, the natural frequencies of the lower order modes, have been estimated over time in a continuous fashion using classic spectral analysis and a more advanced automated SSI technique. These natural frequencies have been also compared with those obtained by a FEM model developed in a previous study. In general, a good agreement between numerically predicted and experimentally identified modal parameters has been observed, both for natural frequencies and mode shapes.

Overall, the results presented in the paper represent a first attempt to monitor the behavior of large domes using vibration measurements and automated operational modal analysis. The presented results are promising towards the implementation of a vibration-based SHM procedure aimed at the early detection of damages in the structure caused by low return period earthquakes or other types of dynamic loads.

ACKNOWLEDGEMENTS

The Authors gratefully acknowledge the financial support of the "Cassa di Risparmio di Perugia" Foundation that funded this study through the project "Structural Monitoring for the protection of the Cultural Heritage: the bell-tower of the Basilica of San Pietro in Perugia and the dome of the Basilica of Santa Maria degli Angeli in Assisi" (Project Code 2014.0266.021).

The authors are also grateful to the Seraphic Province of St. Francis of Umbria, for the availability and the interest demonstrated to the research, and to the Master student Mr. Luca Botticelli for his cooperation in carrying out the experimental investigations.

BEHAVIOR OF SINGLE STORY BEARING WALL MASONRY STRUCTURES IN VARIOUS CONDITIONS

A.T. Kassem

Department of Civil Engineering, Beni-Suef University
Beni-Suef Egypt
e-mail: abdelraouf_kassem@yahoo.com

Keywords: Bearing walls, Masonry, Bricks, Boulders, principle stresses, Cracks.

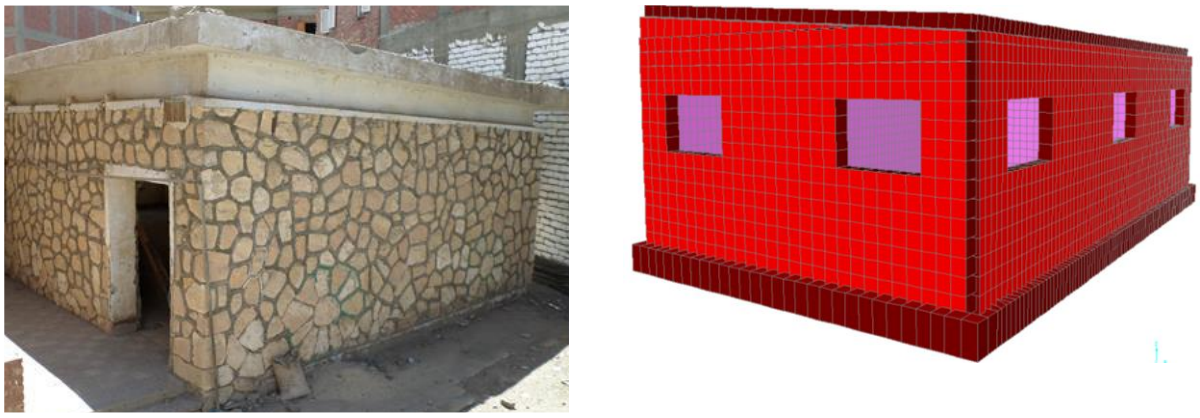
Abstract. As a part of a governmental action for studying the structural condition of public schools across Egypt, there was an awesome opportunity to perform such a research, using a valuable amount of available data for typical school models built in different environments and subjected to various loading and environmental conditions. A field study has been performed on fourteen, geometrically typical, single story schools to study effects of permanent gravitational loads, differential settlement and lateral pressure on the structural response of concrete and masonry. Structures under investigation were built by bricks or boulders and covered with an inclined reinforced concrete deck or steel or timber cladding. Finite element analyses have been performed to allocate regions and directions of principles stresses, expect failure pattern and compare with real structures. Modelling was capable to take into account various material and geometric parameters. Outcomes related to significance of various design parameters, loading and environmental conditions have been extracted. In addition response of various construction materials to the loading environment.

1 INTRODUCTION

Even bearing walls system is an ancient system for building lightly loaded structures, it is still the most used system worldwide, especially for single and double floor buildings. This extensive use of that system imposes a supporting research work studying structural properties, behavior, and response towards various loading conditions. This research was based on the opportunity arising from a governmental project of studying structural safety of school buildings all over EGYPT. The study has been performed on a typical single story bearing wall system used for educational purposes. Field investigation and measurements have been performed, in addition parametric and structural analyses have been established. All buildings studied in that paper have been built about twenty years ago and did not show seismic failure patterns since they did not face any significant seismic motion, in addition low rise restrained bearing walls behave well in moderate seismic actions[1&2]. Two main types of bearing walls materials were adopted in this research. The first is boulders and the second is bricks. The first type is known for its cracking resistance due to having irregular mortar interfaces[3]. Foundations of all the investigated models were of the same configuration and sub-base, resulting in the same stiffness[5].

2 FIELD INVESTIGATION

A typical building model, as shown in figure 1, has been considered for both investigation and analysis. The building is composed of a single compartment with a 15^{o} inclined ceiling.



a) investigation model b) analysis model

Figure 1: Building typical model

Openings for the door and windows are shown in figure 2. Bearing walls are 25 cm thick with a typical strip footing as shown in figure 3. Building geometry and life time were not studied parameters (constants), while construction material for walls and ceiling, soil pattern, natural ground level inclination, presence of neighboring structures, and interference with ground water table were considered as studied parameters.

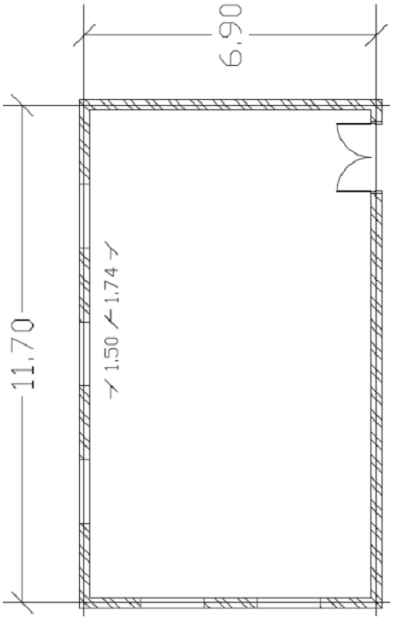


Figure 2: Building typical plan (Dim. in meters)

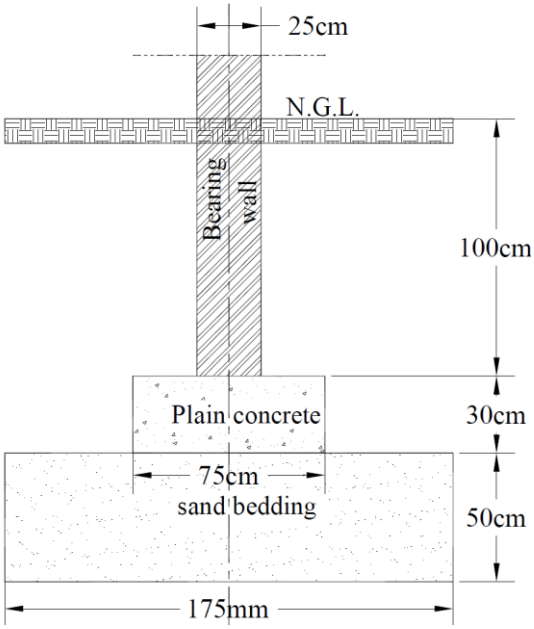

Figure 3: Typical wall x-section

3 FINITE ELEMENT MODEL

A finite element model has been developed to study stress distribution within the bearing walls body considering various loading conditions arising from field investigation. Shell elements were chosen to model walls and ceiling, as shown in figure 4. Specific releases were assigned at ceiling-walls interface to account for the difference in material and absence of rotational constraints. Springs have been used to model foundation elasticity, since foundation and subgrade properties were identical. Concrete slabs and bearing walls material non-linearities have been considered.

d) Fourth side

Figure 4: Finite element model

4 RESULTS AND DISCUSSION

Outputs of the study have been divided into two categories. The first is field investigation and measurements. Investigations considered loading conditions clarifying the structure's status, concentrating on the proposed most significant parameters as building material, ceiling type, soil type, natural ground level profile, presence of close neighboring structures, and interference with ground water level; in addition to crack pattern. While measurements concentrated on major crack width. Special conditions, as the presence of side embankment were found in a single building; so it was not considered as a studying parameter, but a load case. Table 1. Summarizes conditions of each building concerning studied parameters and noticed patterns of failure (major crack pattern and width).

Table 1: Brief Description of buildings condition

	walls		Ceiling			Soil			N.G.L.		Neigh.		G.W.T.		Crack Pattern				Crack width		
Building Id	Brick	Boulders	Concrete	Steel	Timber	Sandy	Clayey	Silty	Horizontal	Inclined	Close	Far	High	Low	Vertical	Inclined	Horizontal	None	x<5	5≤x≤10	x>10
1		■		■			■		■		■		■					■			
2		■		■			■		■		■		■					■			
3		■		■			■		■		■		■					■			
4		■	■				■	■	■		■		■					■			
5		■	■					■	■			■		■				■			
6	■		■				■			■	■		■			■				■	
7	■		■				■		■			■	■			■	■			■	
8	■				■			■	■		■		■					■			
9	■				■			■	■			■	■					■			
10	■		■					■	■			■	■		■				■		
11	■		■				■			■	■			■		■	■			■	
12	■		■			■			■			■		■	■	■					■
13	■		■					■		■		■	■			■	■				■
14	■		■				■	■	■		■		■			■			■		

The second output pattern is the finite element modeling. Two main finite element models have been established. The first reflects normal gravitational loads, while the second reflects the case of side embankment resulting in lateral loads. Figures 5, 6, and 7 represent horizontal normal stress (S11), vertical normal stress (S22), and maximum tensile stresses (Smax) in (kN/m^2).

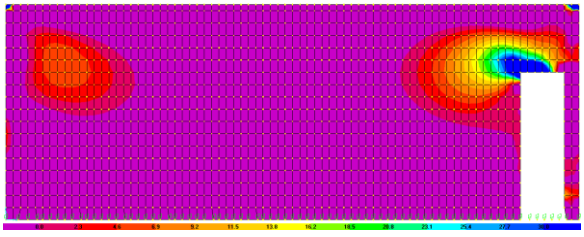

Figure 5a: S11 (gravitational loads)

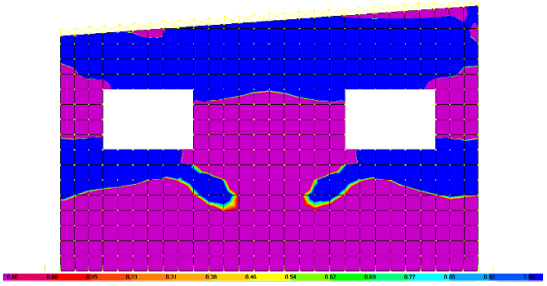

Figure 5b: S11 (gravitational loads)

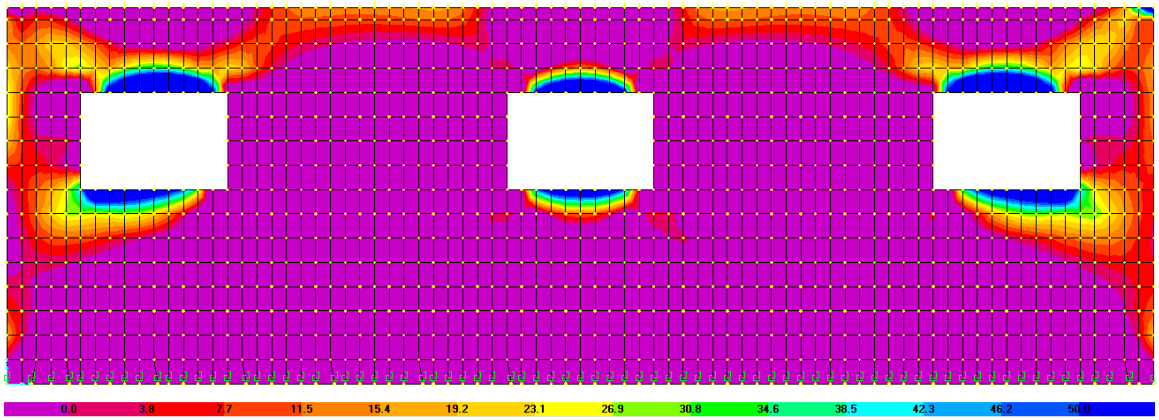

Figure 5c: S11 (gravitational loads)

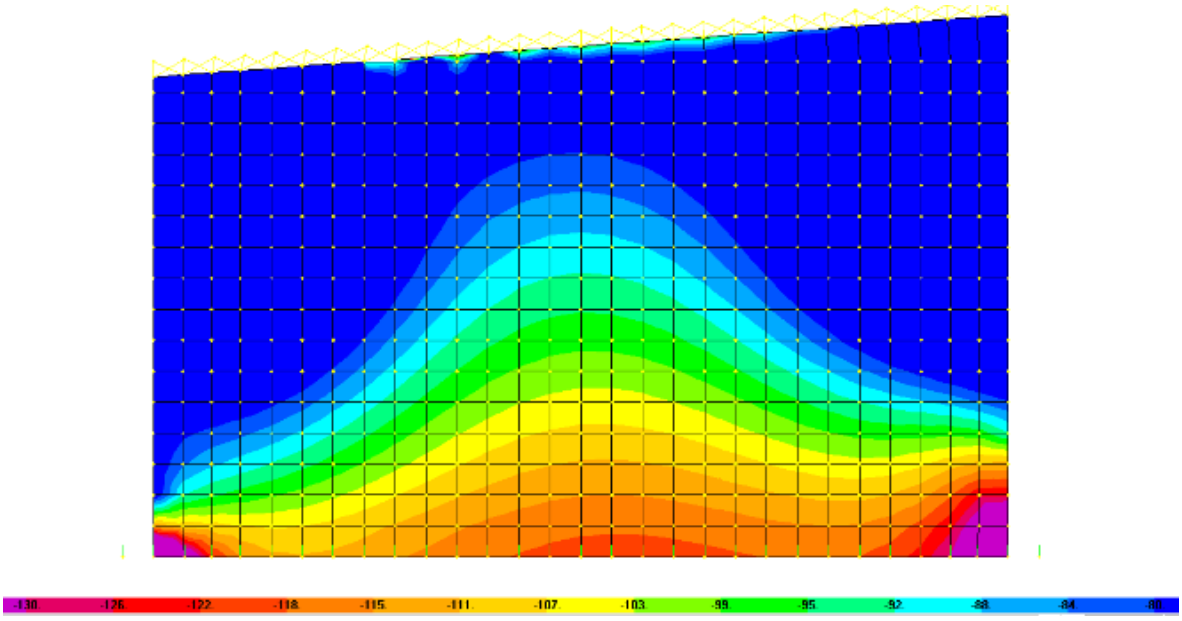

Figure 6a: S22 (gravitational loads)

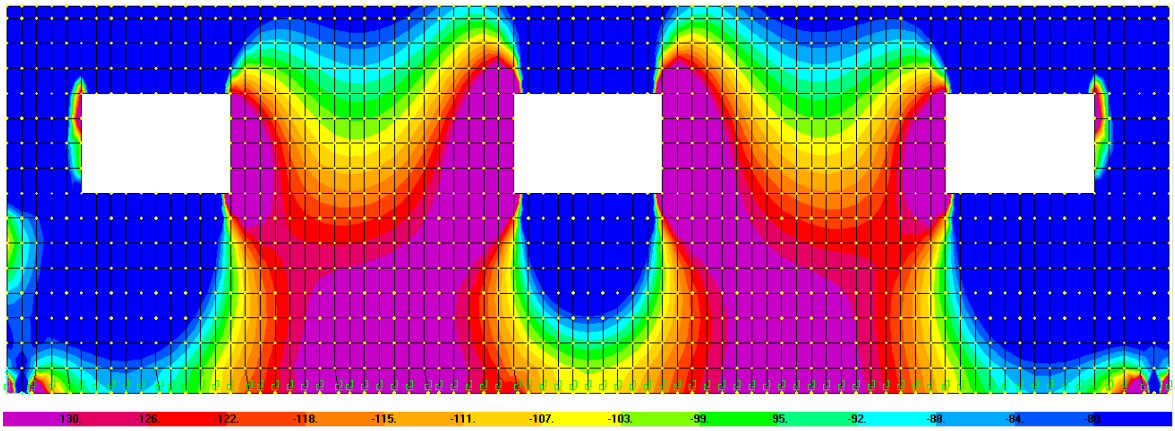

Figure 6b: S22 (gravitational loads)

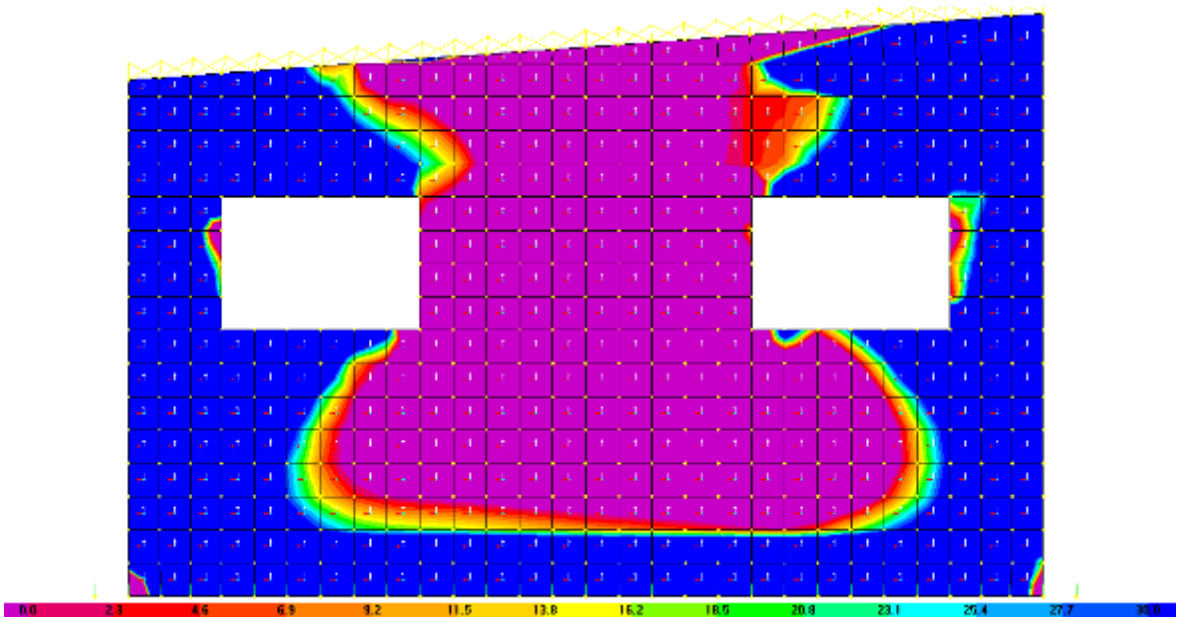

Figure 7a: Smax (lateral loads)

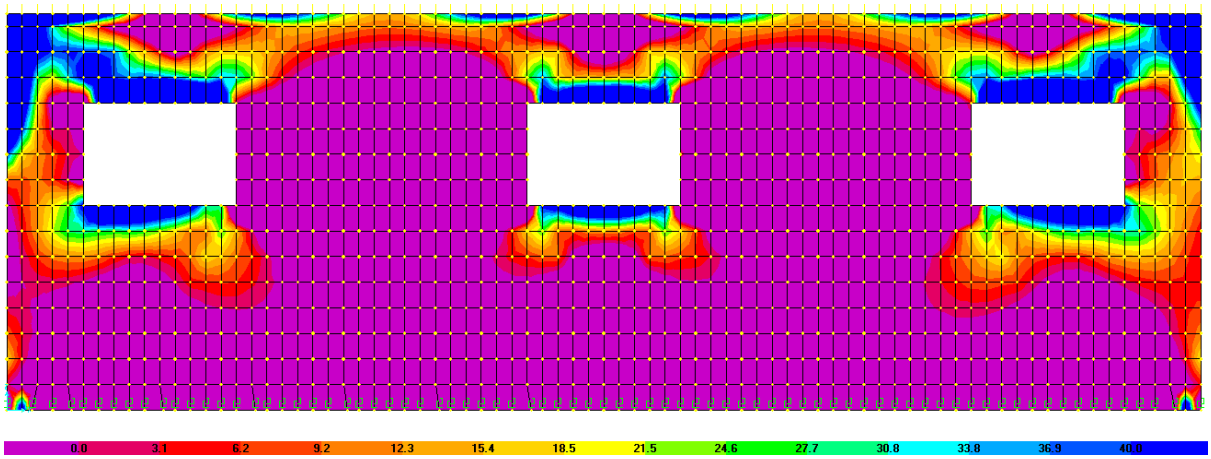

Figure 7b: Smax (lateral loads)

Reviewing field study outputs and analysis outputs showed an accepted level of compatibility between both of them. Consequently both of them have been considered to perform a parametric analysis to study parameters significance. Outputs of the parametric study could be summarized as follows. The most significant parameter concerning cracking is the use of boulders, where 35% of the investigated buildings were constructed by boulders and they all showed a high level of resistance towards cracking, this could be attributed to two factors, the first is the higher strength of boulders relative to bricks, while the second could be due to the irregularity if boulders interfaces that make crack propagation difficult. The second significant parameter is the natural ground level profile, where 21% of the investigated buildings were built on a sloping ground or at the edge of a slope. All these buildings suffered inclined cracking exceeding 5 mm width. The third significant parameter is soil formation, where 57% of structural failure took place in clayey soils, putting into consideration that clayey soils represent 57% of the investigated buildings sub-base. The forth significant parameter is applied loads, where lightly loaded buildings (steel or timber ceilings) did not show any failure patterns. Other parameters as interference with ground water table and the presence of adjacent structures seems to be insignificant.

A comparison has been conducted between field study and structural analyses. This comparison concentrated on location of relatively high tensile stresses, resulting from structural analysis and cracking, noticed in field investigation. Figure 8 shows door cracking at location of maximum tensile force due to gravitational loads, which is compatible with figure 5a. Figure 9. Shows windows cracking at the location of maximum tensile stresses, which is compatible with figure 5b. Figure 10 shows lateral earth pressure resulting from natural embankment reaching windows. This earth pressure resulted in tensile stresses shown in figures 7a and 7b and appeared in the form of cracking shown in figure 11

Figure 8: Door cracking (gravitational loads)

Figure 9: Window cracking (gravitational loads)

Figure 10: Windows Earth pressure loads

Figure 11: Window cracking due to earth pressure loads

5 CONCLUSIONS

Field and analytical studies resulted, concurrently, in the following conclusions:

- Bearing walls, built by boulders showed much more durability than those by bricks.
- Natural ground inclination has a highly passive influence on bearing walls failure.
- Lightly loaded ceilings (timber or corrugated sheets), results in no structural cracking, in case of proper foundations.
- Foundation submergence in ground water table does not influence bearing wall failure significantly.
- Most long-term cracking takes place in non-granular soils

Keywords: SEISMO Research Project, Historic Structures, Seismic Response, Numerical Modeling and Analysis, Documentation, In-situ and laboratory surveying.

Abstract. *The research has developed an integrated, interdisciplinary and innovative methodology to evaluate the seismic behaviour of monuments and historic structures. This methodology enables condition assessment of monuments, in a way that allows selection of effective preservation intervention techniques using appropriate materials. It also yields useful recommendations for engineers and authorities responsible for the procurement, realization and approval of studies and their subsequent applications to protect monuments and historic structures. Given the importance and complexity of historic structures in terms of design, construction techniques and materials, advanced computational tools and methods were utilized to meet the needs of the proposed research. In particular, implementation of the proposed methodology on selected case-study historic structures included: (a) documentation of the existing state through surveys and architectural studies; (b) recording of damage; (c) identification of the construction materials; and (d) monitoring of the monument and the evaluation of parameters, such as regional seismicity and soil conditions, that affect their seismic response. Static tests on wall specimens as well as shaking table tests were conducted, producing valuable data related to the true seismic behaviour of structures. Two well known monuments have been selected as case studies in order to be analysed using several types of analysis and failure criteria. Moreover, methodologies established for the study of monuments and historic structures were assessed in terms of their reliability, accuracy and effectiveness by comparing analytical results with experimental data.*

1 INTRODUCTION

The interest of the scientific community involved in the protection of cultural heritage was rekindled at the end of the Second World War when many monuments across Europe showed irreparable damage [1-3]. This interest focused on the condition assessment of monuments, methods for more efficient maintenance, and development of simulation techniques to model their behaviour, facilitated by the evolution of computational tools and the parallel progress made in many scientific fields.

The study of the behaviour of a monument or a historic building is particularly difficult because of the complexity of the structure, construction method, age, and of course because of its historic significance [4]. These parameters limit the choice of means and methods of monitoring and intervention for these types of structures. Detailed data collection, use of advanced computational methods and development of complex models is usually required [5-7]. Assessing the status of a historic building becomes even more difficult when the structure is prone to seismic activities [8]. In this case the risk of partial or total collapse should be studied [7, 9]. Furthermore, the existence of seismic activity in the vicinity of an aging monument usually suggests that the structure has already suffered damage, which must be considered in the study, and in addition, any proposed interventions should be targeted to protect the structure from future earthquakes [10-13].

Therefore, it is evident that the seismic protection of monuments involves a great number of parameters that should be investigated thoroughly and systematically. Although the surveying of a historic structure is a prerequisite for its study and protection against seismic actions, current practice has demonstrated deficiencies, as demonstrated by several current examples of failures reported in the literature, such as the Tower in Pavia, Italy, an important monument that collapsed without any indication of damage. A similar case- study is a Cathedral in the south of Sicily that was partially propped after an earthquake in 1990, and then collapsed in the 1996 without another seismic event. Use of suitable investigation methods and testing would have allowed an accurate assessment of the status of the above monuments and early detection of damage.

This research develops a methodology for thorough documentation of the geometry, assessment of structural condition and calculation of seismic response through experimental and analytical methods, as well as application or enhancement of innovative preservation techniques to monuments and historic structures.

(a) (b)

Figure 2: The Catholikon of Kaisariani Monastery, Hymettus Athens: (a) western façade; (b) southern view.

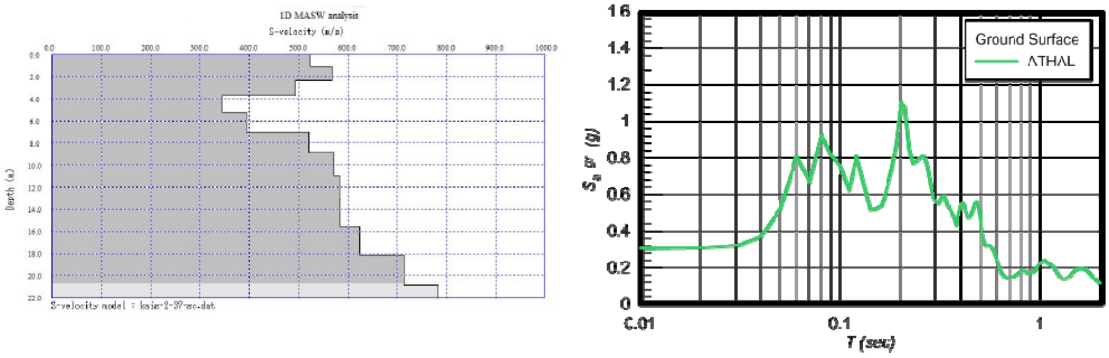
Two monuments of major importance were selected, representing the classical and the byzantine era: (a) the Temple of Hephasteus in the ancient Agora in Athens; (b) the Catholicon of the Kaisariani Monastery. The temple of Hephaestus was probably erected between 460 and 420 BC by a yet unknown architect on top of Agoraios Kolonos hill, which is delimiting the Ancient Agora of Athens to the west. It is one of the best preserved ancient temples, partly because it was transformed into a Christian church. The central church (Catholicon) of the Monastery of Kaisariani is located on a hillside at the foot of Mount Hymettus on the east of Athens, Greece. The Catholicon is a Byzantine crossed-dome church constructed during the 11th/12th centuries. The two monuments are shown in Figures 1 and 2.

2 CONDUCTED RESEARCH

The geometric survey of monuments is a sophisticated and demanding process, as regards to the use of suitable equipment (simple tools, photogrammetry or laser scanners surveys), software, expertise, time and effort. The importance of accuracy in monument surveying is obvious. The need for a detailed record of the architectural elements of the bearing structure, deformation and damage is often a catalyst for the choice of retrofitting methods. A full documentation of the main structure, including the main horizontal, vertical and inclined structural elements that transfer the imposed stresses and strains at the foundation elements, has been performed for the two monuments. In Figure 3 the final 3D model for the temple of Hephaestus derived with the use of a Leica ScanStation 2 laser scanner is shown [14].

Figure 3: Documentation of temple of Hephaestus with laser scanner: View of the 3D model from the northeast corner [14].

Local soil conditions have a profound influence on the structural response. In this context, site surveying includes the study of local topography (i.e., slopes, valleys), nature of the bedrock and nature and geometry of the deposited soils. These factors may contribute to the qualitative interpretation of the observed damage. The role of soil behaviour and site characteristics on the seismic response is now internationally recognized. A Geophysical investigation has been performed for the Kaisariani Monastery to evaluate the velocities for P and S waves along depth, as depicted in Figure 4a. Based on the geological and geotechnical data available at the positions of the two monuments, the soil profiles have been derived and analysis of soil response has been conducted to estimate maximum acceleration, maximum velocity and design spectra at the top of the soil. An indicative elastic acceleration spectrum at the ground surface is shown in Fig. 4(b) [15].



(a) (b)

Figure 4: Soil investigation: (a) determination of S-waves velocity in Kaisariani Monastery; (b) elastic spectral acceleration at ground surface in Hephaestus temple [15].

A detailed study of seismic hazard is also completed, that is, assessment and evaluation of seismic loads resulting from the seismicity of the area in which the monument is located, considering possible nearby active faults and near-fault phenomena. The significance of the monuments requires the probabilistic assessment of seismic risk, which is based on regional seismicity including historic earthquakes and the establishment of the probability distribution of occurrence for seismic events. The combination of the regional seismicity and attenuation relationships of ground motion result in the formation of seismic hazard curves that provide the expected ground acceleration, depending on soil type, for different annual frequencies of exceedance and return periods. Based on typical values of acceleration, appropriate pairs of earthquake magnitude and distance were determined, and used for seismic analysis. In Figure 5 the annual frequency of exceedance of peak ground acceleration for stiff soil conditions is depicted [16].

Another important parameter, necessary for the complete documentation of the structure and for understanding its behaviour, is the identification of material properties, which may have different characteristics depending on construction phases of the structure. Beyond identifying these components, namely the structure and the mechanical properties of the materials, the scientific community interest focuses on the modeling approach of historic mortars, since application of inappropriate mortars for the preservation of monuments in the past resulted in devastating effects, i.e., cracks, failure of the original materials, surface staining or spalling. A thorough and organized survey of the two monuments has been conducted including the implementation of various non-destructive techniques (NDTs) [17-19]. In the case of Kaisariani monastery, after a thorough in-situ macroscopic investigation, a variety of NDTs where ap-

plied: Ground-penetrating Radar (GRP), Infrared Thermography (IR), Fiber Optics Microscopy (FOM) and Schmidt rebound hammer.

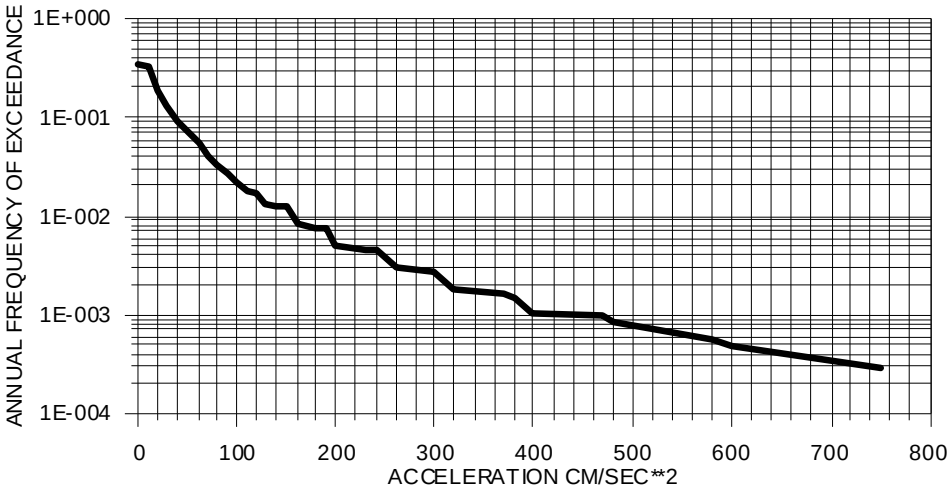


Figure 5: Seismic hazard curve [16].

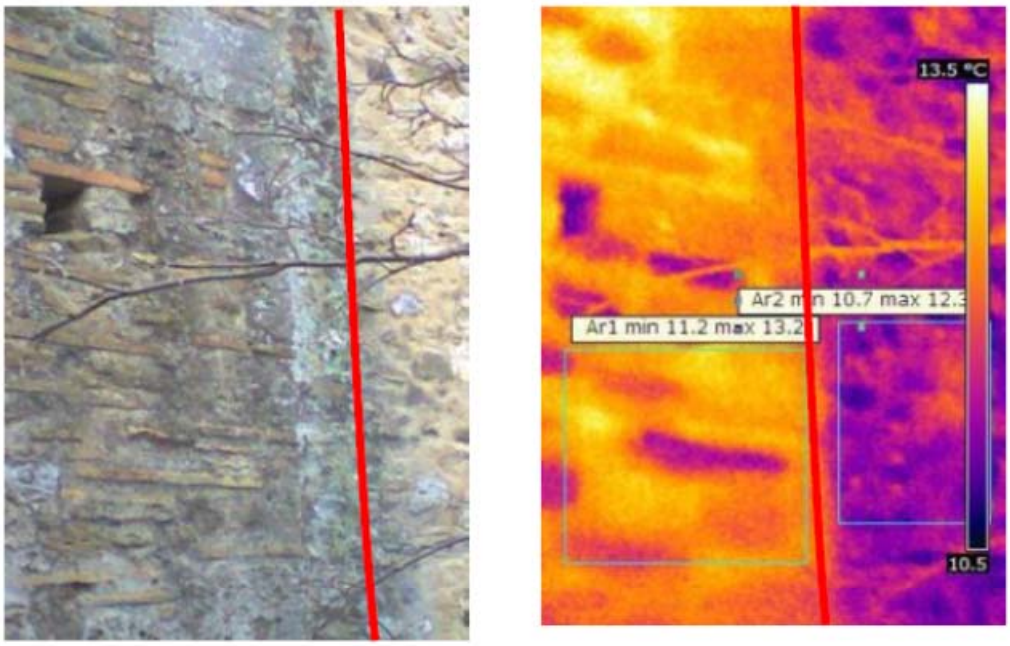

Figure 6: Results of Infrared Thermography at the Catholikon. Detection of different structural phases [17].

The results were analyzed and combined in order to extract information regarding the original building materials, the type of masonry construction, as well as information regarding non-documented different construction phases and problematic areas. In Figure 6 indicative results of infrared thermography are shown regarding the Catholikon. A series of NDT tests have been conducted also at the Hephaestus temple including the use of ground penetrating radar, endoscopy and rebound hammer testing. In Figure 7 the results of radar are shown regarding a wall of the south façade.

Monumental and historic buildings are generally constructed with masonry walls. These construction materials present significant variances of the mechanical and dynamic characteristics, which are very difficult to identify. The identification of these variances is required in

order to perform the analysis of the monument and assess its behaviour. The large dispersion of these characteristics is mainly attributed to the fact that the monument during its life has been strained by several actions, including subsidence, temperature changes, environmental vibration and seismic loads. The impact of these actions is partly depicted in the form of cracks. The existence of severe cracking could result in separating the monument in different parts; thus, increasing the difficulty to assess its behaviour under seismic excitations.

For these reasons, a thorough understanding of the behaviour of the monument is achieved through structural monitoring under small-intensity earthquakes in order to assess the effects of cracking on the behaviour of individual parts. The information from structural monitoring can be a basis for developing numerical and analytical models that will be validated according to the results of a monitoring program in order to approximate the real behaviour of the structure with acceptable accuracy. In Figure 8 the positions for the placement of six triaxial accelerometers are depicted for the Catholikon. The accelerometers are connected with a central data acquisition system.

Another important source of information is through testing of models. These experiments allow simulation of the seismic action by selecting the intensity, frequency spectrum and most parameters that characterize an earthquake motion. The specimens are constructed to satisfy, in as much as possible, the actual construction and to facilitate the study of specific parameters. However, there are few experiments in the literature related to historic structures because of the many implementation difficulties. A number of masonry specimens have been constructed at the Laboratory for Earthquake Engineering of the National Technical University of Athens, LEE-NTUA, to be tested under compression as shown in Figure 9.

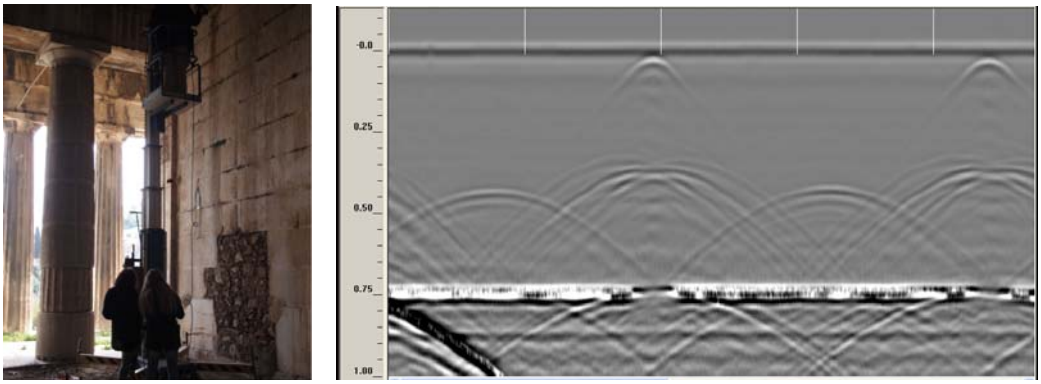

Figure 7: Results of ground penetration radar testing at the Hephaestus temple [19].

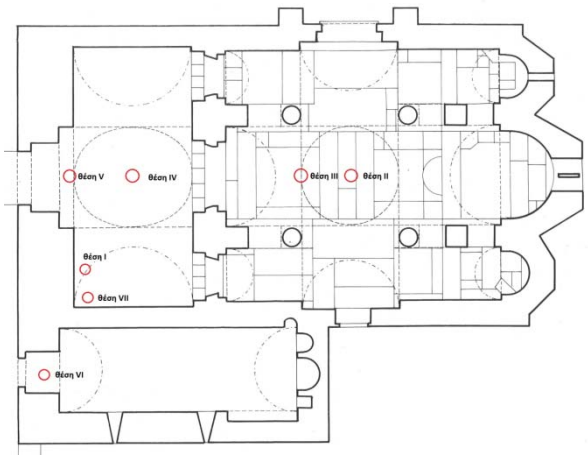

Figure 8: Monitoring scheme for the Kaisariani monastery. Placement of recording devices.

Identifying potential failure modes of a monument or a historic building requires understanding of its structural behaviour. This can be aided by examining the response of pertinent subsets of the structure based on the method of macroelements, or the finite-element method, using linear or non-linear analysis [20, 21]. Development of reliable macroelement and finite element models is necessary to perform elaborate analyses, including nonlinear static and dynamic time-history analysis. In Figure 10(a) and 10(b) the finite element models of the Hephaestus temple and the Catholikon are depicted, respectively [22]. In Figure 11(a) the central apse of the Catholicon is selected as a macroelements in order to study a local mechanism of failure governed by overturning. The transversal behaviour is assessed by means of a macroelement that isolates three arches and the supporting pillars of the central nave as shown in Figure 11(b) [9].

Common practice in describing failure is the application of criteria based on stress distribution. Successful use of an analytical mathematical model that incorporates the particular geometric, mechanical and structural features of a historic structure can provide information on the type, extent and location of damage. The results from such an analysis can be used in a deterministic way or alternatively, following a probabilistic approach with which parametric analyses are performed for a range of values of a critical parameter. The statistical evaluation of the results has led to the development of fragility curves that correlate the estimated damage to the seismic intensity based on a given type of probability. Indicative fragility curves for the Kaisariani monastery are shown in Figure 12b referring to the failure criterion depicted in Figure 12a [18, 23].

The main purpose of the analysis of a monument or a historic building is to assess its seismic risk in order to propose specific intervention measures for an effective seismic upgrade and protection of such structures. In addition to conventional treatments, application of seismic base-isolation is an efficient engineering methodology designed to reduce or even eliminate damage caused by dynamic excitations. In fact, seismic isolation is a type of support that separates the structure from the soil response and results in a reduction of seismic energy input rather than enhancement of structural resistance. The application of this technology leads to structures that continue to behave elastically even during major seismic events [24]. The effectiveness of using base isolation is also studied at LEE-NTUA with the aid of a masonry specimen depicted in the drawing of Figure 13 [25-26].

3 MANAGEMENT STRUCTURE AND PROJECT TEAMS

The conducted research was organized in thirteen Work Packages (WP):

WP 1: Coordination of the project including synchronization of the research groups and financial management;

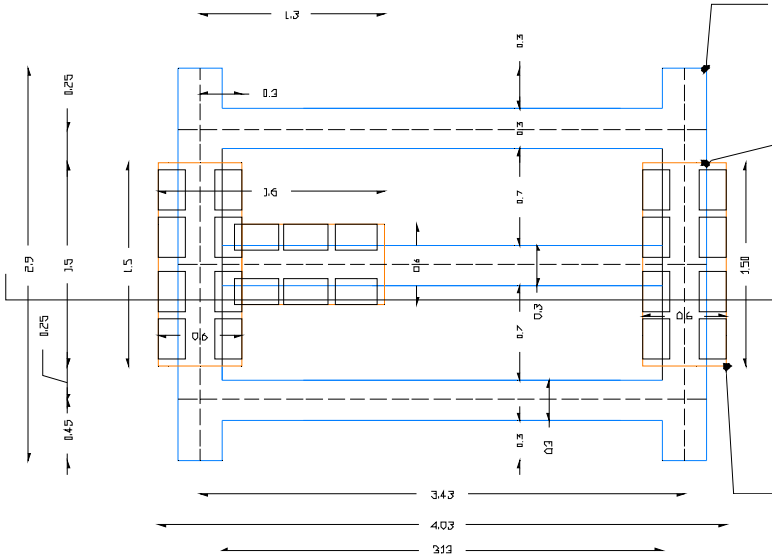

Figure 13: Masonry specimen for the study of base-isolation application in historic structures.

WP 2: Development and implementation of the methodology including development and documentation of the methodology and derivation of instructions for proper application;

WP 3: Geometrical documentation including surveying of the case-study structures, geometrical and damage documentation;

WP 4: Seismic hazard assessment including study of historic seismicity, derivation of Guttenberg-Richter curve, investigation of near-fault phenomena and development of seismic hazard curve;

WP 5: Assessment of the soil influence on seismic response including literature review, geological mapping and geotechnical investigation, seismic response analyses and soil failure analyses;

WP 6: Selection of proper monitoring system including assessment of the effectiveness of the system and installation on a case-study structure;

WP 7: In-situ surveying of materials and characterization of mechanical properties in the laboratory including application of non-destructive techniques, sampling and mapping of materials, damage and mechanical resistances, characterization of structural materials applying laboratory tests, correlation of in-situ results with laboratory results, design and construction of compatible mortars;

WP 8: Experimental evaluation of masonry characteristics including construction and testing of representative masonry wallets and assessment of their behaviour under static and seismic loading;

WP 9: Testing on the shaking table of LEE including construction of specimens, installation of base isolation and testing on shaking table until failure and comparison with the non-isolated behaviour to assess the effectiveness of base-isolation;

WP 10: Development of probabilistic models, fragility curves, evaluation of the results and preparation of recommendations/ instructions;

WP 11: Implementation of probabilistic methodology including application of the methodology on selected monumental and historic structures, correlation of analytical with experimental results and implementation of failure criteria for masonry;

WP 12: Numerical modeling and application of methodologies to determine the seismic response including correlation of the experimental results with analytical linear and non-linear deterministic methodologies and implementation on case-study structures;

WP 13: Application of seismic isolation including dynamic analysis of shaking table tested structures with and without base isolation, correlation with experimental results, analysis of case-study structure with and without base-isolation and preparation of recommendations/ instructions for seismic isolation.

Dr. Constantine Spyrakos, Professor NTU Athens, is the Project Coordinator responsible for the completion of the several stages of the work within the submitted timetable, as well as for the financial management of the project. The First Research Team coordinated by Dr. E. Vintzileou, Professor NTUA, has been responsible for the methodological development that determined the priorities of other groups and provided the theoretical framework of the activities. It has provided data to the other two research teams, through either field measurements or experimental results. The Second Research Team coordinated by Dr. A. Moropoulou, Professor NTUA has been responsible for the study and evaluation of critical parameters affecting the determination of the seismic response of monuments and historic structures. The results of the second group were essential for the continuity and reliability of the other research teams, since they were used by the first group during the experiments and by the third group as input data to complete their work packages. The Third Research Team coordinated by Dr. I. Psycharis, Professor NTUA has been responsible for the evaluation of experimental results from the shake table testing at LEE-NTUA, the development and validation of analytical models that simulated the seismic behaviour of the monuments as well as the evaluation of various methods that calculate the seismic response and estimate structural damage. Substantially, the third team was the receiver of information that was produced by the first and second teams aiming at the formulation of conclusions regarding the seismic behaviour of monuments and historic structures.

4 LEE INFRASTRUCTURE

In LEE an Earthquake Simulator with six degrees-of-freedom has been installed and used in this program. The equipment was initially calibrated and started its operation at the beginning of 1986 and has been operating ever since. The shaking table consists of a rigid steel platform with dimensions 4x4x0.6 (m) and 100 kN weight. It is capable of simultaneous vibration in all six degrees-of-freedom (6 DOFs), with vertical load capacity of 640kN and a horizontal reference at 320 kN. The maximum acceleration in both horizontal directions that can develop is 2g, while in the vertical direction is 4g. The operating frequency rate of the simulator ranges from 0.1 up to 50 Hz. The generation and processing of seismic excitations and analysis of the experimental results is performed by special signal processing programs available in the library of LEE.

An independent reaction wall is also available at the laboratory. Its capacity is 10 MNm, is 6m in height and consists of two sections each 4 and 5 m long, 1.1 m width. Several jacks are installed and may function with independent control. The jacks have capacities of 500 kN, 300 kN, 200kN and 100kN. A mobile data multi-channels acquisition system is supporting this facility. An innovative testing apparatus is also functioning at the laboratory in order to test specimens under recyclic loads horizontally applied, such as walls with up to 1.5 m height, 1.0 m long and 0.5 m thickness. The vertically applied load may be up to 1000 kN and can be kept constant without any variation throughout the tests. Innovative testing apparatus are also

functioning at the Laboratory in order to measure mechanical characteristics (compression strength, modulus of elasticity, Poisson's ratio, stress-strain curve) of masonry specimens.

Diverse instrumentation is also available for in-situ testing such as flat jacks, ambient testing, displacement strain measurements, pull-out tests, etc.

In 2000 the LEE-NTUA was certified by TUV CERT (TUV Austria Hellas), for Dynamic and Seismic Tests using the earthquake simulator, according to ISO 9002/1994. Starting on 12/1/2007, it implemented a Quality Management System for DYNAMIC SEISMIC TESTS certified by TUV Austria (the Austrian Organization of Inspection and Certification). The current relevant certification of the LEE by this organization is according to standard EN ISO 9001:2008.

In addition, LEE-NTUA has a highly experienced staff in preparing, testing and analyzing of the experimental results. The staff has over twenty five years of experience and participation in the successful completion of a multitude of national and international research programs. A representative number of international projects relevant to the proposed research are listed:

- New Integrated Knowledge based approaches to the protection of cultural heritage from Earthquake-induced Risk – NIKER (DCT - Università degli Studi di Padova).
- Seismic Engineering Research Infrastructures for European Synergies – SERIES (University of Patras/ European Commission/ Framework Programme 7).
- Performance of Innovative Mechanical Connections in Precast Building Structures under Seismic
- Conditions – SAFECAST (FP7-SME-2007-2).
- Seismic Resistance of new Reinforced or Isolated Perforated- Brick Masonry Housing Construction in Low
- Seismic Region (ECOLEADER Access to Research Infrastructures).
- Seismic Behaviour of Capacity designed masonry Walls in low Seismicity regions (ECOLEADER Access to Research Infrastructures).
- Experimental evaluation of technical interventions for reduced seismic vulnerability of old existing buildings.
- Experimental evaluation of technical interventions to reduce seismic vulnerability of masonry buildings.

ACKNOWLEDGEMENTS

Keywords: shrouded blades, nonlinear vibration, friction.

Abstract. *The variable operation of turbomachinery components turns out as a special challenge in the design process. Changing the turbines rotational speed leads to entirely new load conditions and, thus, to a range of different operating points. Beside structural mechanical dependencies (i.e. stiffening effects), the shroud contact situation is very sensitive to the systems rotational speed. In this paper a model of a real low pressure steam turbine blade is investigated numerically and experimentally. For the calculation, a three dimensional structural mechanical model including a spatial contact model is considered. The steady-state vibration response is calculated by the multi-harmonic balance method (MHBM) and an alternating frequency-time scheme (AFT). The test rig consists of a single blade clamped with two dummies at the shroud. The vibration response of the blade is measured by laser-doppler-vibrometry for various excitation levels and pressure distributions in the shroud contact. The comparison between measured and computed frequency response function (FRF) of the first edgewise bending mode (1E) shows a very good agreement. Both the frequency shift, as well as the reduction of the amplitude were detected by the MHBM and successfully verified experimentally. The obtained results of the single blade system are transferred to a rotating bladed disk assembly.*

1 INTRODUCTION

One of the main challenges in the mechanical design of turbine blades is the prevention of high cycle fatigue (HCF) failures. Successful blade design must account for both high static, caused for example by centrifugal forces, and high dynamic loads, caused, among others, by oscillating forces of the working fluid. These loads, even the static ones, depend on the turbines operating condition. However, not only the loading, but also material parameters, like the elastic modulus, and structural mechanical properties, like the damping ratio, and stiffening or softening of the blade, depend on the turbines operating condition. Indeed, material properties are temperature dependent, the tangent stiffness is stress dependent and the overall damping depends on many factors simultaneously - stress, temperature, contact pressure at the joints. Friction in the joints like the blade root or the blade tip shrouds can be used to dissipate the vibrational energy and, thus, the amplitude of the blade vibrations. However, the nonlinear dependence of the relative displacements on the contact pressure and thus on the operational condition, makes the design for friction a very challenging task.
Nonlinear steady-state forced response analysis, which can aid in such a design, has been a subject of active research for the last three decades [1–5]. However, a forced response analysis under variable operating conditions remained largely unstudied.
In this study, we analyze two different operating points with respect to the turbines rotational speed. The investigation is performed both experimentally and numerically. The experimental setup consists of a single model blade, fixed at its root, with variable contact pressure applied at the shroud through two dummies, mounted on air bearing. The blade is excited by shaker and the frequency response function (FRF) was measured using laser-doppler-vibrometry for various excitation and contact pressure levels. These results were used to verify the numerical approach, based on the multi-harmonic balance method (MHBM), described in [6] and [7], in which the nonlinear forces are computed by the means of an alternating frequency-time (AFT) scheme [8].

2 FORCED RESPONSE CALCULATION

2.1 Computation of the steady state solution by the multi-harmonic balance method

The dynamical behavior of a nonlinear mechanical system can be described by the following equation of motion in the time domain:

$$\mathbf{M}\ddot{\mathbf{u}}(t) + \mathbf{D}\dot{\mathbf{u}}(t) + \mathbf{K}\mathbf{u}(t) + \mathbf{f}_{\mathrm{nl}}(\dot{\mathbf{u}}(t), \mathbf{u}(t)) = \mathbf{f}_{\mathrm{e}}(t) \tag{1}$$

where $\mathbf{M}$, $\mathbf{D}$, $\mathbf{K}$ are the mass, viscous damping and stiffness matrices. The external force is denoted by $\mathbf{f}_{\mathrm{e}}$ and the nonlinear force by $\mathbf{f}_{\mathrm{nl}}$. For a forced response analysis, the external force $\mathbf{f}_{\mathrm{e}}$ is assumed to be a harmonic function

$$\mathbf{f}_{\mathrm{e}}(t) = \Re\left\{\hat{\mathbf{f}}_{\mathrm{e}} \mathrm{e}^{\mathrm{i}\Omega t}\right\}. \tag{2}$$

In the linear case, i.e. $\mathbf{f}_{\mathrm{nl}} = 0$, the resulting displacements, $\mathbf{u}(t)$, are harmonic functions with frequency Ω. In the presence of nonlinearities, e.g. contact forces, the response function $\mathbf{u}(t)$ is no longer harmonic, but nevertheless assumed to be periodic. This assumption allows the approximation of the displacments' vector $\mathbf{u}$, as well as the nonlinear forces $\mathbf{f}_{\mathrm{nl}}$, by a truncated Fourier series. This so-called multi-harmonic balance method (MHBM) is widely used to compute the nonlinear forces in conjunction with an alternating frequency-time scheme (AFT) [8].

Applying Galerkin's procedure the nonlinear equations of motion (1) can be rewritten in the frequency domain with the complex displacements

$$\mathbf{u}(t) = \Re\left\{\sum_{n=0}^{n_\mathrm{h}} \hat{\mathbf{u}}_n \mathrm{e}^{\mathrm{i}n\Omega t}\right\} \tag{3}$$

and the complex nonlinear forces

$$\mathbf{f}_\mathrm{nl}(t) = \Re\left\{\sum_{n=0}^{n_\mathrm{h}} \hat{\mathbf{f}}_{\mathrm{nl},n} \mathrm{e}^{\mathrm{i}n\Omega t}\right\} \tag{4}$$

as

$$\hat{\mathbf{S}}_n \hat{\mathbf{u}}_n + \hat{\mathbf{f}}_{\mathrm{nl},n} - \hat{\mathbf{f}}_{\mathrm{e},n} = \mathbf{R}_n. \tag{5}$$

Here, $\hat{\mathbf{S}}_n$ is the dynamic stiffness matrix

$$\hat{\mathbf{S}}_n = -(\Omega n)^2 \mathbf{M} + \mathrm{i}\Omega n \mathbf{D} + \mathbf{K} \tag{6}$$

and $\mathbf{R}_n$ denotes the residual vector. The set of nonlinear equations (5) constitutes a minimization problem, which has to be solved iterative by means of a Newton-Raphson algorithm. To reduce the computational effort, a model reduction of the dynamic system is performed by the well-known Craig-Bampton reduction technique [10].

2.2 Contact Model

In this study, an elastic point contact model is used to compute the nonlinear contact forces, see Fig. 1, a widely used model in dynamical systems with frictional contacts [6, 7, 11]. For the calculation of a three-dimensional spatial contact, it is assumed that the tangential components are independent of each other, a common assumption in forced response calculations with frictional contacts [7].

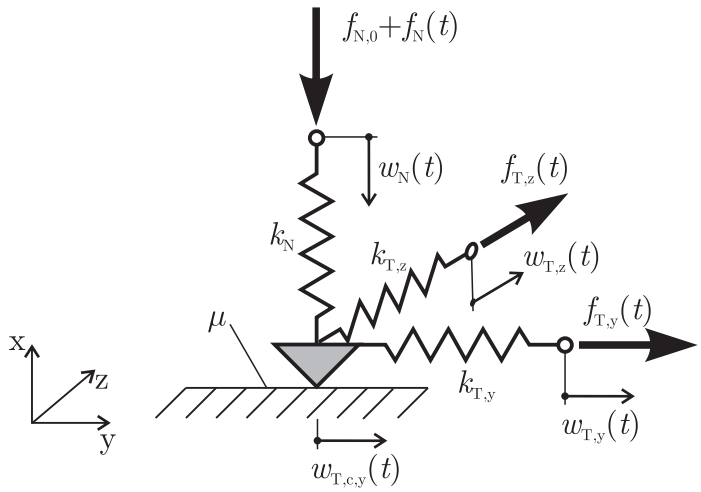

Figure 1: Unilateral elastic contact model

The normal force $f_\mathrm{N}(t)$ is given by the normal relative displacement $w_\mathrm{N}(t)$ and the contact stiffness k_N. The contact state ratio, closed or separated, depends on the static preload $f_{\mathrm{N},0}$ and

determined by the unilateral contact law

$$f_{\mathrm{N}}(t) = \max\left(f_{\mathrm{N},0} + k_{\mathrm{N}} w_{\mathrm{N}}(t), 0\right). \tag{7}$$

A negative preload value of $f_{\mathrm{N},0}$ is equivalent to a gap between the contact nodes and is defined as $g_{\mathrm{N},0} = -f_{\mathrm{N},0}/k_{\mathrm{N}}$. The contact force along the tangential directions y and z is given by the contact stiffness $k_{\mathrm{T},j}$ and the tangential relative displacement $w_{\mathrm{T},j}(t)$, for $j = y, z$. The Coulomb friction law is applied to determine the state ratio in tangential direction by

$$f_{\mathrm{T}}(t) = \begin{cases} k_{\mathrm{T},j}(w_{\mathrm{T},j}(t) - w_{\mathrm{T,c},j}(t)) & \text{sticking contact,} \\ \mu f_{\mathrm{N}}(t)\mathrm{sgn}(w_{\mathrm{T,c},j}(t)) & \text{sliding contact,} \\ 0 & \text{separation.} \end{cases} \tag{8}$$

3 APPLICATION TO SHROUDED TURBINE BLADES

3.1 Mechanical model of a single turbine blade

A model of a single low pressure shrouded turbine blade is investigated, see Fig. 2a. For convenience, the root of the blade is modeled as a rectangular block and the angular pitch is set to zero. The neighbored blades are simplified as dummies with high masses mounted by frictionless supports, see Fig. 2b. Thus, the normal load on the shroud can be stated as $f_{\mathrm{N}} = f_{\mathrm{L}} \sin\alpha$. Compared to a fully assembled bladed disk, changing the loading f_{L} is representing a

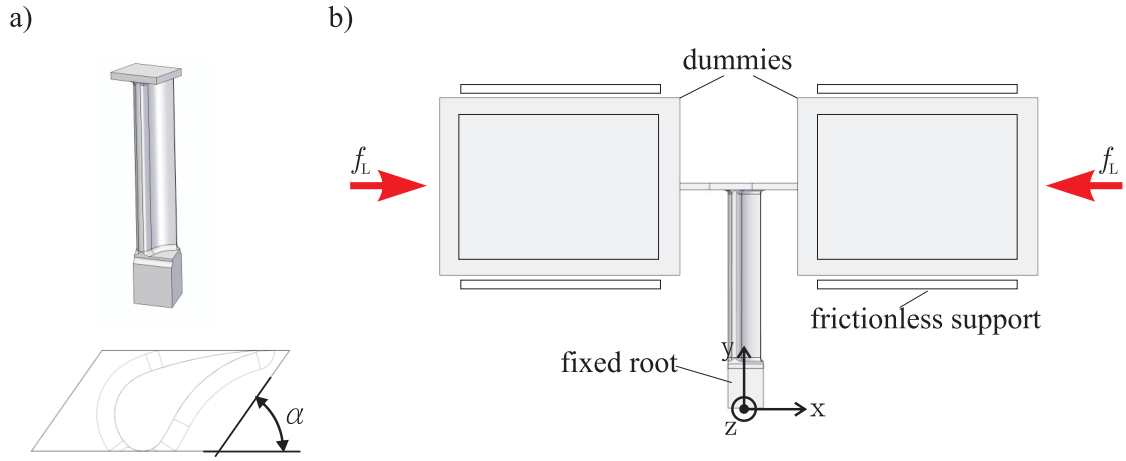

Figure 2: a) Single shrouded turbine blade, b) experimental setup.

variation of the turbine's operating point. Nevertheless, a change of the operating point of the real turbine influences in addition the pressure distribution at the shroud contact or the structural mechanical properties due to centrifugal stiffening. Since the main objective of the presented experimental setup is the correlation between excitation load f_{e}, preload f_{L} and the response of the system, here, the variation of the pressure distribution as the centrifugal stiffening is neglected.

Finite element analysis is used to discretize the shown model with a total number of 16755 elements and 28112 nodes. The shroud contact area is discretized with 30 contact nodes. The

structural mechanical matrices $\mathbf{M}$ and $\mathbf{K}$ of the whole system read:

$$\mathbf{M} = \begin{bmatrix} \mathbf{M}_{\mathrm{Blade}} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{M}_{\mathrm{Dummy,L}} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{M}_{\mathrm{Dummy,R}} \end{bmatrix}, \mathbf{K} = \begin{bmatrix} \mathbf{K}_{\mathrm{Blade}} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{K}_{\mathrm{Dummy,L}} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{K}_{\mathrm{Dummy,R},} \end{bmatrix}. \quad (9)$$

In the first instance, there are uncoupled submatrices in (9). The coupling of the substructures takes place in the nonlinear calculation by contact forces.
In this work the first flapwise bending mode (1F) and the first edgewise bending mode (1E) of the coupled system is investigated. The mode shapes of the coupled and the free standing blade are showed in Fig. 3. Note that the mode shapes are calculated assuming a rigid coupling of the linear system in the case of Fig. 3b. It should be emphasized here that a full separating of the contact is leading to a completely different dynamical system behavior. For the nonlinear forced response, contact parameters must be specified, i.e. contact stiffnesses, friction coefficient and pressure distribution. The contact stiffnesses are defined by a magnitude of 10^9 $\mathrm{N/m}$ and the friction coefficient is set for all simulations to $\mu = 0.3$. The pressure distribution is calculated by a quasi-static nonlinear FE-analysis.

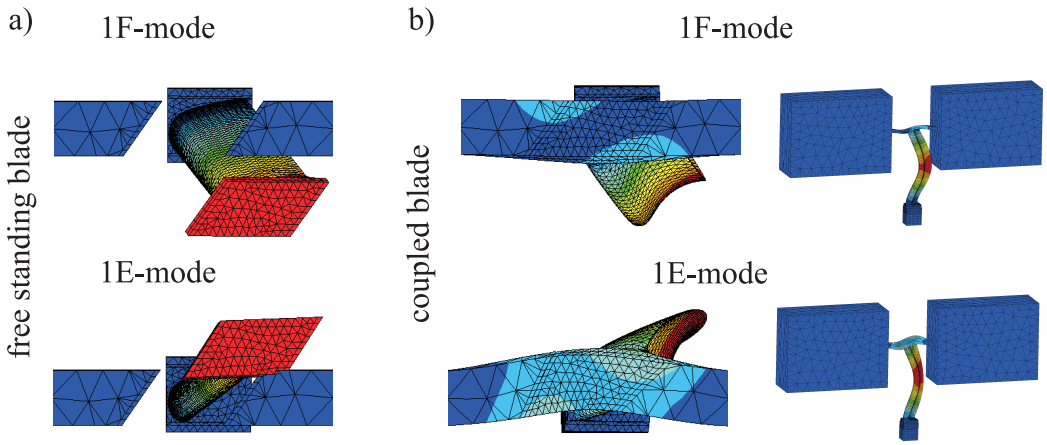

Figure 3: First two mode shapes of: a) the free standing, b) coupled blade.

3.2 Experimental Setup

The test rig in Fig. 4 is used to measure the forced response of the coupled structure. A shaker is set up for the force excitation and the vibration amplitudes are measured by laser-doppler-vibrometry. Due to the strong nonlinearities a controlled force amplitude is necessary. Hence, the excitation force is measured by a piezoelectric force sensor and controlled to the desired excitation level. Weights are applied by rope pulleys to impress the normal loading. The frequency response function is measured for various excitation levels and normal loadings. It is important to note that the measurements are based on the fundamental harmonic.

4 Results

4.1 Comparison of experiment and simulation

The experimental results show that the resonance frequencies of both modes are sensitive to a variation of the normal load f_{L}, see Fig. 5a and b. The reason for this effect depends on

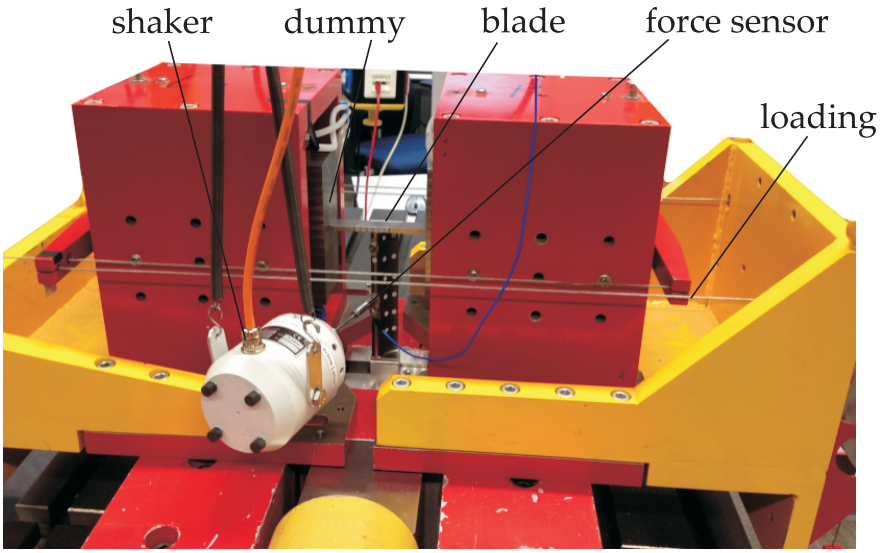

Figure 4: Test rig.

the mode shape and the contact kinematics. In Fig. 5b the maximum amplitude of the 1E-mode decreases for increasing excitation level f_{e} or decreasing normal load f_{L}, a well-known phenomenon of underplatform damper mechanics, see [9]. Due to high relative displacements in tangential direction of the shroud area sliding friction forces are leading to energy dissipation and, thus, to lower amplitudes. Besides, the resonance frequency significantly decrease due to microslip phenomena in the contact area. The 1F-mode shows a quiet different vibrational behavior. The mode shape depends highly on the contact situation and pressure distribution. Separation of the contact results to a shift of the nodal point of the mode shape and much higher amplitudes at the tip of the blade. Nevertheless, friction damping still occurs at the shroud area that is more dominant for lower normal loads, see Fig. 5a. A comparison to the simulation results shows a good agreement. The amplitudes are in the same order of magnitude and, in particular, a relative error of the resonance frequencies of $\frac{\Delta f}{f_0} < 1\%$ is remarkable. In addition, the amplitude reduction caused by friction of the 1E-mode correlates well to the experiment, see Fig. 5b. Note that the amplitude reduction depends on the friction coefficient, which is set to $\mu = 0.3$. The reduction of the resonance frequency due to microslip can also be shown by the simulation model. The simulation results of the 1F-mode show the same dynamical behavior as the experiment, see Fig. 5a. According to Eq. (7) either low normal preloads or high relative displacements lead to separation and at the same time to a loss of contact stiffness. Consequently the FRFs tend to tilt to the left side. However, the increase of the amplitude caused by a change of the mode shape can not be shown by the simulation model. This is motivated by the underlying Craig-Bampton reduction technique [10]. Here, the constraint interfaces are defined by the contact areas and, thus, the fixed interface modes are based on the coupled system.

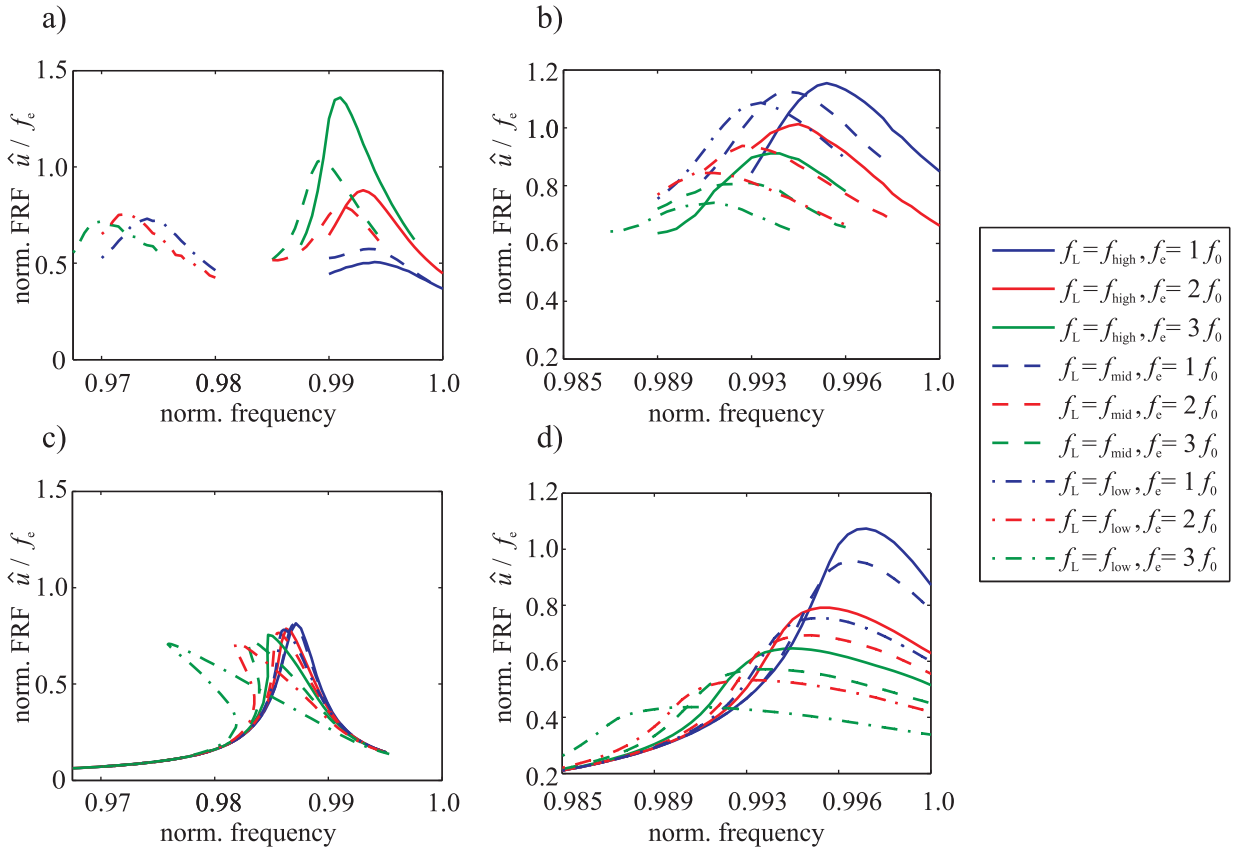

Figure 5: Forced response functions of the experiment a), b) and the simulation c), d) for various excitation levels and preloads.

4.2 Computation of a tuned bladed disk assembly

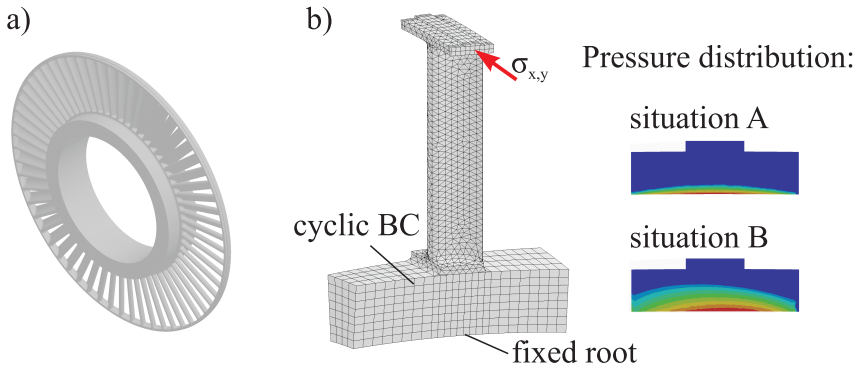

Figure 6: a) Bladed disk assembly, b) FE-model of a cyclic sector and calculated pressure distribution.

In this section a bladed disk with $N_{\mathrm{Seg}} = 60$ blades is analyzed, see Fig. 6a. All blades are assumed to be perfectly tuned and, thus, cyclic symmetry can be used to reduce the computational effort. Two different operating points with respect to the pressure distribution at the shroud contact are investigated, see Fig. 6b. For the forced response analysis Eq. 1 is set up for

one cyclic segment. The displacement vector for any segment k is

$$^{(k)}\mathbf{u}(t) = \mathrm{e}^{-\mathrm{i}(k-1)\Delta\varphi\ (1)}\mathbf{u}(t) \tag{10}$$

where $k = 1(1)N_{\mathrm{Seg}}$ and $\Delta\varphi = 2\pi/N_{\mathrm{Seg}}$ denotes the phase angle [12].
The results of the bladed disk assembly show similar characteristics as the single blade system, see Fig. 7. For pressure distribution A only the lower edge of the shrouds is in contact and the total preload is concentrated on the edge. The FRFs of the 1F-mode show strong nonlinear characteristics, see Fig. 7a. Due to the high normal relative displacement the contact closes and the stiffness of the dynamical system increases strongly. Increasing the excitation force or decreasing the preload is leading to lower maximum amplitudes due to frictional energy dissipation. Changing the pressure distribution, the FRF of the 1F-mode seems to be strongly influenced, see Fig. 7b. Again, an increase of the excitation level leads to lower amplitudes and a shift of the frequency at maximum amplitude. But, at a low preload value local separation of the contact appears and the FRF is tending to lower frequencies. The occurrence of a closing and a separating contact at once have a high impact on the convergence behavior. Care must be taken when choosing numerical parameters. The 1E-mode of the cyclic system is rarely influenced by the variable pressure distribution, see Fig. 7b and d. Both cases show the same behavior as the single blade system in Fig. 5d. The slight increase of the resonance frequencies at pressure distribution B is caused by increased initial contact area and, thus, by higher stiffness.

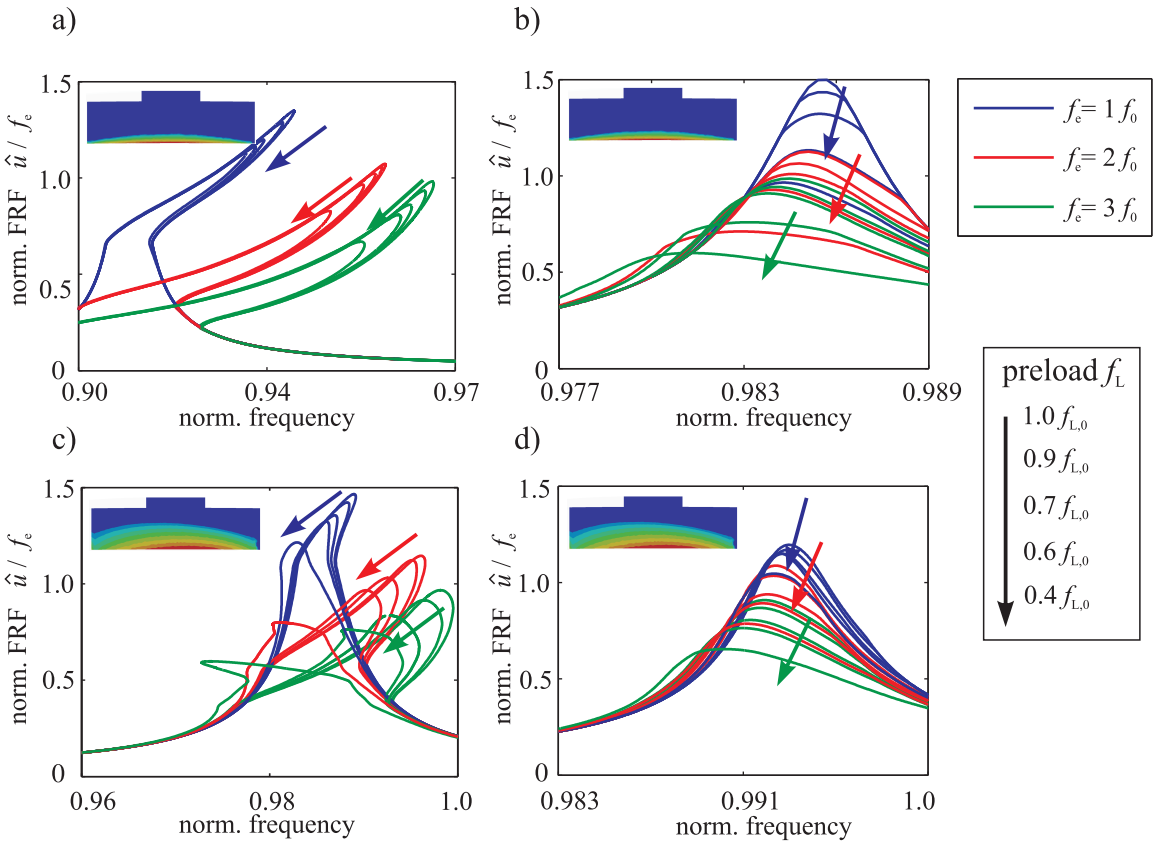

Figure 7: FRF of the 1F- and 1E-mode of the cyclic system (nodal diameter=25) for various preloads and excitation levels: a), b) pressure distribution A, c), d) pressure distribution B.

5 Conclusion and outlook

In this paper the dynamical behavior of a turbine blade model is analyzed numerically and experimentally. A comparison shows a very good agreement, qualitatively as well as quantitatively. The results are transferred to a rotating bladed disk. Two different operating points with respect to the pressure distribution are investigated showing similar phenomena as the single blade system. Regarding variable operating points turns out as a special challenge due to a high sensitivity by minor changes in the shroud contact. In particular, large relative displacements in normal direction may affect the convergence. The outlook of the work is the experimental investigation of a rotating bladed disk assembly for various operating points, i.e. rotational speed.

Keywords: Cylindrical shells, viscoelastic material, Kelvin-Voigt model, lateral loads, non-linear vibrations.

Abstract. *In this work the influence of geometry, load and material properties on the non-linear vibrations of a simply supported viscoelastic circular cylindrical shell subjected to lateral harmonic load is studied. Donnell's non-linear shallow shell theory is used to model the shell, assumed to be made of a Kelvin-Voigt material type, and a modal solution with six degrees of freedom is used to describe the lateral displacements. The Galerkin method is applied to derive a set of coupled non-linear ordinary differential equations of motion. Obtained results show that the viscoelastic dissipation parameter has significant influence on the instability loads and resonance curves.*

1 INTRODUCTION

Circular cylindrical shells have been extensively used in modern industrial applications and have made their analysis an important research area in applied mechanics and biomechanics. Viscoelastic materials are frequently used in sandwich structures such as beams, plates and shells where damping is desired for a wide range of frequencies. However, in spite of a large number of studies on cylindrical shell dynamics, just a small number of these works is related to the analysis of viscoelastic shells.

An approximate theory for the linear dynamic response of viscoelastic cylindrical shells and cylindrical laminated composites with viscoelastic layers was proposed [1]. Also, ed the finite element method was applied to study the vibration of damped viscoelastic shells based on a first-order shear deformation theory including rotation around the normal [2]. A finite element formulation was developed to study the damping effects due to a constrained viscoelastic layer on the natural frequencies and loss factors of empty and fluid filled cylindrical shells [3].

Later, the dynamic behavior of viscoelastic cylindrical shells subjected to axial loads using the Von Kármán-Donnell non-linear shell theory, together with the Boltzmann laws to model the linear viscoelastic material was studied and observing the complex non-linear responses of the shell such as hyperchaos, chaos, strange attractors, and limit cycles [4]. The post buckling behavior of imperfect cylindrical panels considering a non-linear Schapery viscoelastic material was considered. It was possible to observe that, if linear viscoelastic and non-linear viscoelastic models are compared, the non-linear viscoelastic constitutive model predicts higher deflections than the linear viscoelastic ones [5].

After, a general methodology looking to describe the non-linear vibrations of viscoelastic shell structures, considering periodic or damped responses through the coupling of the harmonic balance method with one mode Galerkin discretization was considered [6]. The radial motions of compressible non-linearly viscoelastic cylindrical and spherical shells under lateral time-dependent pressures [7]. Considering temperature effects, the thermal post-buckled characteristics of cylindrical composite shells with viscoelastic layers by applying the finite element method considering transversal shear deformation and variable in-plane displacements through the thickness of the shell [8].

The problem of dynamic stability of viscoelastic, extremely shallow, circular cylindrical shells considering any viscoelastic functions as well as the inclusion of time-dependence of Poisson's ratio was also considered [9]. Forced vibrations of elastic and viscoelastic arches, panels and cylindrical shells using an asymptotic numerical method was studied in [10]. In the analysis, a mathematical formulation was developed in order to take into account various viscoelastic models in the frequency domain.

In a series of papers [11, 12, 13, 14, 15, 16] the vibrations and dynamic stability of viscoelastic cylindrical shells and cylindrical panels, with and without concentrated masses, using the Kirchhoff-Love hypothesis and Timoshenko theories and taking into account shear deformation and rotary inertia were considered.

Based on the profile of displacement fields of the core layer in static deformation, a new higher-order expansion of transverse and in-plane displacement fields in the thickness direction of the core layer was developped [17].

Recently, a detailed literature review of current studies on non-linear vibrations of shells where, a reduced number of studies dedicated to the analysis of viscoelastic cylindrical shells can be confirmed [18].

In the present paper, the influence of geometric relations, load and material properties on the non-linear vibrations and dynamic instability of a simply supported viscoelastic circular

cylindrical shells subjected to lateral harmonic load is studied. Donnell's non-linear shallow shell theory is used to model the shell, which is assumed to be made of a Kelvin-Voigt material type, and a modal solution with six degrees of freedom. The Galerkin method is applied to derive a set of coupled non-linear ordinary differential equations of motion that are, in turn, solved by the Runge-Kutta method. Results show that the viscoelastic dissipation parameter has a very significant influence on the instability loads and resonance curves.

2 MATHEMATICAL FORMULATION

Consider a perfect thin-walled simply supported circular cylindrical shell of radius *R*, length *L* and thickness *h*. The axial, circumferential and radial coordinates are denoted by x, $y = R\theta$ and *z*, respectively, and the corresponding displacements of the shell middle surface are denoted by *u*, *v* and *w*, as shown in Figure 1. The shell is assumed to be made of a Kelvin-Voigt viscoelastic material with initial Young's modulus *E*, Poisson ratio ν, and density ρ.

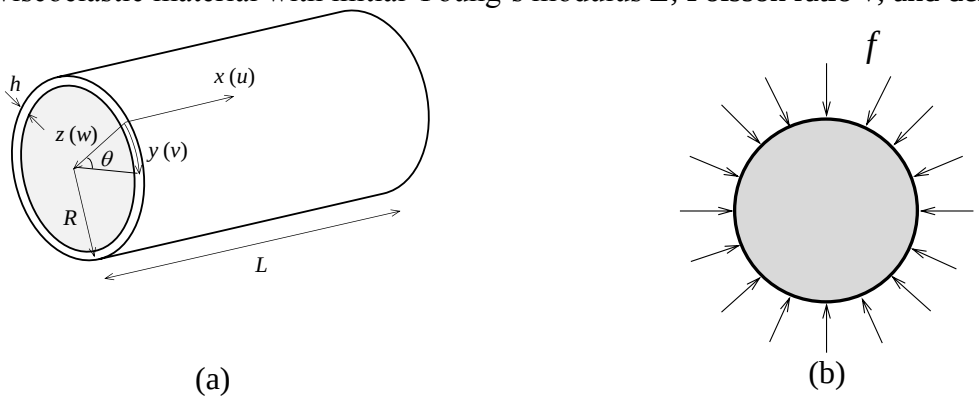

Figure 1: Shell characteristics. (a) Shell geometry; (b) Harmonic lateral pressure f.

The shell is subjected to the following harmonic lateral pressure:

$$f = F_L h^2 \rho \omega_o^2 \sin\left(\frac{m\pi x}{L}\right)\cos(n\theta)\cos(\omega_L t) \tag{1}$$

where F_L is the nondimensional coefficient of the amplitude of the load, ω_o is the natural frequency of the shell, *m* ,the number of axial half-waves, *n*, the circumferential wave number, ω_L , the frequency of the load and t the time.

Based on Donnell shallow-shell theory, the middle surface kinematic relations are given, in terms of the three displacement components, by:

$$\varepsilon_{x,0} = u_{,x} + \frac{1}{2}w_{,x}^2, \qquad \varepsilon_{\theta,0} = \frac{v_{,\theta}}{R} - \frac{w}{R} + \frac{1}{2}\frac{w_{,\theta}^2}{R^2}, \qquad \gamma_{x\theta,0} = \frac{u_{,\theta}}{R} + v_{,x} + w_{,x}\frac{w_{,\theta}}{R},$$
$$\chi_{xx} = -w_{,xx}, \qquad \chi_{\theta\theta} = -\frac{w_{,\theta\theta}}{R^2}, \qquad \chi_{x\theta} = -\frac{w_{,x\theta}}{R}, \tag{2}$$

where $\varepsilon_{x,0}$ and $\varepsilon_{\theta,0}$ are the strains in the axial and circumferential directions, $\gamma_{x\theta,0}$ is the shearing strain component at a point on the shell middle surface, χ_{xx} and $\chi_{\theta\theta}$ are the curvature changes and $\chi_{x\theta}$ is the twist.

The strain components ε_{xx}, $\varepsilon_{\theta\theta}$ and $\gamma_{x\theta}$ at an arbitrary point of the shell are related to the middle surface strains $\varepsilon_{x,0}$, $\varepsilon_{\theta,0}$ and $\gamma_{x\theta,0}$ and to the changes in the curvature by the following relations:

$$\varepsilon_{xx} = \varepsilon_{x,0} + z\chi_{xx}, \qquad \varepsilon_{\theta\theta} = \varepsilon_{\theta,0} + z\chi_{\theta\theta}, \qquad \gamma_{x\theta} = \gamma_{x\theta,0} + z\chi_{x\theta}. \tag{3}$$

In this analysis, the viscoelastic behavior of the material is modeled in the base of the Kelvin-Voigt viscoelastic theory. This viscoelastic model can be represented by a viscous damper element and an elastic spring element connected in parallel as illustrated in Fig. 2.

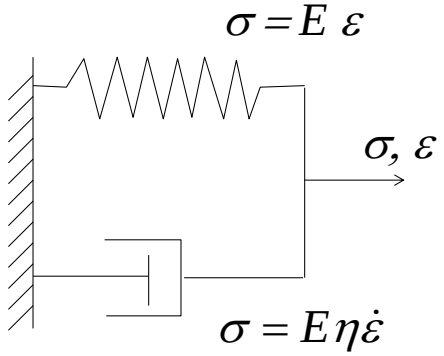

Figure 2. Kelvin – Voigt viscoelastic model

Considering the plane stress problem and the Kelvin-Voigt constitutive model of a viscoelastic material, the stress-strain relations can be written as [19]:

$$\sigma_{xx} = \frac{E}{1-\nu^2}\left[\varepsilon_{xx} + \nu\,\varepsilon_{\theta\theta} + \eta\frac{d}{dt}\left(\varepsilon_{xx} + \nu\,\varepsilon_{\theta\theta}\right)\right] \tag{4}$$

$$\sigma_{\theta\theta} = \frac{E}{1-\nu^2}\left[\varepsilon_{\theta\theta} + \nu\,\varepsilon_{xx} + \eta\frac{d}{dt}\left(\varepsilon_{\theta\theta} + \nu\,\varepsilon_{xx}\right)\right] \tag{5}$$

$$\sigma_{x\theta} = \frac{E}{2(1+\nu)}\left[\gamma_{x\theta} + \eta\frac{d}{dt}\left(\gamma_{x\theta}\right)\right] \tag{6}$$

where E is the Young's modulus , ν is the Poisson coefficient, t is the time and η is the coefficient of the viscoelastic dissipation parameter, also named retardation time, and it is measured in seconds.

Using the stress function F, the forces in the axial, circumferential and tangential directions are

$$N_x = \frac{1}{R^2}\frac{\partial^2 F}{\partial\theta^2}, \qquad N_\theta = \frac{\partial^2 F}{\partial x^2}, \qquad N_{x\theta} = -\frac{1}{R}\frac{\partial^2 F}{\partial x\,\partial\theta} \tag{7}$$

The non-linear equation of motion, based on the Donnell shallow shell theory, in terms of a stress function F, the lateral displacement w is given by:

$$\begin{aligned}&\frac{Eh^3}{12(1-\nu^2)}\left[\frac{\partial^4 w}{\partial x^4} + \frac{2}{R^2}\frac{\partial^4 w}{\partial x^2\,\partial\theta^2} + \frac{1}{R^4}\frac{\partial^4 w}{\partial\theta^4}\right] + \frac{Eh^3}{12(1-\nu^2)}\eta\frac{\partial}{\partial t}\left[\frac{\partial^4 w}{\partial x^4} + \frac{2}{R^2}\frac{\partial^4 w}{\partial x^2\,\partial\theta^2} + \frac{1}{R^4}\frac{\partial^4 w}{\partial\theta^4}\right]\\ &+ c\,h\frac{\partial w}{\partial t} + \rho\,h\frac{\partial^2 w}{\partial t^2} = f + \frac{1}{R^2}\frac{\partial^2 F}{\partial\theta^2}\frac{\partial^2 w}{\partial x^2} - 2\frac{1}{R^2}\frac{\partial^2 F}{\partial x\,\partial\theta}\frac{\partial^2 w}{\partial x\,\partial\theta} + \frac{\partial^2 F}{\partial x^2}\left(\frac{\partial^2 w}{R^2\,\partial\theta^2} + \frac{1}{R}\right)\end{aligned} \tag{8}$$

where $c = 2\zeta\rho\omega_o$ (kg/m^3 s) is the viscous damping coefficient, ζ is the viscous damping ratio of the shell and f is the radial pressure applied to the surface of the shell due to external

force. In equation (8) a global viscous damping has been introduced in addition to the viscoelasticity of the shell material.

The compatibility equation is given by

$$\frac{\partial^4 F}{\partial x^4}+\frac{2}{R^2}\frac{\partial^4 F}{\partial x^2\partial\theta^2}+\frac{1}{R^4}\frac{\partial^4 F}{\partial\theta^4}=E\,h\left[-\frac{1}{R}\frac{\partial^2 w}{\partial x^2}+\frac{1}{R^2}\left(\frac{\partial^2 w}{\partial x\partial\theta}\right)^2-\frac{1}{R^2}\frac{\partial^2 w}{\partial x^2}\frac{\partial^2 w}{\partial\theta^2}+\right.$$
$$\left.\eta\left(-\frac{1}{R^2}\frac{\partial^3 w}{\partial x^2\partial t}\frac{\partial^2 w}{\partial\theta^2}-\frac{1}{R^2}\frac{\partial^2 w}{\partial x^2}\frac{\partial^3 w}{\partial\theta^2\partial t}-\frac{1}{R}\frac{\partial^3 w}{\partial x^2\partial t}+\frac{2}{R^2}\frac{\partial^3 w}{\partial x\partial\theta\partial t}\frac{\partial^2 w}{\partial x\partial\theta}\right)\right]. \tag{9}$$

The simply supported out-of-plane (Eq. 10) and the in-plane (Eq. 11) boundary conditions are respectively given by:

$$w=0,\qquad M_x=0\qquad \text{at } x=0,L \tag{10}$$

$$N_x=0,\qquad v=0\qquad \text{at } x=0,L \tag{11}$$

For a formulation based on a stress function, the in-plane boundary conditions are satisfied on the average by introducing the following conditions, as justified, for example, in [20, 21, 22, 23, 24]

$$\int_0^{2\pi} N_x R\,d\theta=0\qquad \text{at } x=0,L \tag{12}$$

$$\int_0^{2\pi}\int_0^{L} N_{x\theta} R\,d\theta=0\qquad \text{at } x=0,L \tag{13}$$

Equation (12) assures a zero axial force *Nx* on the average, while Eq. (13) is satisfied when *u* and *w* are continuous in θ on average, and *v* = 0 on average at both ends.

In this work, the following modal expansion for the lateral displacements $w(x,\theta,t)$ in terms of the circumferential and axial variables is adopted:

$$w(x,\theta,t)=\xi_1(t)h\sin\left(\frac{m\pi x}{L}\right)\cos(n\theta)+\xi_2(t)h\sin\left(\frac{m\pi x}{L}\right)\sin(n\theta)+$$
$$\xi_3(t)h\sin\left(\frac{m\pi x}{L}\right)+\xi_4(t)h\sin\left(\frac{3m\pi x}{L}\right)+\xi_5(t)h\sin\left(\frac{5m\pi x}{L}\right)+ \tag{14}$$
$$\xi_6(t)h\sin\left(\frac{7m\pi x}{L}\right)$$

where $\xi_1(t)$, $\xi_2(t)$, $\xi_3(t)$, $\xi_4(t)$, $\xi_5(t)$ and $\xi_6(t)$ are the time-dependent non-dimensional modal amplitudes, where the shell thickness *h* has been used as non-dimensionalization parameter. This leads to a six-degrees-of-freedom reduced order model. This modal expansion satisfies the out-of-plane boundary conditions (10) and includes the basic vibration mode, the companion mode and four axi-symmetric modes and has been thoroughly tested in [20, 21, 24].

The solution for the stress function may be written as $F = F_h + F_p$, where F_h is the homogeneous solution and F_p, the particular solution. The particular solution F_p is obtained analytically by substituting the assumed form of the lateral displacement, Eq. (14), on the right-hand side of the compatibility equation, Eq. (9), and by solving the resulting partial differential equation together with the relevant boundary and continuity conditions.

The homogeneous part of the stress function can be written as (Amabili et al, 1999):

$$F_h = \frac{1}{2}\tilde{N}_x R^2 \theta^2 + \frac{1}{2}x^2\left\{\tilde{N}_\theta - \frac{1}{2\pi R L}\int_0^L\int_0^{2\pi}\frac{\partial^2 F_p}{\partial x^2} R\, d\theta\, dx\right\} - \tilde{N}_{x\theta} xR\theta \tag{15}$$

where $\tilde{N}_x$, $\tilde{N}_\theta$ and $\tilde{N}_{x\theta}$ are the in-plane restrain stresses at the ends of the shell.

Upon substituting the modal expressions for F and $w(x, \theta, t)$ into the equation of motion, Eq. (8), and applying the Galerkin method, a set of six non-linear ordinary differential equations is obtained in terms of the time-dependent modal amplitudes, $\xi_i(t)$.

In analysis, the following non-dimensional parameters are used for time and shell frequency:

$$\tau = \omega_o t; \qquad \Omega = \omega_L / \omega_o \tag{16}$$

3 NUMERICAL RESULTS

Consider a simply supported viscoelastic cylindrical shell with the following physical and geometrical properties: R = 0.2 m, L = 0.4 m, ρ = 1340.0 kg/m^3, ν = 0.195, E = 45.5e9 N/m^2 [25], ζ = 0.001.

To study the influence of geometry on nonlinear dynamic behavior of the orthotropic shells, Table 1 displays the selected L/R ratio, R/h ratios, associated longitudinal and circumferential wavenumber and natural frequencies which will be used on the foregoing analysis.

L/R	R/h	(m,n)	ω_o (rad/sec)
2,0	100	(1,5)	3447.29
	300	(1,7)	2007.06
	600	(1,8)	1427.86

Table 1: Selected shell geometries

To try to understand the influence of both the viscoelastic dissipation parameter and the lateral load on the non-linear dynamic behavior of the shell, several resonance curves and time responses have been computed. The bifurcation diagrams were obtained using Poncaré mapping and considering the excitation frequency as control parameter. The nondimensional coefficient of the amplitude of the lateral load F_L was assumed as 0.2; for the coefficient of the viscoelastic dissipation parameter of the Kelvin-Voigt model η, the following values were assumed: 0.0, 1.0e-5, 2.0e-5 and 3.0e-5 and 1.0e-4 s.

Figure 3 displays the resonance curves of driven mode for F_L = 0.2; L/R = 2.0; R/h=100 and increasing values of the dissipation parameter. As it can be observed in Fig. 3(a), for a shell without viscoelasticity (η = 0.0), as the frequency parameter Ω is increased the shell displays small amplitude period oscillations (1T). At excitation frequency near Ω = 0.90 the shell displays a jump from small to large amplitude oscillations displaying softening behavior. As the value of Ω is increased, the shell shows a reduction of the amplitude of oscillations.

Now, when the viscoelastic dissipation parameter is considered ($\eta \neq 0$), the non-linear behavior of the shell is strongly influenced. Figure 3(b) shows the resonance curve for η = 1.0e-5 s and as the frequency parameter Ω is increased, the shell displays small amplitude 1T period oscillations. Again at a value close to Ω = 0.90, the shell displays a jump to large amplitude oscillations with strong softening behavior. Then, for Ω between 0.72 and 0.77, the shell displays three different stable equilibrium points, which means that there will be three stable

attractors. At large amplitude a folding of the backbone curve (turning point) associated with large bending effects occurs.

When η is increased to 2.0e-5 s as shown if Fig. 3(c), the resonance curve is again affected and it shows softening behavior but with smaller vibration amplitudes than for the previous case. Also, in Figs. 3(b) and 3(c) for Ω=1.0 the shell displays a bifurcation point where the unstable path is linked to the large vibrations amplitudes path. Now, in Fig. 3(d) for n = 3.0e-5 s, the shells displays only small amplitude vibrations without any jump.

Figure 4 displays the resonance curves for F_L = 0.2; L/R = 2.0; R/h=300 and increasing values of the dissipation parameter. Now, in Fig. 4(a) for η = 0.0, as the frequency parameter Ω is increased the shell displays small amplitude period oscillations (1T). At excitation frequency near Ω = 0.92 the shell displays a jump from small to large amplitude oscillations displaying softening behavior, as can be observed, the vibrations amplitudes for this case are higher than those of Fig. 3(a) showing the great influence of geometric relations on the non-linear oscillations of the shell. For this case, it is also possible to observe a bifurcation point near to Ω = 1.00 where stable solutions coexist.

Now, if dissipation parameter is considered ($\eta \neq 0.0$), Fig. 4(b) the shells depicts the resonance curve for η = 1.0e-5s, as can be observed, there is softening behavior with large amplitude 1T oscillations with similar behavior as Fig. 4(a). Now, if dissipation parameter is increased to η = 2.0e-5s as displayed on Fig. 4(c), the non-linear response of the shell is affected and the shell displays softening behavior with smaller amplitude oscillations and the coexistence of stable and chaotic vibrations. When dissipation parameter is increased up to η = 3.0e-5s as shown in Fig. 4(d), the system displays a jump with softening behavior but again with smaller vibration amplitudes that in previous cases.

Finally, Fig. 5 depicts the resonance curves considering F_L = 0.2; L/R = 2.0; R/h=300. In Fig. 5(a) the dissipation parameter is not considered (η = 0.0) and, as observed, the shell displays softening behavior with very large amplitude if compared with previous cases. In Fig. 5(b), Fig. 5(c) and Fig. 5(d) the shell always shows softening behavior but only with 1T stable oscillations. For η = 3.0e-5s as seen in Fig. 5(d), the amplitude of oscillations are smaller than in Fig. 5(b) or Fig. 5(c).

From these diagrams, it is possible to see the strong influence that geometry ratios and dissipation parameter have on the non-linear dynamic response of the shell. For a shell with low R/h ratio the shell displays smaller vibration amplitudes than a shell with high R/h ratio. When dissipation parameter is considered, for low values the amplitude of oscillations of the shell are increased even knowing that this parameter is a dissipation, for higher values of the parameter the vibration amplitudes of the shell will be reduced.

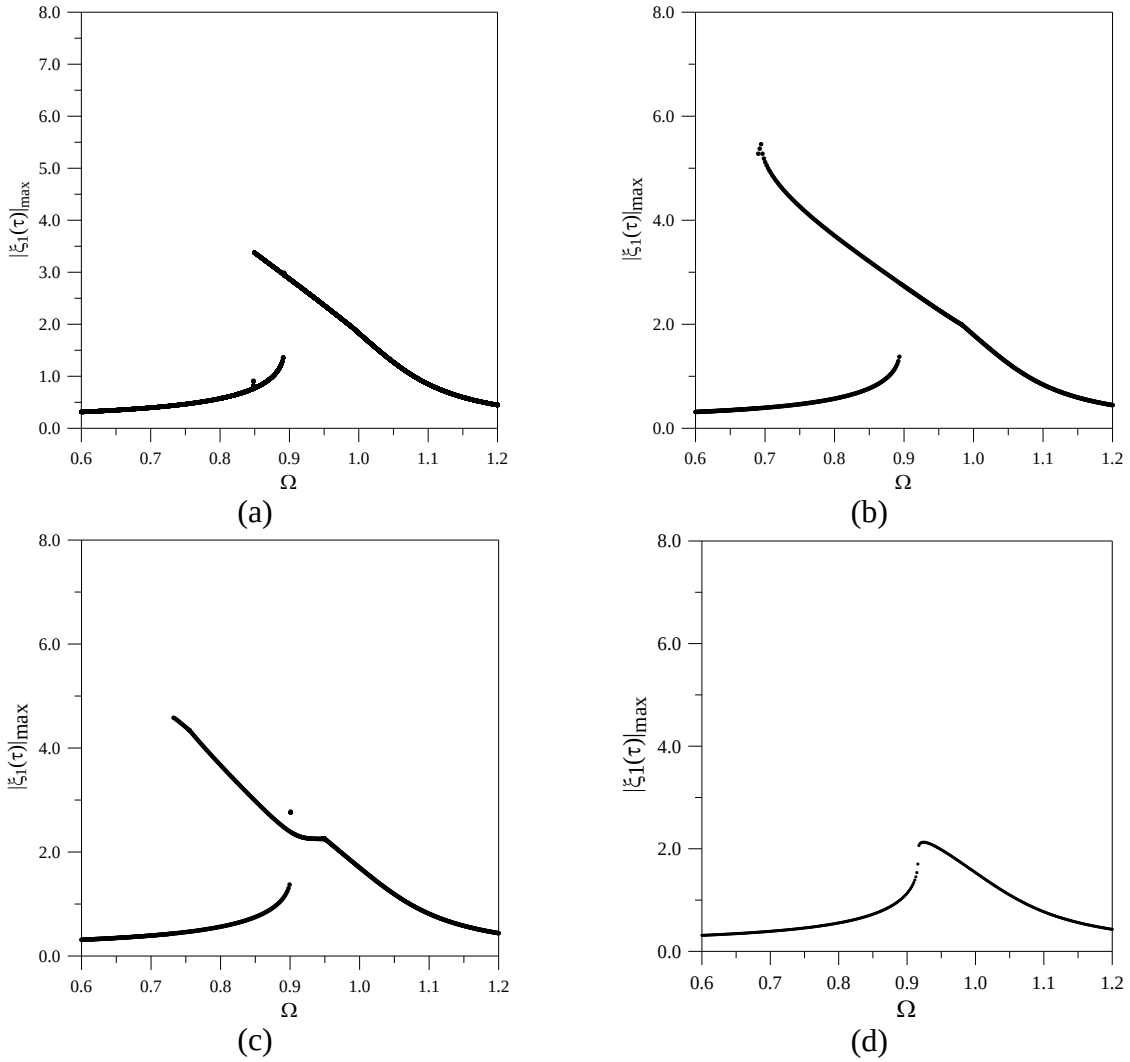

Figure 3. Ressonance curves for L/R = 2,0 and R/h = 100. (a) η = 0.0; (b) η = 1.0e-5s; (c) η = 2.0e-5s; (d) η = 3.0e-5s.

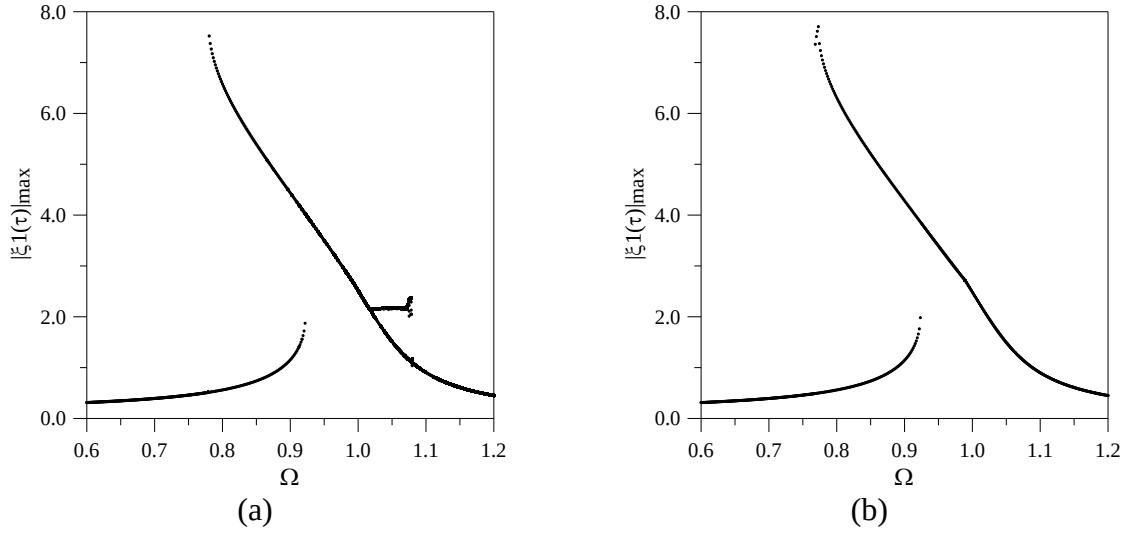

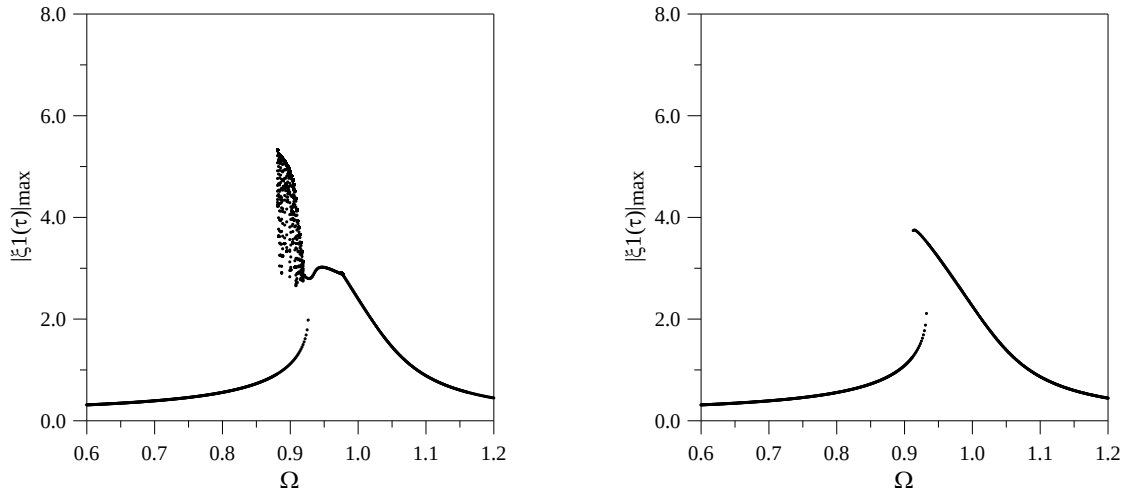

Figure 4. Ressonance curves for L/R = 2.0 and R/h = 300. (a) η = 0.0; (b) η = 1.0e-5s; (c) η = 2.0e-5s; (d) η = 3.0e-5s.

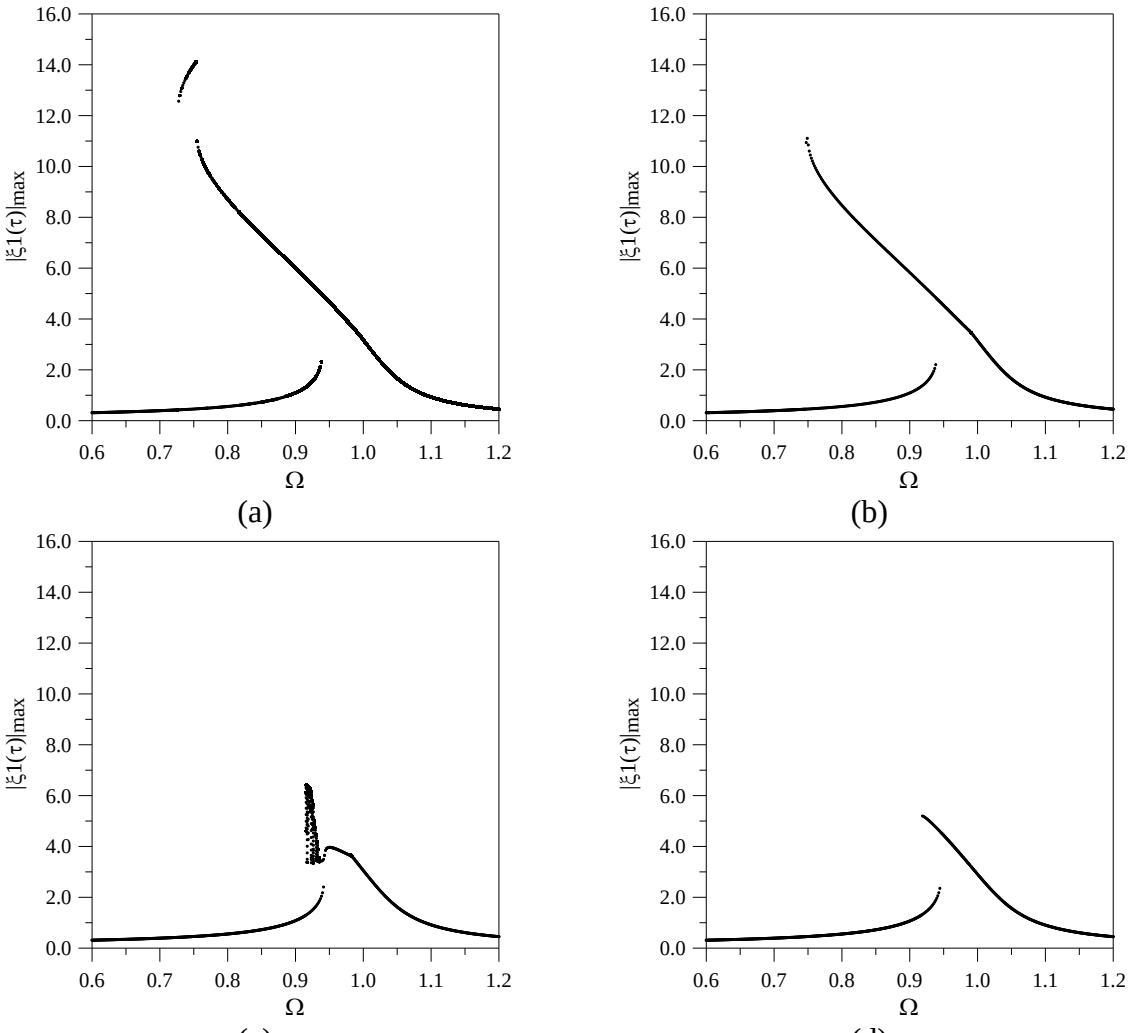

Figure 5. Ressonance curves for L/R = 2.0 and R/h = 600. (a) η = 0.0; (b) η = 1.0e-5s; (c) η = 2.0e-5s; (d) η = 3.0e-5s.

4 CONCLUSIONS

In this work, the non-linear vibrations analysis of a viscoelastic Kelvin-Voigt simply supported cylindrical shell subjected to lateral time dependent loads is analyzed. To model the shell, the Donnell's non-linear shallow shell theory is applied and an expansion with 6 degrees of freedom is used to describe the lateral displacements. Results show that the inclusion of the viscoelastic dissipation parameter η of the Kelvin-Voigt material affects strongly the non-linear response of the shell.

It is observed that the complexity of the non-linear response and consequently the number of bifurcations, non-linear paths and coexisting solutions depends on the value of the viscoelastic dissipation parameter.

For higher values of the dissipation parameter, the shell only displays small amplitude vibrations without jumps, hysteresis and multiple solutions. This illustrates the beneficial effect of viscoelasticity in reducing large amplitude unwanted vibrations. The amplitudes of vibrations obtained in the numerical results calls to the necessity to use a more refined shell theory to describe the non-linear dynamic behavior with good accuracy.

Keywords: anti-vibration junctions, elastomer material, reduced order model

Abstract. *Due to their damping properties, elastomer materials are commonly used in the industry to achieve anti-vibration junctions between mechanical subsystems. These links are usually made of various materials (metallic, composites and elastomers) and have complex geometries based on the targeted application. In order to predict the dynamic behavior of these junctions in their environment, efficient numerical dynamic models have to be developed. They should take into account the viscoelastic behavior of the elastomer and the material and geometric nonlinearity. The objective of this work is thus to develop effective models of flexible damping devices made of elastomer for the prediction of the dynamic behavior of complex systems.*

Firstly, a three-dimensional finite element nonlinear code using hyper-viscoelasticity constitutive relations is developed for the numerical modeling of the elastomer junctions. Secondly, the parameters of the viscoelastic law are identified in the frequency domain from experimental tests using DMA (Dynamic Mechanical Analysis). Thirdly, a reduced order model is developed. It is based on a component mode synthesis approach adapted to highly damped structures. We also propose in this study to construct models based on input-output laws connecting the generalized quantities of the faces of the junction in contact with substructures. In other words, the model links displacements and rotations of the faces to forces and torques applied to these faces.

1 INTRODUCTION

Due to their capacities to dissipate energy, elastomers are highly used in damping devices like silent blocs or joints. A typical example of this use is found in the spatial industry: during take off and flight, launchers are subject to a significant amount of vibrations from either the propulsion engine or the acoustical environment. Shocks may also occur during the pyrotechnic separation of the different floors of the launcher. All these vibration sources may damage the satellite or any other sensitive equipments on-board, and a common solution is to use viscoelastic damping devices to dissipate a part of the mechanical energy. The design and optimization of theses damping devices are usually done by using finite element codes. The computational cost of the associated models may become prohibitive. Many solutions already exist to reduce the numerical model of linear undamped structures, but only a few give access to reduced models with damping behavior, especially when it comes from viscoelasticity which may be seen as a strong form of damping. Two types of solutions for the reduction of viscoelastic models can be found in the literature. The first one is based on the theory of triboelasticity [6] and consists in the replacement of the damping device model by an equivalent rheological model which can be identified through a series of experimental measurements on the damper [7]. The main problem with this type of approach is that the behavior of the rheological model may not fit the real behavior of the damper in all directions, and more importantly it can't be used for a design purpose due to the non predictive aspect of the rheological model that is done for a specific geometry and material [8]. The second way of reducing a viscoelastic model is to extend the classical modal projection methods to the frequency dependent case and a review of the most common methods can be found in [2]. The chosen method in this work to achieve the reduction of the damper model is a modified Craig-Bampton method, based upon the work of Balmès [3] and Rouleau [2]. The original Craig-Bampton method [4] uses a combination of static and dynamic modes to reduce the finite element model of a sub-structure to a smaller finite element model called super-element. The super-element is first obtained by using a kinematical constraint to enforce rigid body motion of the sub-structure interfaces. Then, to further reduce the finite element model, the reduced finite element matrices are condensed onto the previously kinematically constrained interfaces. The combination of all these techniques leads to a twelve dofs super element replacing the initial full model.

2 STUDIED CASE AND MATERIAL MODELS

The complete model is composed of a support structure mounted on four hourglass shaped dampers, as seen on figure (1). The support structure is made of aluminum and the dampers are made of two aluminum thin interface plates and an elastomer core. Two different material models are used: a classic linear elastic Hooke's model is chosen for the aluminum, and a viscoelastic fractional Zener model for the elastomer. This fractional model is defined by its complex frequency dependent modulus $\mathrm{G}^*(\omega)$:

$$\mathrm{G}^*(\omega) = \frac{\mathrm{G}_0 + \mathrm{G}_\infty(\mathrm{i}\omega\tau)^\alpha}{1 + (\mathrm{i}\omega\tau)^\alpha} \tag{1}$$

where G_0 and G_∞ are two asymptotic values: the static modulus $\mathrm{G}_0 = \mathrm{G}^*(\omega \to 0)$ and the high frequency limit of the dynamic modulus $\mathrm{G}_\infty = \mathrm{G}^*(\omega \to \infty)$. Also, τ is the relaxation time and α is the order of the fractional derivative. More information about this model, its identification and its finite element implementation in time domain can be found in [5]. The adimensional viscoelastic modulus $\mathrm{G}^*(\omega)/\mathrm{G}_0$ is then used in the dynamic equation to take into account the

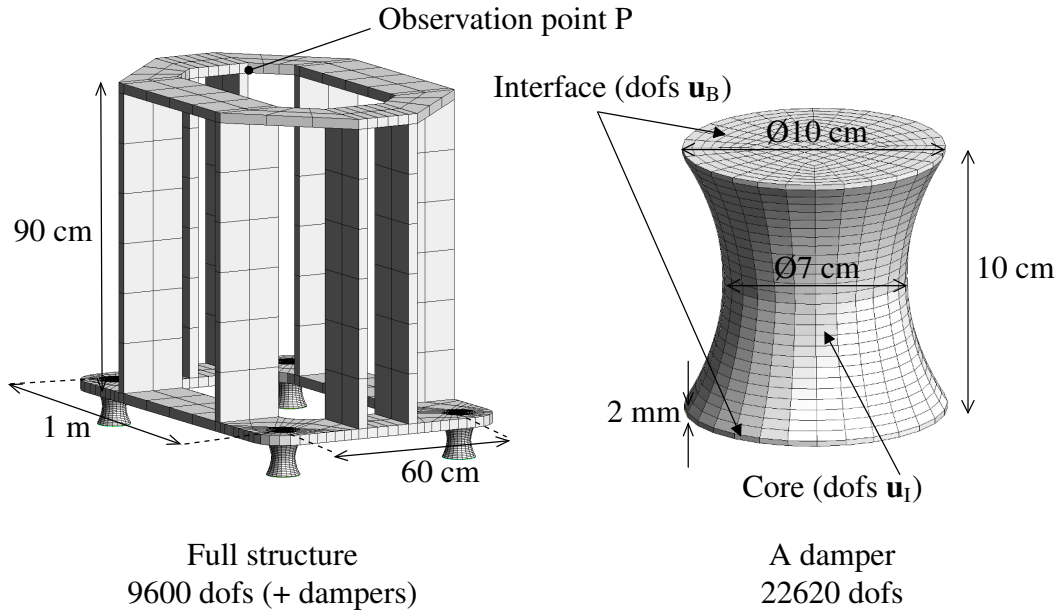

Figure 1: The complete structure mounted on four dampers, and details of a damper

viscoelastic behavior of the elastomer:

$$\left(\mathbf{K}^{\mathrm{e}} + \mathbf{K}^{\mathrm{v}}_{\mathrm{sph}} + \frac{\mathrm{G}^*(\omega)}{\mathrm{G}_0}\mathbf{K}^{\mathrm{v}}_{\mathrm{dev}} - \omega^2\mathbf{M}\right)\mathbf{u} = \mathbf{f} \tag{2}$$

where $\mathbf{M}$ is the mass matrix, $\mathbf{K}^{\mathrm{e}}$ is the purely elastic part of the stiffness matrix which is assembled on the aluminum interfaces dofs and $\mathbf{K}^{\mathrm{v}}$ is the viscoelastic part of the stiffness matrix which is assembled on the elastomer core dofs. The viscoleastic stiffness matrix is also separated into a spheric part $\mathbf{K}^{\mathrm{v}}_{\mathrm{sph}}$ and a deviatoric part $\mathbf{K}^{\mathrm{v}}_{\mathrm{dev}}$. This separation is used due to the fact that the viscoelastic behavior of elastomer is mainly caused by distorsional strain (not by volume change). This deviatoric stiffness matrix is the only matrix subjected to the complex modulus $G^*(\omega)$. The dynamic equation can also be expressed in terms of a static stiffness matrix $\mathbf{K}^0$ and a frequency dependent stiffness matrix $\mathbf{K}^\omega$:

$$\left(\mathbf{K}^0 + i\omega \mathrm{h}^*(\omega)\mathbf{K}^\omega - \omega^2\mathbf{M}\right)\mathbf{u} = \mathbf{f} \tag{3}$$

where $\mathbf{K}^0 = \mathbf{K}^{\mathrm{e}} + \mathbf{K}^{\mathrm{v}}_{\mathrm{sph}} + \mathbf{K}^{\mathrm{v}}_{\mathrm{dev}}$ and $\mathbf{K}^\omega = \left(\mathrm{G}_\infty/\mathrm{G}_0 - 1\right)\mathbf{K}^{\mathrm{v}}_{\mathrm{dev}}$ and where $\mathrm{h}^*(\omega)$ is a dimensionless frequency dependent modulus:

$$\mathrm{h}^*(\omega) = \frac{\tau^\alpha (i\omega)^{\alpha-1}}{1 + (i\omega\tau)^\alpha} \tag{4}$$

The material parameters used to build the mass and stiffness matrices are given in table 1 for the aluminum and table 2 for the elastomer. The materials parameters in table 2 comes from [1]. The structure is composed of 7540 nodes for each rubber damper, which is enough to get converged results in the frequency range of interest, and 3200 nodes for the upper aluminum structure. Only the computational cost of the dampers model is studied and reduced here, so the mesh of the upper structure is kept small for convenient computation time. Each damper represents 22620 dofs. The total number of dofs in the complete structure is about 10^5, including more than 90% for the dampers only, thus underlining the need for an efficient reduction

method. The finite element code for this study is an in house program developed in both Python and Fortran. The finite elements are 8 nodes hexahedra anywhere in the structure. Rubber dampers are connected to the aluminum structure through their upper interface.

3 MODEL REDUCTION OF THE DAMPERS

3.1 Rigid interfaces assumption

Due to the difference between the aluminum and the elastomer stiffness, the aluminum interfaces may be considered to be rigid compared to the rubber core. A kinematical constraint is used to enforce the rigid body motion of the interfaces. The velocity of any point A of an interface can be written in terms of the velocity of the center C of the same interface and the cross-product of the distance between point A and point C and the rotation Ω of the interface. This relationship can be extended to the displacement within the context of small displacement, namely:

$$\overrightarrow{u}_A = \overrightarrow{u}_C + \overrightarrow{AC} \times \overrightarrow{\Omega} \tag{5}$$

In matrix form, the same constraint is written by:

$$\begin{bmatrix} u_A \\ v_A \\ w_A \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 & (z_A - z_C) & (y_C - y_A) \\ 0 & 1 & 0 & (z_C - z_A) & 0 & (x_A - x_C) \\ 0 & 0 & 1 & (y_A - y_C) & (x_C - x_A) & 0 \end{bmatrix} \begin{bmatrix} u_C \\ v_C \\ w_C \\ \Omega_x \\ \Omega_y \\ \Omega_z \end{bmatrix} \tag{6}$$

where x, y and z are coordinates in the 3D space, u_X, v_X and w_X are the displacements of a point X following axes $\vec{x}$, $\vec{y}$ and $\vec{z}$, and Ω_x, Ω_y and Ω_z are the interface rotation around the same axes. Following this approach, all interfaces dofs are eliminated from the global finite element model dofs list, thus reducing the computational cost of the structure model. In place of those eliminated dofs, each damper face is now represented by 6 dofs: 3 translational dofs and 3 rotational dofs.

3.2 Model reduction of the core of the dampers

The method used here to reduce the damper finite element model combine a Craig-Bampton method [4] and a multi-model approach [2] [3]. In the case of a structure made of elastic and viscoelastic materials, the dynamic equation is given by equation (3). Following the Craig-Bampton method, boundary and internal dofs are separated. Here, the boundary dofs are the 12 dofs of the rigid interfaces noted $\mathbf{u}_{\mathrm{B}}$ and the internal dofs are the remaining dofs of the dampers noted $\mathbf{u}_{\mathrm{I}}$. This leads to write equation (3) as:

$$\left(\begin{bmatrix} \mathbf{K}^0_{\mathrm{BB}} & \mathbf{K}^0_{\mathrm{BI}} \\ \mathbf{K}^0_{\mathrm{IB}} & \mathbf{K}^0_{\mathrm{II}} \end{bmatrix} + i\omega \mathrm{h}^*(\omega) \begin{bmatrix} \mathbf{K}^\omega_{\mathrm{BB}} & \mathbf{K}^\omega_{\mathrm{BI}} \\ \mathbf{K}^\omega_{\mathrm{IB}} & \mathbf{K}^\omega_{\mathrm{II}} \end{bmatrix} - \omega^2 \begin{bmatrix} \mathbf{M}_{\mathrm{BB}} & \mathbf{M}_{\mathrm{BI}} \\ \mathbf{M}_{\mathrm{IB}} & \mathbf{M}_{\mathrm{II}} \end{bmatrix} \right) \begin{bmatrix} \mathbf{u}_{\mathrm{B}} \\ \mathbf{u}_{\mathrm{I}} \end{bmatrix} = \begin{bmatrix} \mathbf{f}_{\mathrm{B}} \\ \mathbf{0} \end{bmatrix} \tag{7}$$

where the right-hand side is only composed of reaction forces $\mathbf{f}_{\mathrm{B}}$ at the interfaces.

The first part of the reduced basis is composed of the static modes $\mathbf{\Psi}_{\mathrm{IB}}$ which are defined by:

$$\mathbf{\Psi}_{\mathrm{IB}} = -(\mathbf{K}^0_{\mathrm{II}})^{-1} \mathbf{K}^0_{\mathrm{IB}} \tag{8}$$

The number of static modes is equal to the number of interfaces dofs, 12 in the present case.

The second part of the reduced basis is composed of the eigenmodes of the fixed interface problem solutions of the following generalised :

$$\left(\mathbf{K}^0_{\mathrm{II}} + i\omega \mathrm{h}^*(\omega) \mathbf{K}^\omega_{\mathrm{II}} - \omega^2 \mathbf{M}_{\mathrm{II}} \right) \mathbf{u}_{\mathrm{I}} = \mathbf{0} \tag{9}$$

Solving equation (9) would lead to the vibration modes of the structure but due to the frequency dependence of the the term $i\omega \mathrm{h}^*(\omega)$, this eigenproblem is non-linear in frequency and can not be solved directly. The proposed solution is to use a multi-model approach which is inspired by the Takagi-Sugeno fuzzy model. It has been often used to represent non-linear dynamic systems by interpolating locally linear models obtained from the sampling of the non-linear system [9]. It has been applied by Balmès [3] and Rouleau [2] to build a projection basis representative of the complex non-linear eigenvalue of equation (9). The multi-model basis is here built by the combination of many smaller basis $\mathbf{\Phi}_{\omega_j}$ and each of these basis is computed by solving the pseudo-eigenvalue problem (10) where only the real part of the equation is kept:

$$\left(\mathbf{K}^0_{\mathrm{II}} + \Re\left(i\omega_j \mathrm{h}^*(\omega_j) \right) \mathbf{K}^\omega_{\mathrm{II}} - \omega_k^2 \mathbf{M}_{\mathrm{II}} \right) \mathbf{\Phi}_{\omega_j,k} = \mathbf{0} \tag{10}$$

where ω_j values are chosen to sample the whole frequency range of interest. In any basis $\mathbf{\Phi}_{\omega_j}$ the modes are independent but the modes from two different basis may be co-linear so a Gramm-Schmidt orthonormalisation algorithm may be necessary. In the literature, two modal basis evaluated at the minimum and the maximum frequency of the range of interest combined with a static correction lead to a good approximation of the dynamic response of highly damped structures. In this study, the static correction is already taken into account by the static modes of the static response, so only the modal basis at the minimum and maximum frequency need to be computed. Solving equation (10) for $\omega = \omega_{\min}$ and $\omega = \omega_{\max}$ lead to the two basis $\mathbf{\Phi}_{\min}$ and $\mathbf{\Phi}_{\max}$ which both respect the orthogonality conditions:

$$\mathbf{\Phi}^{\mathrm{T}}_{\bar{\omega}} \Re\left(\mathbf{K}^*_{\mathrm{II}}(\bar{\omega}) \right) \mathbf{\Phi}_{\bar{\omega}} = \mathrm{diag}\left(\omega_1^2, ..., \omega_{\mathrm{I}}^2 \right) \tag{11}$$

$$\mathbf{\Phi}^{\mathrm{T}}_{\bar{\omega}} \mathbf{M}_{\mathrm{II}} \mathbf{\Phi}_{\bar{\omega}} = \mathbf{1}_{\mathrm{I}} \tag{12}$$

where $\bar{\omega}$ stands for $\omega_{\min}$ or $\omega_{\max}$ and where:

$$\mathbf{K}^*_{\mathrm{II}}(\bar{\omega}) = \mathbf{K}^0_{\mathrm{II}} + i\bar{\omega} \mathrm{h}^*(\bar{\omega}) \mathbf{K}^\omega_{\mathrm{II}} \tag{13}$$

Both $\mathbf{\Phi}_{\text{min}}$ and $\mathbf{\Phi}_{\text{max}}$ diagonalize the $\Re\left(\mathbf{K}^*_{\text{II}}(\bar{\omega})\right)$ matrix but they don't diagonalize $\mathbf{K}^0$ or $\mathbf{K}^\omega$ and this will have an impact on the further condensation step. The dynamic of the system is then reduced by truncating the basis $\mathbf{\Phi}_{\text{min}}$ into $\mathbf{\Phi}_{\text{I}p}$ and the basis $\mathbf{\Phi}_{\text{max}}$ into $\mathbf{\Phi}_{\text{I}q}$ with $p < \text{I}$ and $q < \text{I}$. The complete dynamic response is then obtained by combining the two truncated modal basis $\mathbf{\Phi}_{\text{I}p}$ and $\mathbf{\Phi}_{\text{I}q}$ into matrix $\mathbf{\Phi}_{\text{I}m}$, with $m = p + q < \text{I}$.

By combining the static response coming from the behavior of structures connected to the damper's interfaces, and the dynamic response from the core of the damper, a complete reduced basis can be assembled in the form:

$$\begin{bmatrix}\mathbf{u}_{\text{B}}\\ \mathbf{u}_{\text{I}}\end{bmatrix} = \begin{bmatrix}\mathbf{I}_{\text{BB}} & \mathbf{0}_{\text{B}m}\\ \mathbf{\Psi}_{\text{IB}} & \mathbf{\Phi}_{\text{I}m}\end{bmatrix}\begin{bmatrix}\mathbf{u}_{\text{B}}\\ \mathbf{q}_m\end{bmatrix} \tag{14}$$

The projection of equation (7) onto this reduced basis gives the following reduced system:

$$\left(\begin{bmatrix}\bar{\mathbf{K}}^0_{\text{BB}} & \mathbf{0}_{\text{B}m}\\ \mathbf{0}_{m\text{B}} & \bar{\mathbf{K}}^0_{mm}\end{bmatrix} + i\omega\text{h}^*(\omega)\begin{bmatrix}\bar{\mathbf{K}}^\omega_{\text{BB}} & \bar{\mathbf{K}}^\omega_{\text{B}m}\\ \bar{\mathbf{K}}^\omega_{m\text{B}} & \bar{\mathbf{K}}^\omega_{mm}\end{bmatrix} - \omega^2\begin{bmatrix}\bar{\mathbf{M}}_{\text{BB}} & \bar{\mathbf{M}}_{\text{B}m}\\ \bar{\mathbf{M}}_{m\text{B}} & \bar{\mathbf{M}}_{mm}\end{bmatrix}\right)\begin{bmatrix}\mathbf{u}_{\text{B}}\\ \mathbf{q}_m\end{bmatrix} = \begin{bmatrix}\mathbf{f}_{\text{B}}\\ \mathbf{0}\end{bmatrix} \tag{15}$$

where $\bar{\mathbf{K}}^\omega_{m\text{B}} = \left(\bar{\mathbf{K}}^\omega_{\text{B}m}\right)^{\text{T}}$ and $\bar{\mathbf{M}}_{m\text{B}} = \left(\bar{\mathbf{M}}_{\text{B}m}\right)^{\text{T}}$. The details of the different terms of these reduced matrices are given by:

$$\bar{\mathbf{K}}^0_{\text{BB}} = \mathbf{K}^0_{\text{BB}} + \mathbf{K}^0_{\text{BI}}\mathbf{\Psi}_{\text{IB}} \tag{16}$$
$$\bar{\mathbf{K}}^0_{mm} = \mathbf{\Phi}^{\text{T}}_{\text{I}m}\mathbf{K}^0_{\text{II}}\mathbf{\Phi}_{\text{I}m} \tag{17}$$

$$\bar{\mathbf{K}}^\omega_{\text{BB}} = \mathbf{K}^\omega_{\text{BB}} + \mathbf{K}^\omega_{\text{BI}}\mathbf{\Psi}_{\text{IB}} + \mathbf{\Psi}^{\text{T}}_{\text{IB}}\mathbf{K}^\omega_{\text{IB}} + \mathbf{\Psi}^{\text{T}}_{\text{IB}}\mathbf{K}^\omega_{\text{II}}\mathbf{\Psi}_{\text{IB}} \tag{18}$$
$$\bar{\mathbf{K}}^\omega_{m\text{B}} = \mathbf{\Phi}^{\text{T}}_{\text{I}m}\left(\mathbf{K}^\omega_{\text{IB}} + \mathbf{K}^\omega_{\text{II}}\mathbf{\Psi}_{\text{IB}}\right) \tag{19}$$
$$\bar{\mathbf{K}}^\omega_{mm} = \mathbf{\Phi}^{\text{T}}_{\text{I}m}\mathbf{K}^\omega_{\text{II}}\mathbf{\Phi}_{\text{I}m} \tag{20}$$

$$\bar{\mathbf{M}}_{\text{BB}} = \mathbf{M}_{\text{BB}} + \mathbf{M}_{\text{BI}}\mathbf{\Psi}_{\text{IB}} + \mathbf{\Psi}^{\text{T}}_{\text{IB}}\mathbf{M}_{\text{IB}} + \mathbf{\Psi}^{\text{T}}_{\text{IB}}\mathbf{M}_{\text{II}}\mathbf{\Psi}_{\text{IB}} \tag{21}$$
$$\bar{\mathbf{M}}_{m\text{B}} = \mathbf{\Phi}^{\text{T}}_{\text{I}m}\left(\mathbf{M}_{\text{IB}} + \mathbf{M}_{\text{II}}\mathbf{\Psi}_{\text{IB}}\right) \tag{22}$$
$$\bar{\mathbf{M}}_{mm} = \mathbf{\Phi}^{\text{T}}_{\text{I}m}\mathbf{M}_{\text{II}}\mathbf{\Phi}_{\text{I}m} \tag{23}$$

It is also important to note that due to the multi-model approach used in the computation of the dynamic response, a major difference arises between the method presented here and the usual Craig-Bampton: the classic method would results in null matrix in place of $\bar{\mathbf{K}}^\omega_{m\text{B}}$ and the blocks $\bar{\mathbf{K}}_{mm}$ and $\bar{\mathbf{M}}_{mm}$ would be diagonals which is not the case here.

3.3 Condensing the system on interfaces dofs

In order to further reduce the size of the system, it is proposed to condense the generalized unknowns $\mathbf{q}_m$ on the boundary dofs. The second line of system (15) gives the following relation between the generalized coordinates $\mathbf{q}_m$ and the interfaces displacements $\mathbf{u}_{\text{B}}$:

$$\mathbf{q}_m = -\left(\bar{\mathbf{K}}^0_{mm} + i\omega\text{h}^*(\omega)\bar{\mathbf{K}}^\omega_{mm} - \omega^2\bar{\mathbf{M}}_{mm}\right)^{-1}\left(\bar{\mathbf{K}}^0_{m\text{B}} + i\omega\text{h}^*(\omega)\bar{\mathbf{K}}^\omega_{m\text{B}} - \omega^2\bar{\mathbf{M}}_{m\text{B}}\right)\mathbf{u}_B \tag{24}$$

For the undamped case, the terms in the first parentheses are diagonal so the inversion is instantaneous, but in the damped case these terms are non-diagonal and the inversion adds some

computation time. In order to limit this cost, it is possible to exploit the fact that the non-diagonal matrices are sparse. Replacing equation (24) into equation (15) leads to a condensed system on the interfaces which is equivalent to a super-element where its dimension is equal to the number of interface dofs (12 here):

$$\left(\mathbf{K}_{\text{super}}(\omega) - \omega^2 \mathbf{M}_{\text{super}}(\omega)\right) \mathbf{u}_{\text{B}} = \mathbf{f}_{\text{B}} \tag{25}$$

where the super-element mass and stiffness matrices are given by:

$$\mathbf{K}_{\text{super}}(\omega) = \bar{\mathbf{K}}^0_{\text{BB}} + i\omega \text{h}^*(\omega)\bar{\mathbf{K}}^\omega_{\text{BB}} - \left(\bar{\mathbf{K}}^0_{\text{B}m} + i\omega \text{h}^*(\omega)\bar{\mathbf{K}}^\omega_{\text{B}m}\right)\left(\bar{\mathbf{K}}^0_{mm} + i\omega \text{h}^*(\omega)\bar{\mathbf{K}}^\omega_{mm} - \omega^2\bar{\mathbf{M}}_{mm}\right)^{-1} \left(\bar{\mathbf{K}}^0_{m\text{B}} + i\omega \text{h}^*(\omega)\bar{\mathbf{K}}^\omega_{m\text{B}} - \omega^2\bar{\mathbf{M}}_{m\text{B}}\right) \tag{26}$$

$$\mathbf{M}_{\text{super}}(\omega) = \bar{\mathbf{M}}_{\text{BB}} - \bar{\mathbf{M}}_{\text{B}m}\left(\bar{\mathbf{K}}^0_{mm} + i\omega \text{h}^*(\omega)\bar{\mathbf{K}}^\omega_{mm} - \omega^2\bar{\mathbf{M}}_{mm}\right)^{-1} \left(\bar{\mathbf{K}}^0_{m\text{B}} + i\omega \text{h}^*(\omega)\bar{\mathbf{K}}^\omega_{m\text{B}} - \omega^2\bar{\mathbf{M}}_{m\text{B}}\right) \tag{27}$$

4 APPLICATION TO THE SUPPORT STRUCTURE MOUNTED ON 4 DAMPERS

A comparison between the reference full finite element model and the proposed super-element is made. An harmonic displacement is imposed on the structure lower interfaces, in a direction that is parallel to these interfaces: the dampers are not moving up and down but rather in a left-forward/right-backward kind of motion. The frequency range is chosen from 0 Hz to 500 Hz and the resulting displacements at observation point P (see figure (1)), for both the full reference model and the super-element, are plotted on figure (2). The displacement of point P for the full model without damping is also plotted to show that the chosen viscoelastics parameters lead to a well damped structure. In the same time, the error in displacement is plotted on figure (4). Two types of modes (damper only or full structure) are shown in figure (3) and their frequencies are plotted in vertical line on figure (2)

One hundred modes are taken in the dynamic modal basis at null frequency in the multi-model approach. The high number of modes needed here is due to the same stiffness difference that is exploited for the kinematical constraint of the dampers interfaces: the stiffness of the elastomer core is so low that around a hundred modes are found in the frequency range 0-500 Hz. The frequency limit chosen for the calculation of this modal basis is 512 Hz, which is roughly equal to the max frequency of the frequency range, so the method is accurate.

For the second basis of the multi-model, the one that contains the pseudo-normal modes at the max frequency, only ten modes are needed to give a good approximation. This is due to the fact that pseudo-normal modes are computed from the real part of the complex stiffness matrix at a given frequency. The real part of the complex modulus is greater than one thus adding stiffness to the system so a lower number of modes is present in the frequency range of interest. The frequency limit chosen for the calculation of this second modal basis is 582 Hz, which again is roughly equal to the max frequency of the frequency range.

As it can be seen on figure (2) and (4), the super-element matches the results of the reference model with a maximal error in displacement around 0.016%, thus validating the modified Craig-Bampton proposed in this work. The different computational times from both the FRF calculation of the reference model and the super-element are given in table 3. The same computer is used to do both of them. The assembly of the super-element is done once for all, before

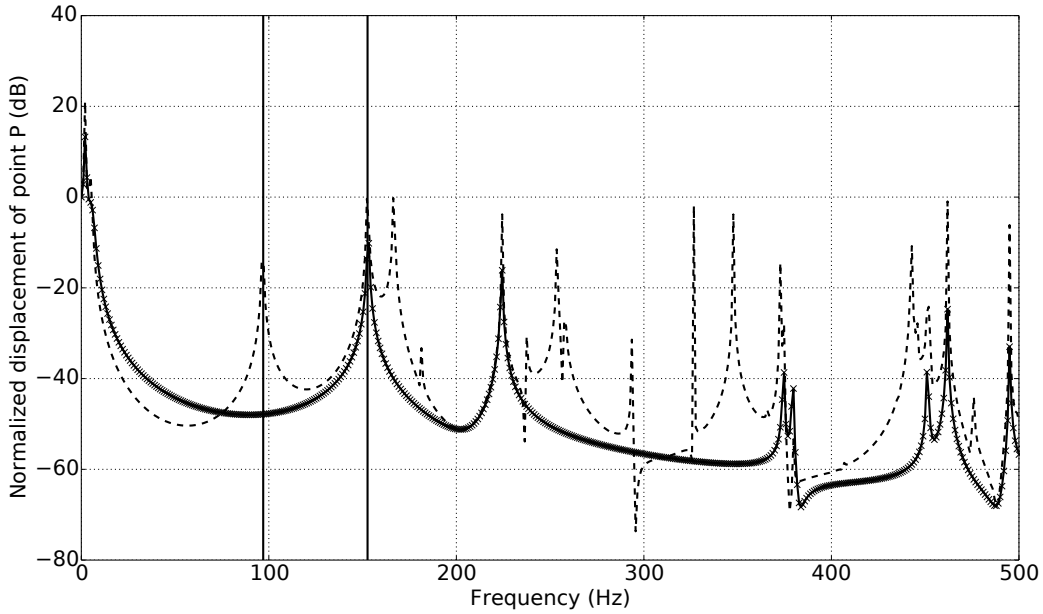

Figure 2: Normalized displacement of point P (see figure (1)) for the reference undamped model (dotted line), the reference damped (full line) and for the reduced model (cross-dotted line)

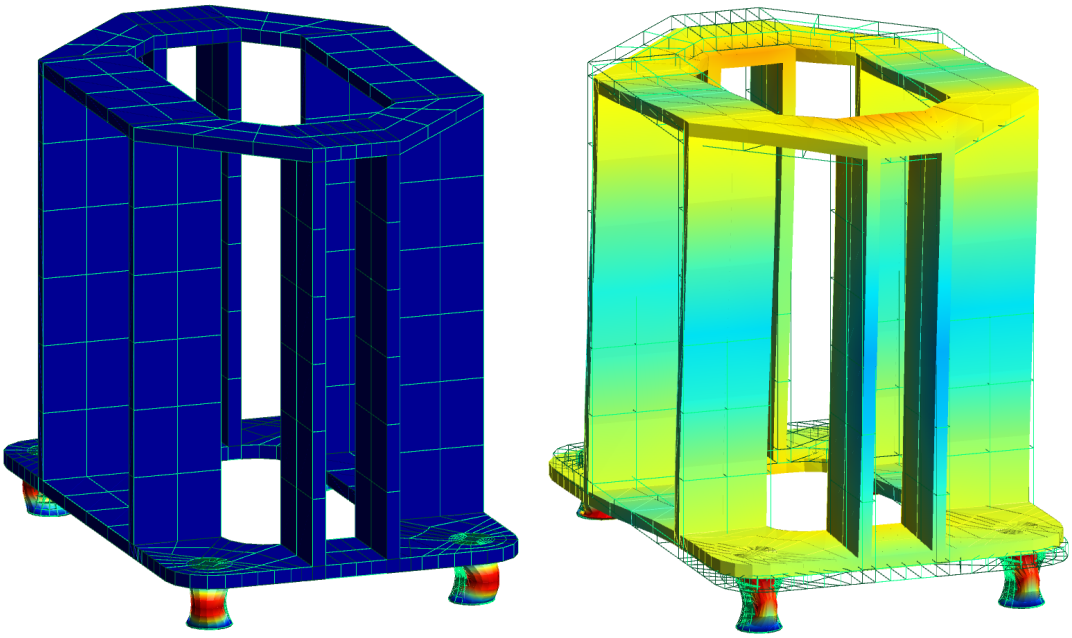

Figure 3: Modes of the undamped full structure at 98.23 Hz and 152.64 Hz (see the two vertical lines on figure 2)

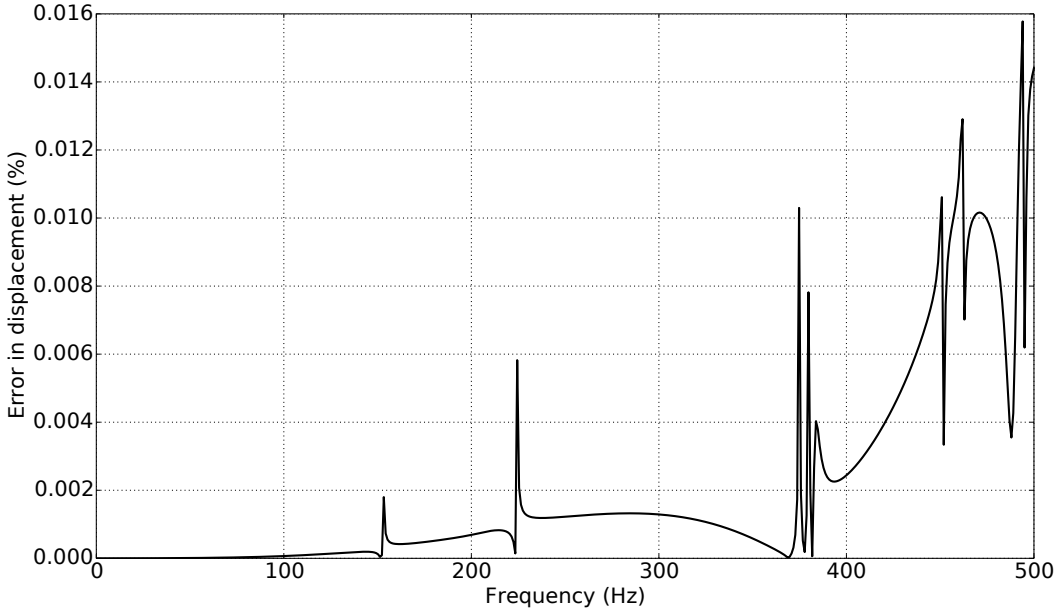

Figure 4: Error (norm 2) in displacement of the reduced model compared to the reference model

the FRF calculation, and the corresponding computational times is given under the name of Pre CPU time in table 3.

The sum of both the super-element assembly time and the FRF computational time of the modified Craig-Bampton is more than 10 times lower than the computational time of the reference model, thus further validating the present super-element approach.

Table 3: Computational time of both the reference and super-element models.

	Reference model	Super-element
Pre CPU time	-	23 min
FRF CPU time	14 h 40 min	51 min
total CPU time	14 h 40 min	1 h 14 min

5 Conclusion

The aim of the presented method is to reduce the finite element model of a damper made of elastomer and aluminium to a 12 dofs super-element. This super-element is built through the combination of a kinematical constraint to enforce rigid body motion at the damper interface and a Craig-Bampton to reduce and condense the finite element model on it's interfaces dofs. A multi-model approach is used to keep the frequency dependence of the finite element model during the Craig-Bampton reduction process. The result is a 12 dofs super-element that replace the more than 2.10^5 dofs finite element model. This super-element can be connected to any other finite element model through its interfaces nodes, each of them having three translational dofs and three rotational dofs. To test this method, the case of an aluminium structure supported on four dampers is studied. A reference model, consisting in the structure and four non-reduced

dampers, and a reduced model, made of the same structure with four super-elements, are compared. Displacements of one of the structure point are computed for both the reference and reduced models and are shown to be very close, and the error in displacement roughly stays under 0.016% on the whole frequency range thus validating the proposed method. The computational times of both models are also investigated and show that the reduced model is more than 10 times faster to compute than the reference model. A library of super-elements corresponding to different damper geometries and materials can be built off-line through this approach and then be used for design and optimization purposes in a full model.

Keywords: Nonlinear oscillators, vibratory energy, multi-scales method, passive control

Abstract. *In this paper, dynamics of a five degree-of-freedom system formed by a main linear oscillator coupled to four light nonlinear systems in series is studied. The aim is to control and/or to harvest the energy of the main structure under harmonic excitations around its resonance. A multiple scales method is used to derive the behavior of the system at different time scales. At fast time scale, detected slow invariant manifold gives an overall comprehension of the possible behaviors that the system can undergo. At slow time scale, the modulated behavior of the system around its invariant is described by traced equilibrium and singular points. The former predict periodic regimes, while the latter hint at strongly modulated responses characterized by persisting bifurcations of the system around its unstable zones. All analytical results are validated by numerical simulations.*

1 INTRODUCTION

Nonlinear oscillators are known to be efficient to passively attenuate vibratory energy of mechanical systems. Several works in the literature deal with two degree-of-freedom (dof) systems. Gendelman [1] studies energy pumping by means of energy transfer to a nonlinear mode of a system consisting of a linear and a nonlinear coupled oscillators. Kerschen et al. [2] make experimental investigations on energy transfer from a linear oscillator to a cubic nonlinear one. Passive control of nonlinear systems have also been studied. Dahl type and piece-wise linear systems coupled to a piece-wise linear oscillator are examined by Ture Savadkoohi and Lamarque [3] and Lamarque et al. [4], respectively. The present work aims to study passive control of a linear system by four nonlinear oscillators in series. This represents a step towards investigation of system with higher dof, i.e. a main system coupled to a chain of oscillators. It is organized as it follows: model of the system and methodology of treatment are given in Sect. 2. Study of the system behavior at fast and slow time scale, leading to detection of slow invariant manifold and equilibrium and singular points, respectively, is led in Sect. 3. Analytical predictions are compared to numerical results in Sect. 4. Finally, concluding remarks are summarized in Sect. 5.

2 MODEL DESCRIPTION AND SYSTEM EQUATIONS

The five dof system described in Fig. 1 is studied. A linear structure under external excitation $F(t)$ which has a mass M, a stiffness K and a damping $\hat{a}$ is coupled to four nonlinear oscillators in series via a linear spring ρ and a damper $\tilde{a}$. The nonlinear oscillators have a mass m, a damping $\tilde{a}$ and a nonlinear potential $\tilde{V}$. Their masses is very small compared to the main system one's ($m = \epsilon M$, $0 < \epsilon \ll 1$).

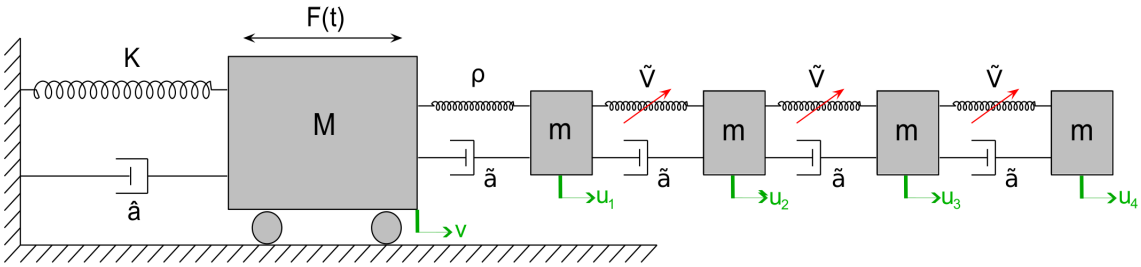

Figure 1: Five dof model studied consisting of a forced linear structure coupled to four nonlinear oscillators ($m = \epsilon M$, $0 < \epsilon \ll 1$)

Displacements of the main system and the nonlinear oscillators are called as v and u_j, $j = 1, \ldots, 4$, respectively. Let us introduce w_l as new variables of the system:

$$\begin{aligned} w_1 &= u_1 - v \\ w_l &= u_l - u_{l-1} \quad l = 2, 3, 4 \end{aligned} \tag{1}$$

Besides, new parameters are defined as followed: $\frac{K}{M} = \omega_0^2$, $\frac{\rho}{M} = \epsilon r$, $\frac{\tilde{V(z)}}{M} = \epsilon(Bz + Dz^3)$, $\frac{\hat{a}}{M} = \epsilon a$, $\frac{\tilde{a}}{M} = \epsilon a_1$ and $\frac{F(t)}{M} = \epsilon f(t)$. External forcing is assumed to be sinusoidal, oscillating at the angular frequency ω: $f(t) = f^0 \sin(\omega t)$. We study the system around resonance of the main structure: $\omega^2 = \omega_0^2(1 + \sigma\epsilon)$. Finally, a multiple scale method [5] is used by embedding

time to different scales, i.e. fast time scale $\tau_0 = t$ and slow time scales $\tau_j = \epsilon^j t,\ \ j = 1, 2 \ldots$ Governing equations of the system read:

$$\ddot{\mathbf{y}} + (\mathbf{C}_0 + \epsilon\mathbf{C}_1)\dot{\mathbf{y}} + (\mathbf{A}_0 + \epsilon\mathbf{A}_1)\mathbf{y} + \mathcal{N}(\mathbf{y}) = \epsilon\mathcal{F}(t) \tag{2}$$

where

$$\mathbf{A}_0 = \begin{pmatrix} \omega_0^2 & 0 & 0 & 0 & 0 \\ -\omega_0^2 & r & -B & 0 & 0 \\ 0 & -r & 2B & -B & 0 \\ 0 & 0 & -B & 2B & -B \\ 0 & 0 & 0 & -B & 2B \end{pmatrix} \quad \mathbf{A}_1 = \begin{pmatrix} 0 & -r & 0 & 0 & 0 \\ 0 & r & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix}$$

$$\mathbf{C}_0 = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 \\ 0 & a_1 & -a_1 & 0 & 0 \\ 0 & -a_1 & 2a_1 & -a_1 & 0 \\ 0 & 0 & -a_1 & 2a_1 & -a_1 \\ 0 & 0 & 0 & -a_1 & 2a_1 \end{pmatrix} \quad \mathbf{C}_1 = \begin{pmatrix} a & -a_1 & 0 & 0 & 0 \\ -a & a_1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix} \tag{3}$$

$$\mathcal{N}(\mathbf{y}) = D \begin{pmatrix} 0 \\ -w_2^3 \\ 2w_2^3 - w_3^3 \\ -w_2^3 + 2w_3^3 - w_4^3 \\ -w_3^3 + 2w_4^3 \end{pmatrix} \quad \mathbf{y} = \begin{pmatrix} v \\ w_1 \\ w_2 \\ w_3 \\ w_4 \end{pmatrix} \quad \mathcal{F}(t) = \begin{pmatrix} f^0 \sin(\omega t) \\ 0 \\ 0 \\ 0 \\ 0 \end{pmatrix}$$

As $\mathbf{A}_0$ is diagonalizable, there exists a matrix $\mathbf{P}_0$ such as $\mathbf{P}_0^{-1}\mathbf{A}_0\mathbf{P}_0 = \mathbf{\Lambda}_0^2$, i.e. $\mathbf{A}_0$ and $\mathbf{\Lambda}_0^2$ are similar matrices. Furthermore, we assume that $\mathbf{\Lambda}_0^2 = \omega^2\mathbf{Id}_5 + \tilde{\mathbf{\Lambda}}_0^2$, where $\mathbf{Id}_5$ is the 5×5 identity matrix. System (2) can be rewritten:

$$\ddot{\mathbf{y}} + \omega^2\mathbf{y} + (\mathbf{C}_0 + \epsilon\mathbf{C}_1)\dot{\mathbf{y}} + \mathbf{P}_0\tilde{\mathbf{\Lambda}}_0^2\mathbf{P}_0^{-1}\mathbf{y} + \epsilon\mathbf{A}_1\mathbf{y} + \mathcal{N}(\mathbf{y}) = \epsilon\mathcal{F}(t) \tag{4}$$

Following complex variables of Manevitch [6] are introduced to the system (4):

$$\mathbf{\Phi}e^{i\omega t} = \dot{\mathbf{y}} + i\omega\mathbf{y} \quad \text{with} \quad \mathbf{\Phi} = \begin{pmatrix} \varphi_1 \\ \varphi_2 \\ \varphi_3 \\ \varphi_4 \\ \varphi_5 \end{pmatrix} \tag{5}$$

In order to keep only first harmonics and to truncate higher order ones, a Galerkin method is used by applying following formula on each equations $s_j,\ j = 1, \ldots, 5$ of system (4):

$$S_j = \frac{\omega}{2\pi}\int_0^{\frac{2\pi}{\omega}} s_j(\tau_0)e^{-i\omega\tau_0}d\tau_0 \tag{6}$$

Φ is supposed to be independent of τ_0, which will be eventually verified at least for an asymptotic state. Finally, system (4) reads:

$$\dot{\mathbf{\Phi}} + \frac{1}{2}(\mathbf{C}_0 + \epsilon\mathbf{C}_1)\mathbf{\Phi} + \frac{1}{2i\omega}(\mathbf{P}_0\tilde{\mathbf{\Lambda}}_0^2\mathbf{P}_0^{-1} + \epsilon\mathbf{A}_1)\mathbf{\Phi} - \frac{3iD}{8\omega^3}\mathcal{N}_m(\mathbf{y}) = \epsilon\mathcal{F}_m(t) \tag{7}$$

$$\mathcal{N}_m(\mathbf{y}) = \begin{pmatrix} 0 \\ -|\varphi_2|^2\varphi_2 \\ 2|\varphi_2|^2\varphi_2 - |\varphi_3|^2\varphi_3 \\ -|\varphi_2|^2\varphi_2 + 2|\varphi_3|^2\varphi_3 - |\varphi_4|^2\varphi_4 \\ -|\varphi_3|^2\varphi_3 + 2|\varphi_4|^2\varphi_4 \end{pmatrix} \quad \mathcal{F}_m(t) = \begin{pmatrix} \frac{f^0}{2i} \\ 0 \\ 0 \\ 0 \\ 0 \end{pmatrix} \tag{8}$$

3 SYSTEM BEHAVIOR AT DIFFERENT TIME SCALES

3.1 Fast time scale τ_0

The system behavior at fast time scale is described by system (7) derived at ϵ^0 order:

$$\begin{gathered} \frac{\partial \mathbf{\Phi}}{\partial \tau_0} + \frac{1}{2}\mathbf{C}_0\mathbf{\Phi} + \frac{1}{2i\omega_0}\mathbf{P}_0\tilde{\mathbf{\Lambda}}_0^2\mathbf{P}_0^{-1}\mathbf{\Phi} - i\mathcal{D}\mathcal{N}_m(\mathbf{y}) = 0 \\ \Leftrightarrow \frac{\partial \mathbf{\Phi}}{\partial \tau_0} + \begin{pmatrix} 0 \\ \mathcal{H}_2(\mathbf{\Phi}) \\ \mathcal{H}_3(\mathbf{\Phi}) \\ \mathcal{H}_4(\mathbf{\Phi}) \\ \mathcal{H}_5(\mathbf{\Phi}) \end{pmatrix} = 0 \end{gathered} \tag{9}$$

where $\mathcal{D} = \dfrac{3D}{8\omega_0^3}$.

Fix points of system (9) verify $\lim\limits_{\tau_0 \to +\infty} \dfrac{\partial \tilde{\mathbf{\Phi}}}{\partial \tau_0} = 0$ where $\tilde{\mathbf{\Phi}} = (\ \phi_1 \quad \phi_2 \quad \phi_3 \quad \phi_4 \quad \phi_5\ )^T$. They define the slow invariant manifold (SIM) of the system:

$$\mathcal{H} = \begin{pmatrix} \mathcal{H}_2(\tilde{\mathbf{\Phi}}) \\ \mathcal{H}_3(\tilde{\mathbf{\Phi}}) \\ \mathcal{H}_4(\tilde{\mathbf{\Phi}}) \\ \mathcal{H}_5(\tilde{\mathbf{\Phi}}) \end{pmatrix} = 0 \tag{10}$$

Introducing polar coordinates as $\phi_j = N_j e^{i\delta_j}$, $j = 1, \ldots, 5$, SIM can be written after some cumbersome algebra:

$$\begin{pmatrix} \phi_2 \\ \phi_3 \\ \phi_4 \\ \phi_5 \end{pmatrix} = \frac{\phi_1}{g(N_3^2, N_4^2, N_5^2)} \begin{pmatrix} h_2(N_3^2, N_4^2, N_5^2) \\ h_3(N_3^2, N_4^2, N_5^2) \\ h_4(N_3^2, N_4^2, N_5^2) \\ h_5(N_3^2, N_4^2, N_5^2) \end{pmatrix} \tag{11}$$

$h_j(N_3^2, N_4^2, N_5^2)$ and $g(N_3^2, N_4^2, N_5^2)$ are complex functions. From system (11), SIM can be plotted in the $(N_1, N_2, N_3, N_4, N_5)$ space. This manifold houses all possible asymptotic states of the system.

Stability of the SIM can be computed by introducing an infinitesimal perturbation of $\mathbf{\Phi}$ in system (9) around the SIM as:

$$\mathbf{\Phi} \to \tilde{\mathbf{\Phi}} + \mathbf{\Delta}\tilde{\mathbf{\Phi}} \quad , \quad \mathbf{\Delta}\tilde{\mathbf{\Phi}} = \big(\ 0 \quad \Delta\phi_2 \quad \Delta\phi_3 \quad \Delta\phi_4 \quad \Delta\phi_5\ \big)^T \tag{12}$$

Linearizing the obtained system leads to the following matrix system:

$$\begin{pmatrix} \dfrac{\partial \boldsymbol{\Delta}\tilde{\boldsymbol{\Phi}}}{\partial \tau_0} \\ \\ \dfrac{\partial \boldsymbol{\Delta}\tilde{\boldsymbol{\Phi}}^*}{\partial \tau_0} \end{pmatrix} = \boldsymbol{\Sigma} \begin{pmatrix} \boldsymbol{\Delta}\tilde{\boldsymbol{\Phi}} \\ \\ \boldsymbol{\Delta}\tilde{\boldsymbol{\Phi}}^* \end{pmatrix} \tag{13}$$

where $\boldsymbol{\Sigma}$ is an 10×10 matrix. Points where real parts of the eigenvalues of $\boldsymbol{\Sigma}$ are negative determine unstable zones of the SIM.

3.2 Slow time scale τ_1

Let us consider first equation of system (7) derived at ϵ^1 order:

$$\frac{\partial \varphi_1}{\partial \tau_1} + \left(\frac{i\sigma\omega_0}{2} + \frac{a}{2}\right)\varphi_1 + \left(\frac{ir}{2\omega_0} - \frac{a_1}{2}\right)\varphi_2 + \frac{if^0}{2} = 0 \tag{14}$$

This equation provide necessary additional information to detect equilibrium and singular points at slow time scale. Equilibrium points predict periodic regimes whereas singular points are hints of strongly modulated response (SMR) [7] which is characterized by persistent bifurcations of the system around its unstable zones. Separating its real and imaginary parts and using system (11), Eq. (14) becomes:

$$\begin{aligned} &\frac{\partial \varphi_1}{\partial \tau_1} + \underbrace{\left(\frac{i\sigma\omega_0}{2} + \frac{a}{2} + \frac{h_2}{g}\left(\frac{ir}{2\omega_0} - \frac{a_1}{2}\right)\right)}_{\alpha}\varphi_1 + \frac{if^0}{2} = 0 \\ &\Leftrightarrow \begin{cases} \dfrac{\partial N_1}{\partial \tau_1} = -\alpha_r N_1 - \dfrac{f^0}{2}\sin(\delta_1) = E_1 \\ \dfrac{\partial \delta_1}{\partial \tau_1} = -\alpha_i - \dfrac{f^0}{2N_1}\cos(\delta_1) = E_2 \end{cases} \end{aligned} \tag{15}$$

where $._r$ and $._i$ stand for real and imaginary parts, respectively. Moreover, from systems (10) and (15), one can obtain:

$$\begin{aligned} &\frac{\partial \mathcal{H}}{\partial \tau_1} = 0 \\ &\Rightarrow \det(\mathbf{S}_2)\mathbf{Id}_8 \begin{pmatrix} \dfrac{\partial N_2}{\partial \tau_1} \\ \vdots \\ \dfrac{\partial N_5}{\partial \tau_1} \\ \\ \dfrac{\partial \delta_2}{\partial \tau_1} \\ \vdots \\ \dfrac{\partial \delta_5}{\partial \tau_1} \end{pmatrix} = \underbrace{-\mathrm{adj}(\mathbf{S}_2)\mathbf{S}_1 \begin{pmatrix} E_1 \\ \\ E_2 \end{pmatrix}}_{\mathcal{G}} \end{aligned} \tag{16}$$

where $\mathrm{adj}(.)$ stands for the adjugate matrix and:

$$\mathcal{G} = \begin{pmatrix} \mathcal{G}_1 \\ \vdots \\ \mathcal{G}_8 \end{pmatrix} \mathbf{S}_1 = \begin{pmatrix} \frac{\partial \mathcal{H}_{2r}}{\partial N_1} & \frac{\partial \mathcal{H}_{2r}}{\partial \delta_1} \\ \frac{\partial \mathcal{H}_{2i}}{\partial N_1} & \frac{\partial \mathcal{H}_{2i}}{\partial \delta_1} \\ \vdots & \vdots \\ \frac{\partial \mathcal{H}_{5r}}{\partial N_1} & \frac{\partial \mathcal{H}_{5r}}{\partial \delta_1} \\ \frac{\partial \mathcal{H}_{5i}}{\partial N_1} & \frac{\partial \mathcal{H}_{5i}}{\partial \delta_1} \end{pmatrix} \quad \mathbf{S}_2 = \begin{pmatrix} \frac{\partial \mathcal{H}_{2r}}{\partial N_2} & \cdots & \frac{\partial \mathcal{H}_{2r}}{\partial N_5} & \frac{\partial \mathcal{H}_{2r}}{\partial \delta_2} & \cdots & \frac{\partial \mathcal{H}_{2r}}{\partial \delta_5} \\ \frac{\partial \mathcal{H}_{2i}}{\partial N_2} & \cdots & \frac{\partial \mathcal{H}_{2i}}{\partial N_5} & \frac{\partial \mathcal{H}_{2i}}{\partial \delta_2} & \cdots & \frac{\partial \mathcal{H}_{2i}}{\partial \delta_5} \\ \vdots & & \vdots & \vdots & & \vdots \\ \frac{\partial \mathcal{H}_{5r}}{\partial N_2} & \cdots & \frac{\partial \mathcal{H}_{5r}}{\partial N_5} & \frac{\partial \mathcal{H}_{5r}}{\partial \delta_2} & \cdots & \frac{\partial \mathcal{H}_{5r}}{\partial \delta_5} \\ \frac{\partial \mathcal{H}_{5i}}{\partial N_2} & \cdots & \frac{\partial \mathcal{H}_{5i}}{\partial N_5} & \frac{\partial \mathcal{H}_{5i}}{\partial \delta_2} & \cdots & \frac{\partial \mathcal{H}_{5i}}{\partial \delta_5} \end{pmatrix} \tag{17}$$

Equilibrium points verify:

$$\begin{cases} \det(\mathbf{S}_2) \neq 0 \\ E_1 = E_2 = 0 \end{cases} \Leftrightarrow \begin{cases} \det(\mathbf{S}_2) \neq 0 \\ \mathcal{G}_1 = \ldots = \mathcal{G}_8 = 0 \end{cases} \tag{18}$$

Singular points verify:

$$\begin{cases} \det(\mathbf{S}_2) = 0 \\ \mathcal{G}_1 = \ldots = \mathcal{G}_8 = 0 \end{cases} \tag{19}$$

4 NUMERICAL RESULTS

Analytical developments are compared in this section with numerical simulations obtained for direct integration of system (2). This task has been carried out thanks to function *ode45* of Matlab. Following parameters are fixed all along this section: $\omega_0 = 1$, $a = 0.2$, $\epsilon = 0.001$, $B = 0.2$, $r = 0.5$, $a_1 = 0.2$ and $D = 10$. Assumed initial conditions are: $v = 1$ and $\dot{v} = u_1 = \dot{u}_1 = u_2 = \ldots = \dot{u}_4 = 0$.

4.1 SIM

SIM of the system is illustrated in Fig. 2. Figures 2(a)-(d) represent N_1 versus N_2, N_3, N_4 and N_5, respectively. Unstable zones are plotted in dotted red line. The SIM presents two local extrema for N_1 which delimit an unstable zone. Furthermore, one can see what appears to be a double point in Fig. 2(a). This is an effect of the projection in the plane (N_1, N_2), as shown by the three-dimensional flow of the SIM in the (N_1, N_2, N_3)-space in Fig. 2(e).

4.2 $\mathbf{f^0 = 0.2}$ and $\sigma = 0$ (exact resonance)

Position of equilibrium and singular points are given in Fig. 3. The system possesses one stable equilibrium point (no. 1). SIM of the system and corresponding numerical results are given in Figs. 4(a) and (b). We picked two representations, N_1 versus N_2 and N_1 versus N_5, among four possible. Corresponding time series are given in Figs. 4(c),(d) and (e), where amplitudes of predicted equilibrium point no. 1 (see Fig. 3) are depicted by a blue dashed line. Besides, the amplitude that the main system would have without additional nonlinear oscillators is plotted in solid black line in Fig. 4(c). One can see that numerical results match analytical predictions, as the system behavior is instantaneously attracted to the SIM and stabilizes around the above-cited equilibrium point. Moreover, vibratory energy has been localized in the nonlinear oscillators, as the main system's amplitude equates to around 27% of the amplitude it would have on its own.

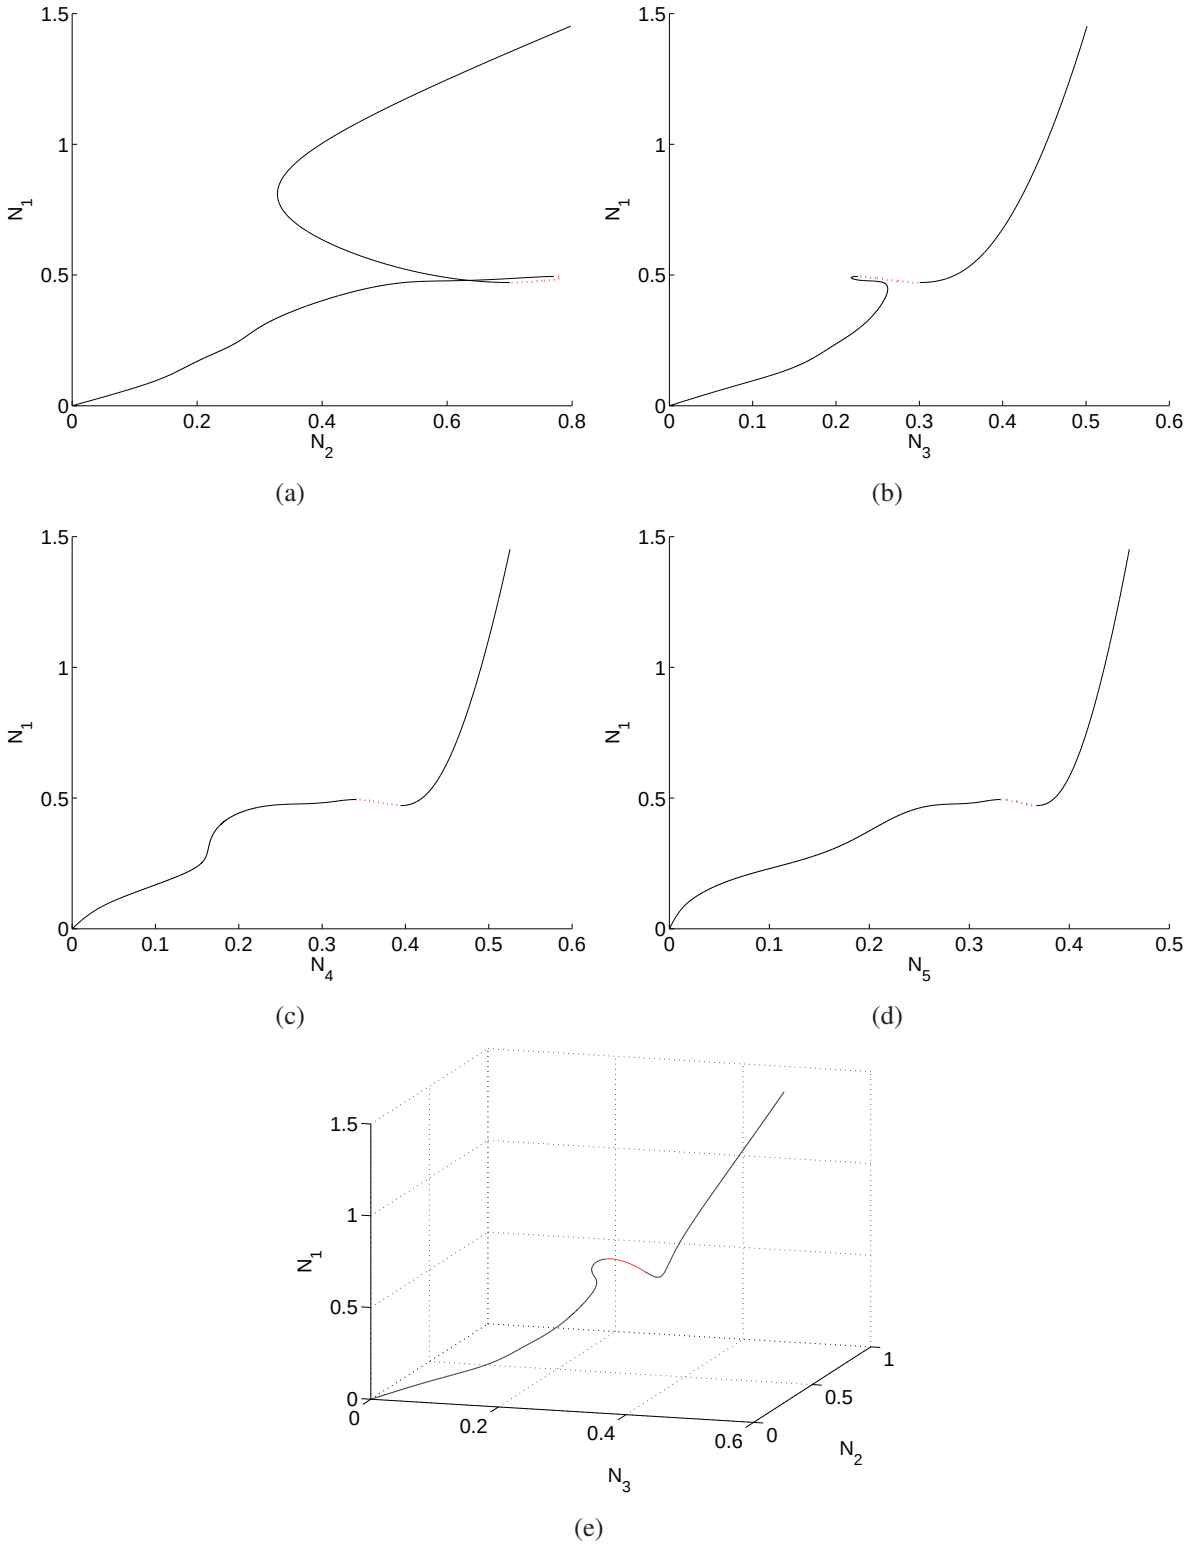

Figure 2: SIM of the system. (a) N_1 versus N_2, (b) N_1 versus N_3, (c) N_1 versus N_4, (d) N_1 versus N_5 and (e) Three-dimensional flow of the SIM in the (N_1, N_2, N_3)-space. Stable and unstable zones of the SIM are plotted in black solid line and dotted red line, respectively

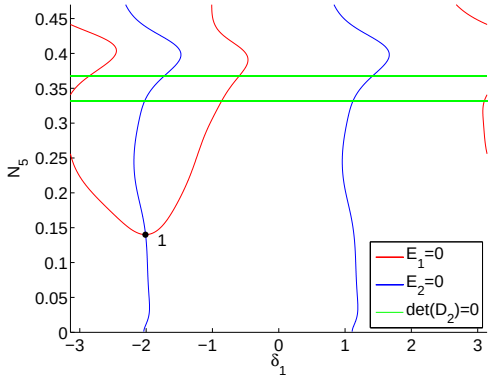

Figure 3: Position of equilibrium and singular points of the system with $f^0 = 0.2$ and $\sigma = 0$. The system possesses one equilibrium point (no. 1). Black points represent points where $\mathcal{G}_1 = \ldots = \mathcal{G}_8 = 0$ (see Sect. 3.2)

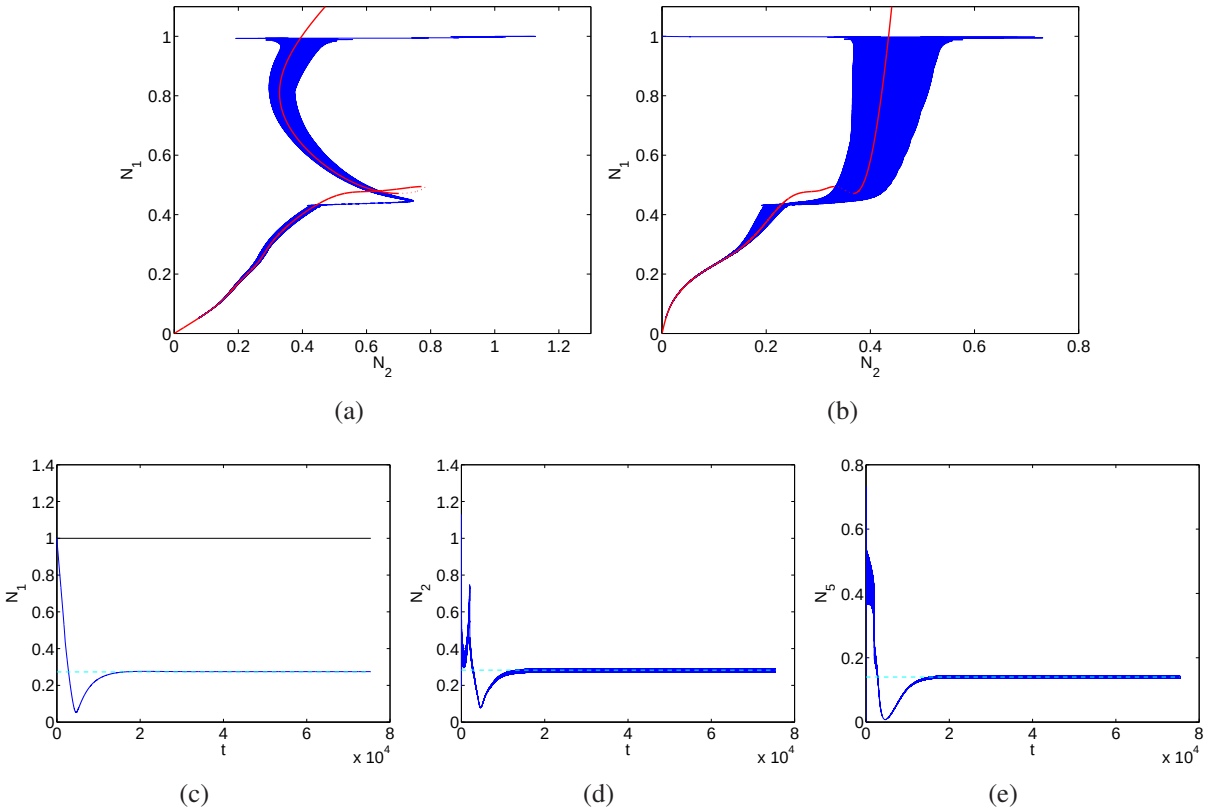

Figure 4: $f^0 = 0.2$ and $\sigma = 0$. (a) SIM of the system in red and corresponding numerical results in blue: N_1 versus N_2, (b) SIM of the system in red and corresponding numerical results in blue: N_1 versus N_5, (c) N_1 versus time, (d) N_2 versus time and (e) N_5 versus time. Amplitude of predicted equilibrium point no. 1 (see Fig. 3) is depicted by a blue dashed line. Amplitude that the main system would have without nonlinear oscillators is plotted in black

4.3 $f^0 = 0.5$ and $\sigma = 0.6$

Position of equilibrium and singular points are given in Fig. 5. The system possesses one unstable equilibrium point (no. 1) and four singular points (no. 2, no. 3, no. 4 and no. 5). Consequently, SMR is expected. Figures 6(a)-(e) depict SIM of the system, corresponding

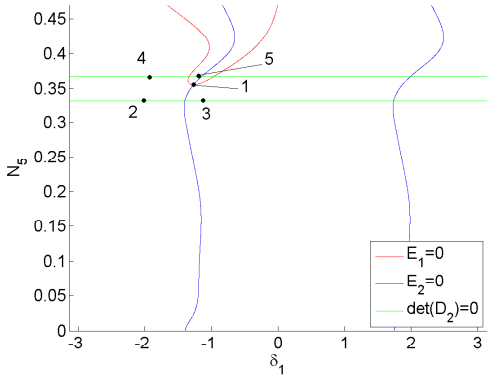

Figure 5: Position of equilibrium and singular points of the system with $f^0 = 0.5$ and $\sigma = 0.6$. The system possesses one equilibrium point (no. 1) and four singular points (no. 2, no. 3, no. 4 and no. 5). Black points represent points where $\mathcal{G}_1 = \ldots = \mathcal{G}_8 = 0$ (see Sect. 3.2)

numerical results and evolution versus time of the same variables as in the previous section. This time, the system faces repeated bifurcations around its unstable zone, i.e. it undergoes SMR. The system behavior during SMR is plotted in green in Figs. 6(a)-(b). Again, passive control has been operated on the main system as shown by the difference of its amplitude with nonlinear oscillators and without (marked by a solid black line in Fig. 6(c)).

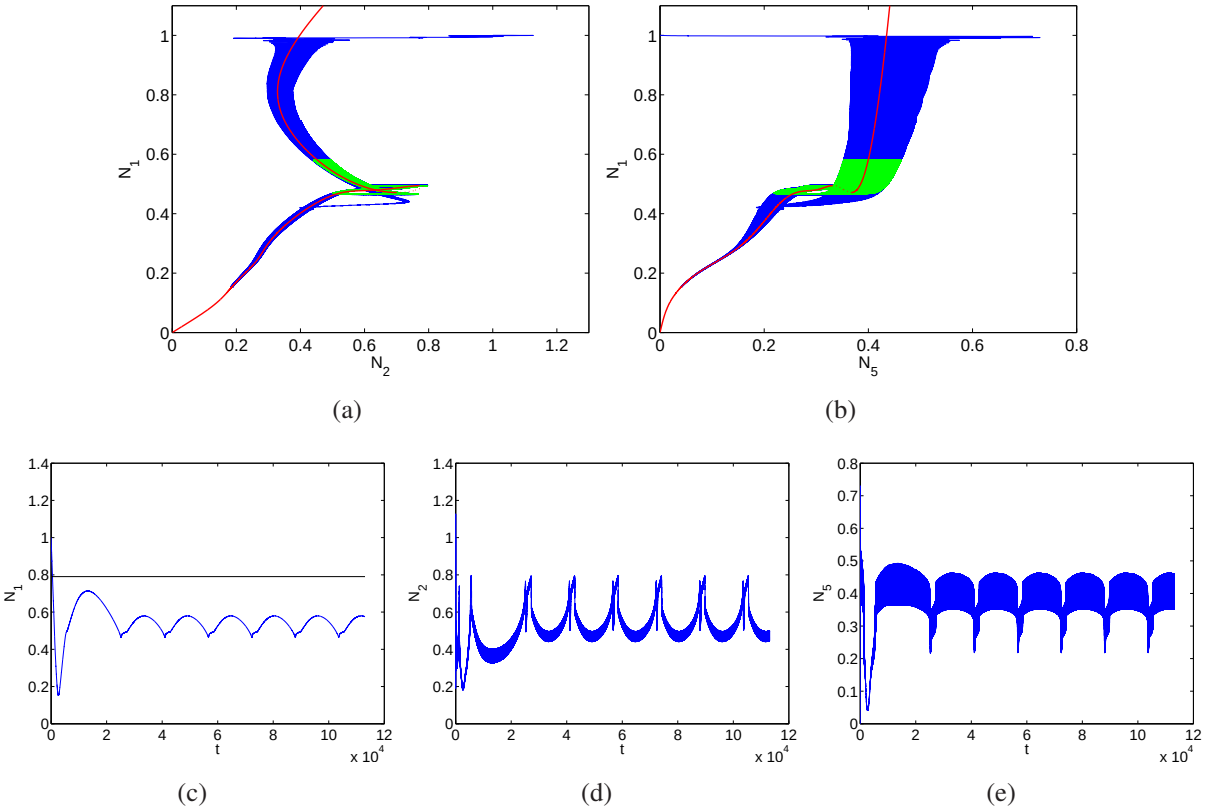

Figure 6: $f^0 = 0.2$ and $\sigma = 0$. (a) SIM of the system in red and corresponding numerical results in blue: N_1 versus N_2, (b) SIM of the system in red and corresponding numerical results in blue: N_1 versus N_5, (c) N_1 versus time, (d) N_2 versus time and (e) N_5 versus time. Amplitude that the main system would have without nonlinear oscillators is plotted in black

5 CONCLUSION

A five degree-of-freedom system consisting of a linear system coupled to four nonlinear oscillators is studied. Theoretical approaches such as implementation of Galerkin technique, complexification and time multi-scale methods are endowed for detection of fast and slow dynamics of the system. Numerical simulations and analytical predictions are in good agreement and provide evidence of passive control of the main system. In prospect, a similar method will be applied on a system with higher degree-of-freedom, in order to compare efficiency of passive control according to the number of nonlinear oscillators. Moreover, it will be interesting to study the behavior of the chain (propagation of a wave, localization in a few degrees of freedom, etc.) and to compare the results obtained with different approaches such as the search of nonlinear modes.

Keywords: Quasi-periodic, Harmonic Balance Method.

Abstract. *Nonlinear systems can have periodic solutions evolving with the parameters of the system. Studying this evolution (numerical continuation of solutions) uncovers sought-after regimes in musical acoustics : many musical instruments rely on auto-oscillation, that is, the excitation of a nonlinear system coupled with a linear resonator, where some parameters may be adjusted by the player. Periodic solutions can be approximated as truncated Fourier series (Harmonic Balance Method) ; the period is one of the unknowns. Several stable or unstable solutions can be found for the same playing parameters thanks to continuation.*
An important challenge is the continuation of quasi-periodic solutions, also called multiphonic sounds by musicians. Depending on the context, these oscillation regimes are considered pleasant (jazz or contemporary music for instance) or unpleasant (classical music). We developed a method based on double Fourier series, coupled with a continuation technique. The two base frequencies are unknowns and incommensurable. The system is reformulated as quadratic in order to allow straight interface with previous work on periodic harmonic balance.
This method is illustrated on simple models relevant to musical acoustics, though the method can be applied to many nonlinear problems, without a priori knowledge of the solutions.

1 INTRODUCTION

Nonlinear systems can have periodic solutions evolving with the parameters of the system. Studying this evolution (numerical continuation of solutions) uncovers sought-after regimes in musical acoustics : many musical instruments rely on auto-oscillation, that is, the excitation of a nonlinear system coupled with a linear resonator, where some parameters may be adjusted by the player. Periodic solutions can be approximated as truncated Fourier series (Harmonic Balance Method) ; the period is one of the unknowns. Then, using a continuation technique, solutions can be continued ; they can be either stable or unstable, and different solutions may occur for the same playing parameters.

However, other solutions can arise, namely quasi-periodic solutions. They are well-known by musicians, who may call them multiphonics. These solutions can be undesirable : for instance, the wolf note on bowed string instruments is a rough, beating sound, and it is an example of a quasi-periodic regime of an autonomous system. These solutions can also be produced voluntarily, using a forced system: singing at a frequency f_1 while playing at a frequency f_2 on a brass instrument can create stunning effects.

Our aim is the continuation of two-frequencies, quasi-periodic solutions. It is important to notice that even the direct computation of quasi-periodic solutions can be difficult. Because of dependence on initial conditions, some solutions may be overlooked when using numerical integration. Moreover, compared to the periodic case, it is not relevant anymore to perform integration on long intervals to get rid of transient solutions : one cannot determine easily if the steady-state solution is reached. These drawbacks have lead to specific algorithms to compute quasi-periodic solutions, first as a response to a quasi-periodic drive [1]. More recently, the computation of quasi-periodic solutions for forced or autonomous systems, based on the Alternating Frequency/Time Domain Method (AFT [2]), was performed with good qualitative agreement on a disc brake model [3]. Peletan *et al.* [4] designed a continuation method, coupling AFT with pseudo-arclength continuation, and applied it to a Jeffcott rotor. For this system, one of the two frequencies is known ; and an harmonic selection procedure improves the efficiency of computations.

For periodic solutions, Cochelin and Vergez [5] showed that given a quadratic reformulation, a coupling of the Harmonic Balance Method and the Asymptotic Numerical Method was straightforward and allowed computations with high number of harmonics. The method developed here is an extension of this idea with double Fourier series. The two base frequencies are unknowns and incommensurable. The system is reformulated as quadratic in order to allow straight interface with previous work on periodic harmonic balance.

This method is illustrated on simple models, with a forced system and an autonomous one. System parameters could be chosen to present results more closely related to musical acoustics. However, simple values underline that the method can be applied to many nonlinear problems, without *a priori* knowledge of the solutions.

2 TWO-FREQUENCY HARMONIC BALANCE METHOD

2.1 Principle : quadratic formulation

Instead of one Fourier series, a variable x is sought after in the form

$$x(t) = \sum_{k_1=-H}^{H} \sum_{k_2=-H}^{H} x_{k_1,k_2} e^{i(k_1\omega_1 + k_2\omega_2)t} \tag{1}$$

where ω_1 and ω_2 are the two unknown pulsations. Adding auxiliary variables, a smooth nonlinear differential system can be transformed into a first-order differential system, with nonlinearities being only products, either of two variables, or a variable and the continuation parameter λ. Let U denote the vector of variables in the time domain, the following system is called quadratic formulation :

$$mU' = c_0 + \lambda c_1 + l_0 U + \lambda l_1 U + q(U,U) \tag{2}$$

where c_0, c_1 are constant vectors, m, l_0 and l_1 are constant linear operators, and q is a constant quadratic operator. Like in the periodic case [5], since eq. (2) is quadratic, and due to the decomposition of variables assumed in eq. (1), substituting this double series in eq. (2) leads to a (larger) quadratical system where the unknowns are Fourier coefficients plus the two pulsations ω_1, ω_2. Note that in the case of a forced system one of these pulsations is the forcing pulsation (see section 2.2). This larger system reads as a quadratical residual function R :

$$R : \mathbf{R}^{N+1} \longrightarrow \mathbf{R}^N, \quad (X,\lambda) \mapsto C_0 + \lambda C_1 + L_0(X) + \lambda L_1(X) + Q(X,X) \tag{3}$$

where X contains Fourier coefficients of U, ω_1 and ω_2. The solution branch $R(X,\lambda) = 0$ can then be followed thanks to the Asymptotic Numerical Method.

2.2 Forced system

An example of a forced system that exhibits a quasi-periodic behaviour is a forced Van der Pol oscillator :

$$x'' - \mu_1 x' + \mu_2 x x' + \mu_3 x^2 x' + a_1 x = \cos(\lambda t) \tag{4}$$

with $\mu_1 = \mu_2 = 0.1$, $\mu_3 = a_1 = 1$. A Neimark-Sacker bifurcation occurs at $\lambda \simeq 1.79$ [6], and the periodic solution at pulsation $\omega = \lambda$ becomes unstable. A quadratic formulation, emphasizing constant, linear and quadratic parts in the right-hand side, is

$$x' = 0 + y + 0 \tag{5}$$

$$y' = \cos(\lambda t) + \mu_1 y - a_1 x - \mu_2 xy - \mu_3 yz \tag{6}$$

$$\underbrace{0}_{mU'} = \underbrace{0}_{c_0} \underbrace{+ z}_{l_0 U} \underbrace{- x^2}_{q(U,U)} \tag{7}$$

The forcing term $\cos(\lambda t)$ is placed in the constant operator, similarly to the periodic version of the method (see [5], example 4).

The continuation of the quasi-periodic solution branch can be performed efficiently and precisely : in this example, Fourier series were truncated with $H = 5$. A plot of L^2 norm of x is shown in figure 2.2. Dots indicate the beginning of each continuation step : the ANM provides smooth continuation with an automatic step size determination. The solution obtained through this quasi-periodic Harmonic Balance is qualitatively good with $H = 2$ (figure 2.2, left) : peak-to-peak amplitude and general shape of the curve in the phase space are reached. But areas left blank are not actually correct, while with $H = 5$ (right), its pointwise agreement with a time integration scheme [7] is excellent.

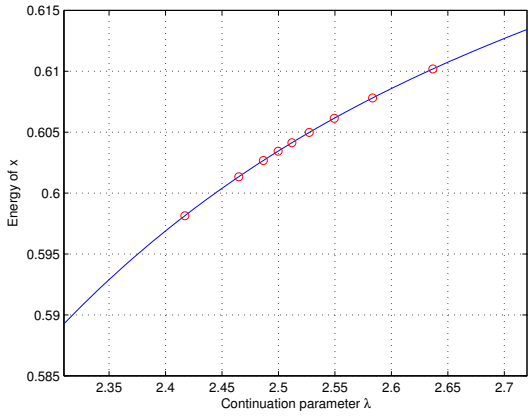

Figure 1: Energy (L^2 norm) of x with respect to the continuation parameter λ. Red dots indicate the beginning of each continuation step.

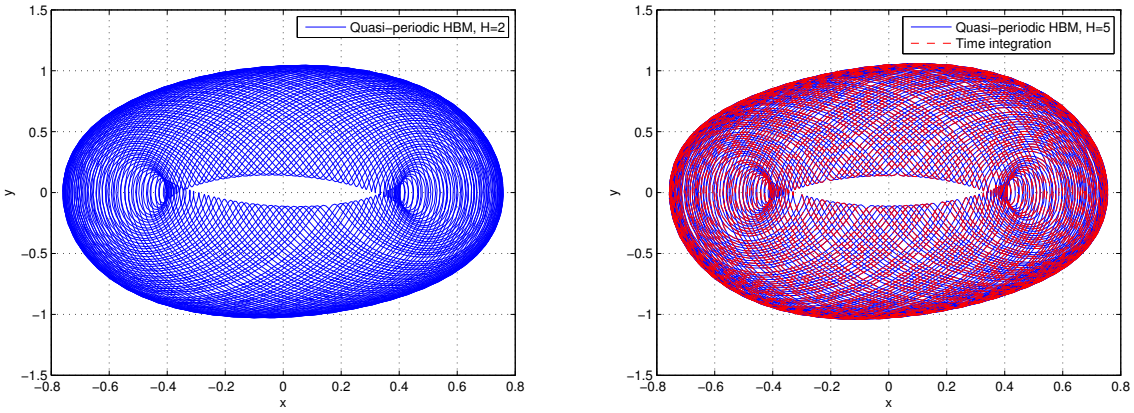

Figure 2: Phase diagrams (x, y), for $\lambda = 2.58$. Left : quasi-periodic Harmonic Balance, $H = 2$. Right : comparison of quasi-periodic Harmonic Balance ($H = 5$, blue solid line) and time integration (red dashed line).

2.3 Autonomous system

The equations used for two coupled Van der Pol oscillators are :

$$x_1'' + a_1 x_1' + \Omega_1^2 x_1 = a_2\lambda(x_1' + x_2') - a_3\lambda(x_1' + x_2')(x_1 + x_2) - a_4\lambda(x_1' + x_2')(x_1 + x_2)^2 \quad (8)$$

$$x_2'' + b_1 x_2' + \Omega_2^2 x_2 = b_2\lambda(x_1' + x_2') - b_3\lambda(x_1' + x_2')(x_1 + x_2) - b_4\lambda(x_1' + x_2')(x_1 + x_2)^2 \quad (9)$$

and the quadratic formulation is :

$$
\begin{aligned}
x_1' &= y_1 + 0 && + 0 && (10)\\
y_1' &= 0 \ - a_1 y_1 - \Omega_1^2 x_1 + \lambda\left(a_2(y_1+y_2) - a_3 v - a_4 w\right) && + 0 && (11)\\
x_2' &= y_2 + 0 && + 0 && (12)\\
y_2' &= 0 \ - b_1 y_2 - \Omega_2^2 x_2 + \lambda\left(b_2(y_1+y_2) - b_3 v - b_4 w\right) && + 0 && (13)\\
0 &= 0 \ + r && - (x_1+x_2)^2 && (14)\\
0 &= 0 \ + v && - (x_1+x_2)(y_1+y_2) && (15)\\
0 &= 0 \ + w && - r(y_1+y_2) && (16)
\end{aligned}
$$

Parameters values are chosen as : $\Omega_1 = 1$, $a_1 = 0.01$, $a_2 = 0.5$, $a_3 = a_4 = 2$; $\Omega_2 = 2.5$, $b_1 = 0.025$, $b_2 = 1$, $b_3 = b_4 = 4$. For these equations, the quasi-periodic solution branch requires higher orders of truncation of Fourier series H than the forced Van der Pol above. For example, around $\lambda = 0.36$, a good agreement with time integration is achieved with $H = 10$ (figure 2.3), and some differences are noticeable if H is too low (areas left empty are not correct with $H = 4$). For this system the continuation process takes roughly 6 seconds per step for $H = 4$, 43 seconds for $H = 6$, 220 seconds for $H = 8$.

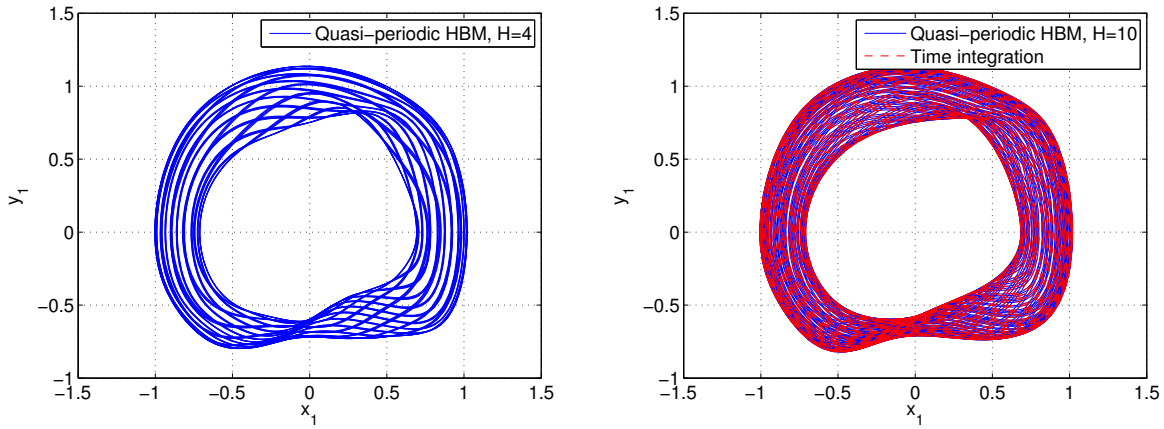

Figure 3: Phase diagrams (x_1, y_1), for $\lambda = 0.36$. Left : quasi-periodic Harmonic Balance, $H = 4$. Right : comparison of quasi-periodic Harmonic Balance ($H = 10$, blue solid line) and time integration (red dashed line).

3 CONCLUSION

The coupling of two-frequencies harmonic balance with the Asymptotic Numerical Method, a robust continuation technique, is performed automatically thanks to the quadratic framework. It proves very efficient to continue quasi-periodic solutions, without any *a priori* knowledge nor optimization. As one could expect, better accuracy is obtained using more Fourier coefficients, and comparison with time integration is successful. Future works will focus on musical examples, though this method is relevant for many nonlinear systems.

Keywords: Lame problem, orthotropic spherical layer, asymptotic analysis

Abstract. *The deformation of the orthotropic spherical layer under normal pressure applied on the outer and inner surfaces is analyzed. The layer is assumed to be slightly orthotropic, it permits to apply asymptotic methods. The equations of zeroth and first approximations are derived. For the shell, which is much softer in the transverse direction than in the tangential plane, one gets singularly perturbed boundary value problem. Solving this problem in the zeroth approximation the asymptotic formula for the change of the relative layer thickness under normal pressure is obtained. Also the effect of Poisson ratio and the layer thickness on the deformation is studied. For the cases of the thick and thin layers the last formula may be simplified. The asymptotic results well agree with the exact solution. The developed formulas are used in analysis of the scleral shell under intraocular pressure and may also be used in solution of the inverse problem, i.e. in analysis of the stress-strain state of a human eye under injection. The solution of the problem helps to estimate the mechanical parameters of the sclera, i.e. to find the ratio of the tangential and transversal Young moduli using clinical data for the sclera thickness change.*

1 INTRODUCTION

The 3D problem for deformation of orthotropic spherical layer under normal pressure is considered. Such model may be used, for example, to describe the changes of the stress strain state of the external human eye shell under intraocular injections. For isotropic spherical layer this problem, known as Lame problem, is discussed, for example, in [1]. For transverse isotropic spherical layer the analytical solution has been obtained in [2, 3] and asymptotic solution in [4]. The stress-strain state of a two-layered transversely isotropic spherical shell is discussed in [5].

2 PROBLEM STATEMENT

2.1 Equilibrium equations in displacements

Consider orthotropic spherical layer with the internal radius R_1, external radius R_2 and thickness $h = R_2 - R_1$ (see Fig. 1).

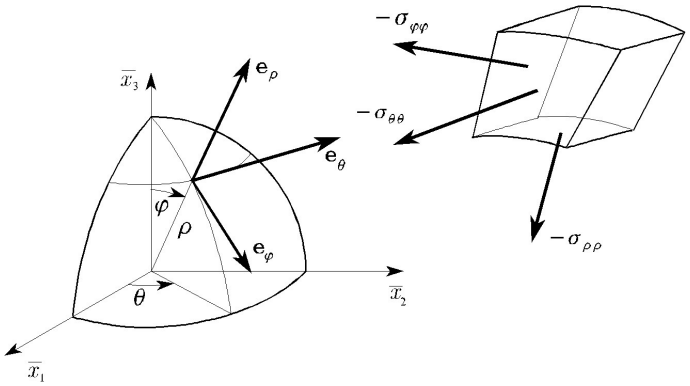

Figure 1: Orthotropic spherical layer

The position of the point of the spherical layer in given by spherical coordinates: ρ — radial coordinate, φ — meridional coordinate, θ — circumferential coordinate. Equilibrium equations for the spherical layer have the form [1]

$$\begin{aligned}
\frac{\partial\sigma_{\rho\rho}}{\partial\rho}+\frac{1}{\rho}\frac{\partial\sigma_{\rho\varphi}}{\partial\varphi}+\frac{1}{\rho\sin\varphi}\frac{\partial\sigma_{\rho\theta}}{\partial\theta}+\frac{\cos\varphi}{\rho\sin\varphi}\sigma_{\rho\varphi}+\frac{1}{\rho}(2\sigma_{\rho\rho}-\sigma_{\varphi\varphi}-\sigma_{\theta\theta})+f_\rho &= 0,\\
\frac{\partial\sigma_{\varphi\rho}}{\partial\rho}+\frac{1}{\rho}\frac{\partial\sigma_{\varphi\varphi}}{\partial\varphi}+\frac{1}{\rho\sin\varphi}\frac{\partial\sigma_{\varphi\theta}}{\partial\theta}+\frac{3}{\rho}\sigma_{\varphi\rho}+\frac{\cos\varphi}{\rho\sin\varphi}(\sigma_{\varphi\varphi}-\sigma_{\theta\theta})+f_\varphi &= 0,\\
\frac{\partial\sigma_{\theta\rho}}{\partial\rho}+\frac{1}{\rho}\frac{\partial\sigma_{\theta\varphi}}{\partial\varphi}+\frac{1}{\rho\sin\varphi}\frac{\partial\sigma_{\theta\theta}}{\partial\theta}+\frac{3}{\rho}\sigma_{\theta\rho}+\frac{2\cos\varphi}{\rho\sin\varphi}\sigma_{\theta\varphi}+f_\theta &= 0,
\end{aligned}$$

here $\sigma_{\rho\rho}$, $\sigma_{\varphi\varphi}$ and $\sigma_{\theta\theta}$ — normal stress, $\sigma_{\rho\varphi}$, $\sigma_{\rho\theta}$, $\sigma_{\varphi\theta}$ — tangential stress, f_ρ, f_φ, f_θ — projections of the external forces in corresponding directions.

We consider axisymmetric problem without external forces. In this case the displacements do not depend on angle θ, and tangential stresses $\sigma_{\rho\theta}$, $\sigma_{\varphi\theta}$ and deformations $\varepsilon_{\varphi\theta}$, $\varepsilon_{\rho\theta}$ are equal to zero.

Thus, system of equations becomes

$$\begin{aligned}
\frac{\partial\sigma_{\rho\rho}}{\partial\rho}+\frac{1}{\rho}\frac{\partial\sigma_{\rho\varphi}}{\partial\varphi}+\frac{\cos\varphi}{\rho\sin\varphi}\sigma_{\rho\varphi}+\frac{1}{\rho}(2\sigma_{\rho\rho}-\sigma_{\varphi\varphi}-\sigma_{\theta\theta}) &= 0,\\
\frac{\partial\sigma_{\rho\varphi}}{\partial\rho}+\frac{1}{\rho}\frac{\partial\sigma_{\varphi\varphi}}{\partial\varphi}+\frac{3}{\rho}\sigma_{\rho\varphi}+\frac{\cos\varphi}{\rho\sin\varphi}(\sigma_{\varphi\varphi}-\sigma_{\theta\theta}) &= 0.
\end{aligned} \tag{1}$$

The displacements of the spherical layer are given with projections of the displacement vector $(w,\, u,\, v)$ in directions ρ, φ and θ correspondingly. For axisymmetrilc problem $v = 0$. The relations for deformations and displacements of the spherical layer are the following [1]

$$\varepsilon_{\rho\rho} = \frac{\partial w}{\partial \rho},\;\; \varepsilon_{\varphi\varphi} = \frac{1}{\rho}\frac{\partial u}{\partial \varphi} + \frac{w}{\rho},\;\; \varepsilon_{\theta\theta} = \cot\varphi\frac{u}{\rho} + \frac{w}{\rho},\;\; \varepsilon_{\rho\varphi} = \frac{1}{2}\left(\frac{1}{\rho}\frac{\partial w}{\partial \varphi} - \frac{u}{\rho} + \frac{\partial u}{\partial \rho}\right). \tag{2}$$

Next consider constitutive relations for stresses and deformations. For the orthotropic media they contain 9 independent elastic moduli: E_ρ, E_φ, E_θ — Young moduli, $\nu_{\varphi\rho}$, $\nu_{\theta\rho}$, $\nu_{\theta\varphi}$, — Poisson ratios, $G_{\rho\varphi}$, $G_{\varphi\theta}$, $G_{\rho\theta}$ — shear moduli [6]

$$\begin{aligned}
\varepsilon_{\rho\rho} &= \frac{1}{E_\rho}\sigma_{\rho\rho} - \frac{\nu_{\rho\varphi}}{E_\varphi}\sigma_{\varphi\varphi} - \frac{\nu_{\rho\theta}}{E_\theta}\sigma_{\theta\theta}, \qquad \varepsilon_{\rho\theta} = \sigma_{\rho\theta}/G_{\rho\theta},\\
\varepsilon_{\varphi\varphi} &= -\frac{\nu_{\varphi\rho}}{E_\rho}\sigma_{\rho\rho} + \frac{1}{E_\varphi}\sigma_{\varphi\varphi} - \frac{\nu_{\varphi\theta}}{E_\theta}\sigma_{\theta\theta}, \quad \varepsilon_{\varphi\theta} = \sigma_{\varphi\theta}/G_{\rho\theta},\\
\varepsilon_{\theta\theta} &= -\frac{\nu_{\theta\rho}}{E_\rho}\sigma_{\rho\rho} - \frac{\nu_{\theta\varphi}}{E_\varphi}\sigma_{\varphi\varphi} + \frac{1}{E_\theta}\sigma_{\theta\theta}, \quad \varepsilon_{\rho\varphi} = \sigma_{\rho\varphi}/G_{\rho\varphi}.
\end{aligned} \tag{3}$$

Due to symmetry of relations (3) the following equalities are valid

$$E_\varphi\nu_{\varphi\rho} = E_\rho\nu_{\rho\varphi}, \quad E_\varphi\nu_{\varphi\theta} = E_\theta\nu_{\theta\varphi}, \quad E_\theta\nu_{\theta\rho} = E_\rho\nu_{\rho\theta}. \tag{4}$$

Introduce new constants [6]

$$\begin{gathered}
\nu^*_{\varphi\theta} = \frac{\nu_{\varphi\theta} + \nu_{\varphi\rho}\nu_{\rho\theta}}{1 - \nu_{\theta\rho}\nu_{\rho\theta}}, \quad \nu^*_{\varphi\rho} = \frac{\nu_{\varphi\rho} + \nu_{\varphi\theta}\nu_{\theta\rho}}{1 - \nu_{\theta\rho}\nu_{\rho\theta}}, \quad \nu^*_{\theta\varphi} = \frac{\nu_{\theta\varphi} + \nu_{\theta\rho}\nu_{\rho\varphi}}{1 - \nu_{\varphi\rho}\nu_{\rho\varphi}},\\
\nu^*_{\theta\rho} = \frac{\nu_{\theta\rho} + \nu_{\theta\varphi}\nu_{\varphi\rho}}{1 - \nu_{\varphi\rho}\nu_{\rho\varphi}}, \quad \nu^*_{\rho\varphi} = \frac{\nu_{\rho\varphi} + \nu_{\theta\varphi}\nu_{\rho\theta}}{1 - \nu_{\varphi\theta}\nu_{\theta\varphi}}, \nu^*_{\rho\theta} = \frac{\nu_{\rho\theta} + \nu_{\varphi\theta}\nu_{\rho\varphi}}{1 - \nu_{\varphi\theta}\nu_{\theta\varphi}},
\end{gathered} \tag{5}$$

$$\begin{gathered}
E^*_\varphi = E_\varphi/\left(1 - \nu^*_{\varphi\theta}\nu_{\theta\varphi} - \nu^*_{\varphi\rho}\nu_{\rho\varphi}\right), \qquad E^*_\theta = E_\theta/\left(1 - \nu^*_{\theta\varphi}\nu_{\varphi\theta} - \nu^*_{\theta\rho}\nu_{\rho\theta}\right),\\
E^*_\rho = E_\rho/\left(1 - \nu^*_{\rho\theta}\nu_{\theta\rho} - \nu^*_{\rho\varphi}\nu_{\varphi\rho}\right),
\end{gathered} \tag{6}$$

where

$$E^*_\rho\nu^*_{\rho\varphi} = E^*_\varphi\nu^*_{\varphi\rho}, \quad E^*_\varphi\nu^*_{\varphi\theta} = E^*_\theta\nu^*_{\theta\varphi}, \quad E^*_\theta\nu^*_{\theta\rho} = E^*_\rho\nu^*_{\rho\theta}. \tag{7}$$

Substituting (3) and (2) into (1) and taking into account (5)–(7) we get equilibrium equations in displacements as

$$\begin{aligned}
c_0\frac{\partial^2 w}{\partial\rho^2} + c_1\frac{\partial w}{\partial\rho} + c_2\frac{\partial^2 w}{\partial\varphi^2} + c_3\frac{\partial w}{\partial\varphi} + c_4 w + c_5\frac{\partial^2 u}{\partial\rho\,\partial\varphi} + c_6\frac{\partial u}{\partial\rho} + c_7\frac{\partial u}{\partial\varphi} + c_8 u &= 0,\\
d_0\frac{\partial^2 u}{\partial\rho^2} + d_1\frac{\partial u}{\partial\rho} + d_2\frac{\partial^2 u}{\partial\varphi^2} + d_3\frac{\partial u}{\partial\varphi} + d_4 u + d_5\frac{\partial^2 w}{\partial\rho\,\partial\varphi} + d_6\frac{\partial w}{\partial\rho} + d_7\frac{\partial w}{\partial\varphi} + d_8 w &= 0,
\end{aligned} \tag{8}$$

where expressions for c_i and d_i are listed in Appendix.

2.2 Boundary conditions

We consider the quarter of the spherical layer, i.e. domain $0 \leqslant \varphi \leqslant \dfrac{\pi}{2}$ and $R_1 \leqslant \rho \leqslant R_2$.

On the boundary $\varphi = 0$ and $\varphi = \dfrac{\pi}{2}$ we assume

$$u(\rho,0) = u\left(\rho,\frac{\pi}{2}\right) = 0, \quad \frac{\partial u}{\partial \varphi}(\rho,0) = \frac{\partial u}{\partial \varphi}\left(\rho,\frac{\pi}{2}\right) = 0, \quad \frac{\partial w}{\partial \varphi}(\rho,0) = \frac{\partial w}{\partial \varphi}\left(\rho,\frac{\pi}{2}\right) = 0. \quad (9)$$

On the boundary $\rho = R_1$ and $\rho = R_2$ we suppose that the normal pressure $P_1,\ P_2$ is given

$$\sigma_{\rho\rho}(R_1,\varphi) = -P_1, \qquad \sigma_{\rho\rho}(R_2,\varphi) = -P_2 \quad (10)$$

where

$$\sigma_{\rho\rho} = E^*_\rho \left(\frac{\partial w}{\partial \rho} + \frac{\nu^*_{\rho\varphi} + \nu^*_{\rho\theta}}{\rho} w + \frac{\nu^*_{\rho\varphi}}{\rho}\frac{\partial u}{\partial \varphi} + \frac{\nu^*_{\rho\theta}\cot(\varphi)}{\rho} u \right).$$

Equations (8) and boundary conditions (9)–(10) provide the boundary value problem.

2.3 Restrictions on elastic constants

As we mention above the descriptions of the orthotropic material requires 9 independent elastic moduli. However, due to the positive definiteness of the elastic potential its coefficient must satisfy Sylvester criterion, from which the following inequalities may be found [6]

$$\begin{aligned} &\nu_{\rho\varphi} < \sqrt{E_\varphi/E_\rho}, \qquad \nu_{\rho\theta} < \sqrt{E_\theta/E_\rho}, \qquad \nu_{\varphi\theta} < \sqrt{E_\theta/E_\varphi}, \\ &\nu_{\rho\varphi}\nu_{\varphi\theta}\nu_{\theta\rho} < 1/2\left(1 - \nu^2_{\rho\varphi}E_\rho/E_\varphi - \nu^2_{\varphi\theta}E_\varphi/E_\theta - \nu^2_{\theta\rho}E_\theta/E_\rho\right). \end{aligned} \quad (11)$$

3 SLIGHTLY ORTHOTROPIC MATERIAL. PERTURBATION METHOD

Consider that the elastic modulus in the circumferential direction is little different from the modulus in the meridional direction. We assume that the following relations for the material elastic constants are valid

$$\begin{aligned} &E_\rho = E_1,\ E_\varphi = E,\ E_\theta = E(1+\mu),\ \nu_{\theta\varphi} = \nu,\ \nu_{\varphi\rho} = \nu_{\theta\rho} = \nu_1. \\ &G_{\varphi\theta} = G + \mu G' = \frac{E}{2(1+\nu)} + \mu G',\ G_{\rho\varphi} = G_1,\ G_{\rho\theta} = G_1 + \mu G'', \end{aligned}$$

where $\mu \ll 1$. For $\mu = 0$ the material becomes transverse isotropic.

In this case the limitations on elastic modulii (11) are

$$\nu < \frac{1}{1+\mu}, \qquad \nu_1 < \sqrt{\frac{E_1}{E}} \cdot \min\left(1, \sqrt{\frac{1}{1+\mu}}, \sqrt{\frac{1+\mu-\nu^2}{(1+\mu)(2+\mu+2\nu)}}\right). \quad (12)$$

The domain of the material parameters (μ, ν, ν_1) is plotted in Fig. 2

Solution of equation (8) we seek in the form

$$w(\rho,\varphi) = w_0(\rho) + \mu w_1(\rho,\varphi) + O(\mu^2), \qquad u(\rho,\varphi) = \mu u_1(\rho,\varphi) + O(\mu^2).$$

Equation of zeroth approximation for function $w_0(\rho)$ have been considered in [4]. This is equation for the transversely isotropic layer. We report shortly the results of [4] in next section.

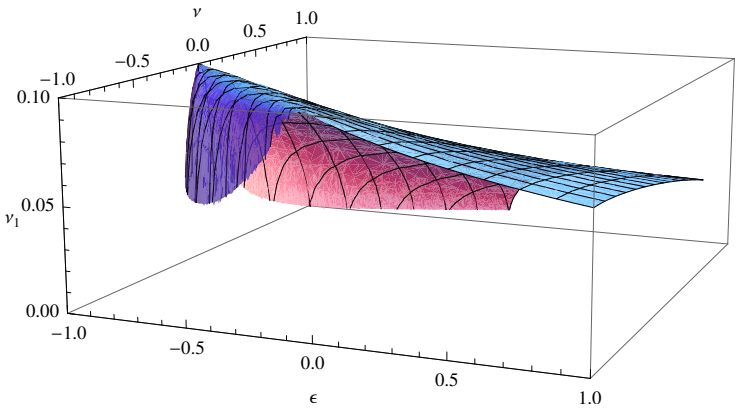

Figure 2: The domain of the elastic moduli (μ, ν, ν_1) for $E/E_1 = 0.01$.

4 EQUATION OF ZEROTH APPROXIMATION

For zeroth approximation the equilibrium equations for the normal displacement may be reduced to a single equation in the form

$$w_0''(\rho) + \frac{2}{\rho} w_0'(\rho) - 2\frac{E(1-\nu_1)}{E_1(1-\nu)\rho^2} w_0(\rho) = 0, \tag{13}$$

and boundary conditions are

$$2EE_1\nu_1 w(R_i) + E_1^2(1-\nu)w'(R_i)R_i = -P_i R_i \left(E_1(1-\nu) - 2E\nu_1^2\right), \qquad i = 1, 2.$$

The restrictions on elastic constants becomes

$$\nu < 1, \qquad \nu_1 < \sqrt{\frac{E_1}{E}} \cdot \min\left(1, \sqrt{\frac{1-\nu}{2}}\right),$$

and since for all known materials $\nu > -1$ then $\sqrt{\dfrac{1-\nu}{2}} < 1$. This problem has an exact analytical solution obtained in [2, 3], but formulas for the displacement w and stress functions are rather complicated. That is why it is more convenient to use an asymptotic approach to analyze the effect of the parameters of the spherical layer on the stress-strain state of the layer.

4.1 Asymptotic analysis

For the layer, which is much softer in the transverse direction than in the tangential surface we assume $E_1 = \varepsilon^2 E$. $\nu_1 = \varepsilon^\alpha \nu_1^*$, where $\varepsilon \ll 1$, $\nu_1^* \approx 1$, $\alpha \geq 1$. In the further analysis $\alpha = 1$. The equation for the normal displacement becomes

$$\varepsilon^2 w_0''(\rho)\rho^2 + 2\varepsilon^2 \rho w_0'(\rho) - (a + b\varepsilon) w_0(\rho) = 0, \tag{14}$$

where $a = \dfrac{2}{1-\nu}$; and $b = -\dfrac{2\nu_1^*}{1-\nu}$, and the boundary conditions are

$$\varepsilon f w(R_i) + \varepsilon^2 g w'(R_i) R_i = -c p_i R_i, \qquad i = 1, 2. \tag{15}$$

Here $p_i = P_i/E$, $c = (1 - \nu - 2\nu_1^{*2})$, $f = 2\nu_1^*$, $g = 1 - \nu$. To solve singularly perturbed equation (14) we follow [7] and seek a solution in the form

$$w(\rho) = e^{\frac{1}{\varepsilon}\int_0^\rho \lambda(t)dt}(w_0(\rho) + \varepsilon w_1(\rho) + \cdots). \tag{16}$$

After substitution in (14) and equating the coefficients at ε^k to zero we obtain a system of equations for the unknowns $\lambda(\rho), w_0(\rho), w_1(\rho), \ldots$

$$\begin{aligned} &w_0(\rho)(-a+\rho^2\lambda^2(\rho))=0,\\ &2\rho^2 w_0'(\rho)\lambda'(\rho)+w_0(\rho)(-b+2\rho\lambda'(\rho)-\rho^2\lambda''(\rho))=0,\\ &\ldots \end{aligned} \tag{17}$$

The solution of the first equation gives $\lambda(\rho)=\pm\dfrac{\sqrt{a}}{\rho}$ and the solution of the second equation is

$$w_0(\rho)=\rho^\beta, \qquad \beta=\frac{1}{2}\left(\pm\frac{b}{\sqrt{a}}-1\right).$$

So, for the first approximation we get

$$w(\rho)=A\rho^{\gamma_1}+B\rho^{\gamma_2}, \tag{18}$$

where $\gamma_{1,2}=\pm\dfrac{\sqrt{a}}{\varepsilon}+\dfrac{1}{2}\left(\pm\dfrac{b}{\sqrt{a}}-1\right)$. Constants A and B may be found from the boundary conditions

$$A=-\frac{c}{\varepsilon}\frac{R_1G_1p_1-R_2G_2p_2}{F^+(G_1^2-G_2^2)}, \qquad B=-\frac{c}{\varepsilon}\frac{G_1G_2(R_2G_1p_2-R_2G_2p_1)}{F^-(G_1^2-G_2^2)}$$

where $F^\pm=\sqrt{a}g\pm f$ and $G_i=R_i^{\sqrt{a}/\varepsilon}$. The change of the layer thickness is obtained using formula for the normal displacement

$$\Delta h=\frac{w(R_2)-w(R_1)}{R_2-R_1}$$

or

$$\Delta h=-\frac{c}{\varepsilon}\frac{p_1R_1(F^+G_2-F^-G_1)+p_2R_2(F^-G_2-F^+G_1)}{(F^-F^+(G_1+G_2))(R_2-R_1)} \tag{19}$$

4.2 Examples and applications

Further simplification of the formula for the change of the layer thickness is based on the assumptions on ratio of the values R_1 and R_2. For example, for the thick layer $R_1 \ll R_2$, then $\xi=R_1/R_2 \ll 1$ ($\xi \ll 1$) and $G_1 \ll G_2$. In this case the first approximation for Δh has the form

$$\Delta h=-\frac{c}{\varepsilon}\frac{p_1\xi F^+ + p_2F^-}{(F^+F^-)(1-\xi)}. \tag{20}$$

For the thin layer $R_1 \approx R_2$. In this case

$$\Delta h=-\frac{c}{\varepsilon\eta}\frac{p_1(1-\eta)(F^+-F^-(1-\eta)^\varkappa)+p_2(F^--F^+(1-\eta)^\varkappa)}{F^-F^+(1+(1-\eta)^\varkappa)},$$

where $R_1=(1-\eta)R_2$ ($\eta=1-\xi \ll 1$), $\varkappa=\sqrt{a}/\varepsilon$.

Let consider as an example the scleral shell with parameters [8] $\nu=0.48$, $P_1=p\times 133.3$ Pa, $P_2=0$ Pa, $E=14$ MPa, $\nu_1^*=0.5$, Here $p=20$ is the intraocular pressure in mm Hg. The change of the layer thickness as a function of ε is represented in Fig. 3 for thick layer ($\eta=0.7$) (left) and for thin layer ($\eta=0.04$) (right).

The change of the layer thickness as a function of ε and $\xi=R_1/R_2$ is represented in Fig. 4

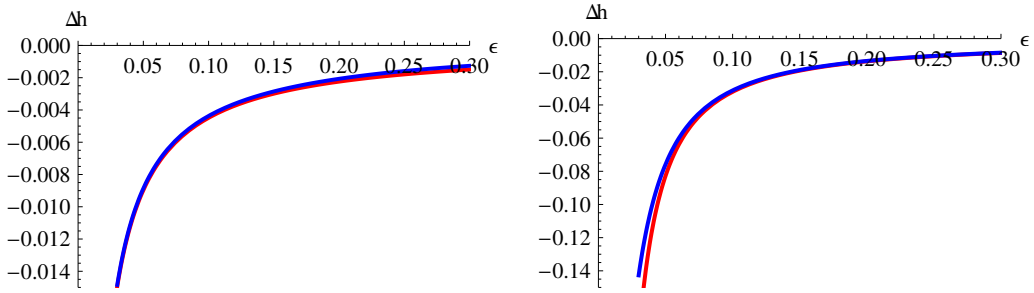

Figure 3: The change of the layer thickness vs. ε (the exact solution (blue line), the asymptotic solution (red line)).

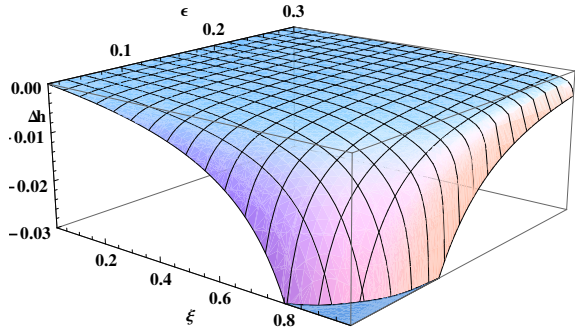

Figure 4: The change of the layer thickness as a function of ε and $\xi = R_1/R_2$.

.

5 EQUATIONS OF FIRST APPROXIMATION

For the first approximation we get equations

$$m_0\frac{\partial^2 w_1}{\partial\rho^2}+m_1\frac{\partial w_1}{\partial\rho}+m_2\frac{\partial^2 w_1}{\partial\varphi^2}+m_3\frac{\partial w_1}{\partial\varphi}+m_4 w_1+m_5\frac{\partial^2 u_1}{\partial\rho\,\partial\varphi}+m_6\frac{\partial u_1}{\partial\rho}+$$
$$+m_7\frac{\partial u_1}{\partial\varphi}+m_8 u_1+m_9 w_0=0, \qquad (21)$$
$$n_0\frac{\partial^2 u_1}{\partial\rho^2}+n_1\frac{\partial u_1}{\partial\rho}+n_2\frac{\partial^2 u_1}{\partial\varphi^2}+n_3\frac{\partial u_1}{\partial\varphi}+n_4 u_1+n_5\frac{\partial^2 w_1}{\partial\rho\,\partial\varphi}+n_6\frac{\partial w_1}{\partial\varphi}+$$
$$+n_7\frac{\partial w_0}{\partial\rho}+n_8 w_0=0,$$

where expressions for m_i and n_i are listed in Appendix and boundary conditions

$$u_1\big|_{\varphi=0}=u_1\big|_{\varphi=\pi/2}=0,\quad \frac{\partial u_1}{\partial\varphi}\Big|_{\varphi=0}=\frac{\partial u_1}{\partial\varphi}\Big|_{\varphi=\pi/2}=0,\quad \frac{\partial w_1}{\partial\varphi}\Big|_{\varphi=0}=\frac{\partial w_1}{\partial\varphi}\Big|_{\varphi=\pi/2}=0, \qquad (22)$$

and

$$\sigma^1_{\rho\rho}(R_1,\varphi)=\sigma^1_{\rho\rho}(R_2,\varphi)=0, \qquad (23)$$

where

$$\sigma^1_{\rho\rho}=l_0\frac{\partial w_1}{\partial\rho}+l_1 w_1+l_2\frac{\partial w_0}{\partial\rho}+l_3 w_0+l_4\frac{\partial u_1}{\partial\varphi}+l_5 u_1,$$

and

$$l_0 = 1, \quad l_1 = \frac{2}{\rho}\frac{E\nu_1}{E_1(1-\nu)}, \quad l_2 = \frac{E\nu_1^2}{(1-\nu)(E_1(1-\nu)-2E\nu_1^2)}, \tag{24}$$
$$l_3 = \frac{l_2}{\nu_1\rho}, \quad l_4 = \frac{E\nu_1}{E_1(1-\nu)\rho}, \quad l_5 = l_4\cot(\varphi).$$

So, the boundary value problem for the first approximation consists of equations (21) and boundary conditions (22)–(23). We note, that the change of the shear moduli (G',G'') do not effect equations and boundary conditions of the first approximation.

Figure 5 depicts deformed orthotropic layer for two different ratio of E_θ/E_φ. The layer parameters are taken as follows $R_2 = 12$ mm, $R_1 = 0.9R_2$, $E_\varphi = E = 14$ MPa, $E_\rho = E_1 = 1.26$ MPa, $\nu = 0.48$, $\nu_1 = 0.03$. The inner boundary $\rho = R_1$ is subjected to normal pressure $P_1 = 20 \times 133.3$ Pa.

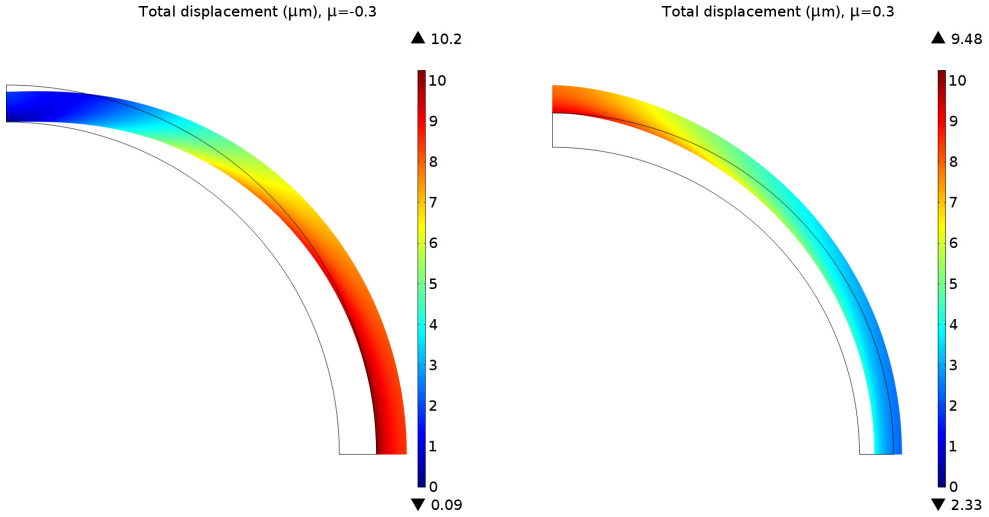

Figure 5: Deformed orthotropic layer with $E_\theta/E_\varphi = 0.7\,(\mu = -0.3)$ and $E_\theta/E_\varphi = 1.3\,(\mu = 0.3)$.

6 CONCLUSIONS

1. For transversely isotropic material the asymptotic formula describing the change of the layer thickness under normal pressure is obtained. Asymptotic relations show that for deformation of the spherical layer under the inner pressure the relative thickness varies more for the layer with smaller thickness.

2. The change of the scleral thickness under intraocular pressure (IOP) well agree with clinical data on decrease of scleral thickness in primary open-angle glaucoma (POAG) [8]. POAG is an eye disease, which is generally accompanied by the IOP increase.

Abstract. *The aim of this paper is to assess the degree of accuracy in modelling the dynamic behaviour of reinforced concrete beams with and without discontinuities. Finite element models of three damaged and undamaged reinforced concrete beams were developed in Abaqus combining solid and beam elements and experimentally validated using experimental modal analysis. For the undamaged beams the agreement between the lowest 24 eigenfrequencies from the models and the measurements were within ≈3 %. For the damaged beams, the agreement was within 4 % above the lowest axial mode, whereas the errors were up to 10 % below the lowest axial mode. The validated finite element models will be used for further studies on the dynamic behaviour of collapsed reinforced concrete buildings.*

1 INTRODUCTION

Every few years an earthquake of high magnitude occurs around the globe leading in collapsed structures with people trapped inside them. When victims are trapped inside a collapsed building, the challenge is to detect and locate survivors within a period of time that will allow them to be rescued. The majority of documented live rescues are accomplished within the first 5 to 6 days [1]. However, important variables affect the survivability including the structure type and void space formation, the cause of the structural collapse, the survival location in the building and the speed and sophistication of available search and rescue capabilities [2].

Airborne sound from survivors tends to be highly attenuated by layers of rubble and requires the existence of air paths for propagation to the surface. For this reason there is greater potential to detect physical movement or signals by measuring vibration due to structure – borne sound (i.e. seismic research method). In a seismic search, a small number of seismic sensors are moved over a regular grid so that the operators can be certain they have searched the entire site. The placement and positioning of these sensors is critical for the successful detection of the survivors. However, grid spacing and sensor placement are often decided simply by checking whether it is possible to detect transients generated by the operators in an adjacent grid area on the surface in places where the structure is safe to walk [3]. This can be misleading because horizontal propagation of vibration across the surface of a collapsed structure is only vaguely indicative of propagation into the depths of a collapsed structure.

This research forms part of a PhD project which is funded by the EPSRC and concerns an approach to search for human survivors using structure-borne sound propagation in collapsed and fragmented structures through the development, validation and use of theoretical models. The aim in this paper is to assess the degree of accuracy in modelling the dynamic behaviour of damaged and undamaged one-dimensional reinforced concrete building elements. Experimental modal analysis is carried out on three reinforced concrete beams with and without discontinuities and the results are used for the validation of finite element models.

2 METHODS

2.1 Test specimens

The experimental samples consist of three reinforced concrete beams (C25/30, S500) with the same dimensions (2.4 m length, 0.2 m width and 0.3 m depth). The beams are reinforced with four longitudinal steel bars of 16 mm diameter and transverse reinforcement consisting of 8 mm diameter stirrups placed at 200 mm centres along the beams (see Figure 1). Three beams were measured: Beam 1 - an undamaged beam, Beam 2 - a beam with a 100 mm discontinuity in one position and Beam 3 - a beam with two 100 mm discontinuities in two positions. Figure 1 shows the structural details of the three reinforced concrete beams.

The discontinuities on beams 2 and 3 were formed by using a diamond saw to cut out the concrete. This also introduced cuts into some of the longitudinal steel bars which randomly reduced their cross-sectional area by 15 to 60%. These cuts into the steel bars are located at the beginning and end of each discontinuity zone (see Figure 2) and increased the uncertainty in the Abaqus models.

Table 1 gives the weight of each reinforced concrete beam that was measured using a crane scale.

Beam	Weight [Kg]
1	352.0
2	330.8
3	322.6

Table 1. Beam weights.

Figure 2. Example of the reduction in the cross-section of a steel bar caused by a diamond saw cut

.

2.2 Experimental work

Experimental modal analysis was carried out on the three reinforced concrete beams in order to identify their dynamic characteristics (i.e. eigenfrequencies and modeshapes). The beams were suspended using polyester slings from an overhead crane in order to approximate a beam with free – free boundary conditions as the sling was assumed to have negligible effect on the dynamic response (Figure 3).

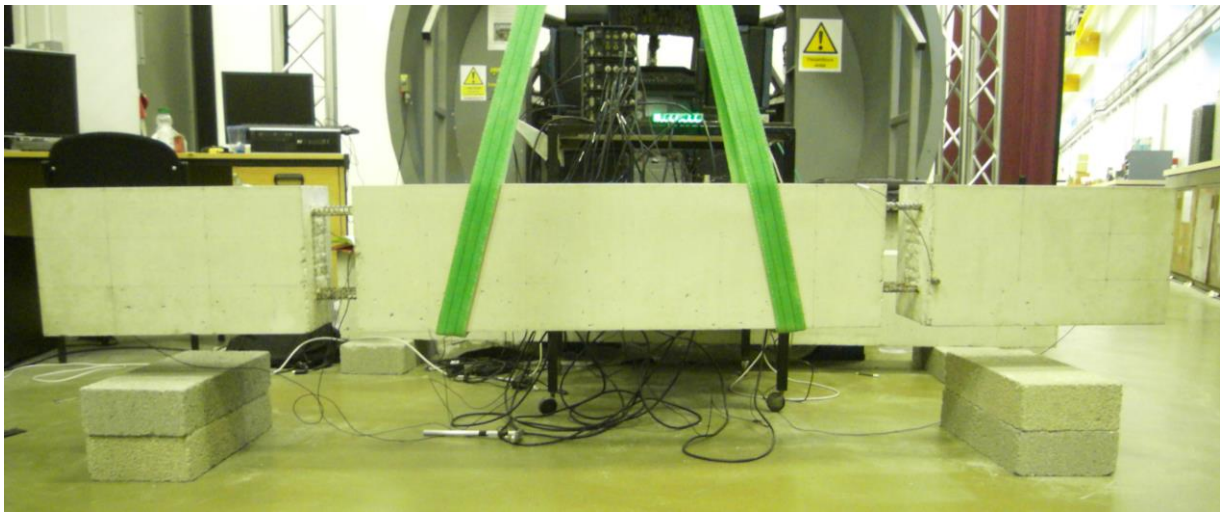

Figure 3 Test setup showing the test equipment and the polyester slings that approximate the free-free boundary condition for Beam 3

The beams were excited using a Brüel & Kjær Type 8200 impact hammer and the response on beams 1, 2 and 3 was measured using three, six and nine Brüel & Kjær Type 4371 accelerometers respectively. The transducers were connected to a Brüel & Kjær Type 3050-A-060 FFT analyser via a Type 2692 Nexus Conditioning Amplifier. The commercial software Brüel & Kjær Pulse Reflex was used for signal processing and the modal analysis. The accelerometers remained at fixed positions whilst the impact hammer was moved along a mesh of excitation points with spacing of 0.15m or 0.2m along the length and 0.1m in the other two directions. It is noted that only the concrete parts of the beams were excited. The total number of excited degrees of freedom was 206, 244 and 282 for beams 1, 2 and 3 respectively.

2.3 Finite element modelling

Finite element models of the three reinforced concrete beams were developed in Abaqus [4] and eigenfrequency analysis was carried out to define their dynamic characteristics (eigenfrequencies and modeshapes).

The solid element C3D20R (20 nodes) and the beam element B32 (3 nodes) were selected from the element library of Abaqus to model the concrete and the steel bars respectively. Both elements were selected to have interpolation functions of the same order (quadratic) to avoid accuracy issues [5]. This technique of combining three–dimensional (solid) with one dimensional (truss or beam) elements for modelling reinforced concrete members is well-established in the finite element analysis literature [6, 7]. A finite element mesh with dimensions of 25 mm in the longitudinal and 20 mm in the other two directions resulted in 27 elements per wavelength for the concrete and 8 elements per wavelength for the steel bars, at 3200 Hz.

This mesh density fulfils the requirement for at least 6 quadratic elements per wavelength in structural and vibroacoustic problems [8].

For the models of Beams 2 and 3 the discontinuities were formed by removing the appropriate number of solid and beam elements in each discontinuity zone (Figure 4). This approach was an efficient way of creating discontinuities in different positions of the beams without re-meshing.

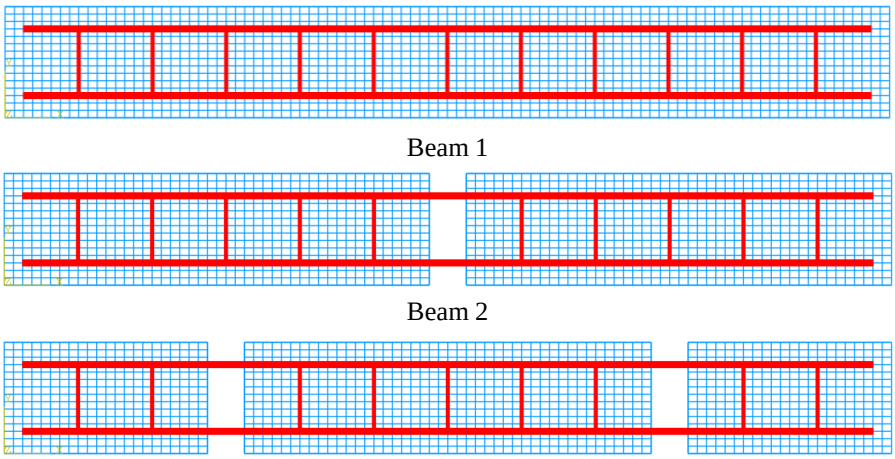

Figure 4. Finite element modeling of the reinforced concrete beams using solid and beam elements.

In order to investigate the influence of the steel cuts in the dynamic behavior of beams 2 and 3, local sectional area reduction zones of 2 mm length were modelled in Abaqus where generalized sections were used to approximate the profile properties.

Table 2 shows the physical and mechanical properties of the materials used in the models. The material properties of the steel and Poisson's ratio of the concrete were taken from the literature [9, 10]. The density of the concrete for each beam was defined by dividing the weight of the beams by their volume after extracting the weight of the steel reinforcement.

The Young's modulus of the concrete, E_c was estimated after model updating against the experimental results. Numerical trials with different Young's modulus, E_c were carried out for beam 1 up to the stage where the first numerical eigenmode had 0% difference against the first experimental eigenmode in terms of eigenfrequencies. The estimated value of the Young's modulus is relatively high but it is inside the range that is proposed in the literature for C25/30 concrete [11].

Material	Density, ρ [Kg/m^3]		Young's modulus, E [N/m^2]	Poisson's ratio, v
Concrete	Beam 1	2328.7	36875E06	0.2
	Beam 2	2277.8		
	Beam 3	2320.8		
Steel	7800		200E09	0.3

Table 2. Material properties.

3 RESULTS

In this section the mode pairs are characterized according to their mode shape as being either bending (B), torsional (T) or axial (A) modes. Table 3 compares the results of the finite element analysis against the experimental results for Beam 1 in terms of eigenfrequencies.

Mode type	Mode pair	Experimental modal analysis [Hz]	FEM [Hz]	Difference [%]
B	1	138.19	138.19	0.00
B	2	209.57	205.59	1.90
B	3	366.30	365.72	0.16
T	4	447.96	446.14	0.41
B	5	529.20	521.30	1.49
B	6	684.87	680.10	0.70
A	7	861.64	838.87	2.64
T	8	896.33	892.54	0.42
B	9	944.14	927.07	1.81
B	10	1069.14	1057.70	1.07
T	11	1343.43	1339.40	0.30
B	12	1408.26	1382.50	1.83
B	13	1499.09	1480.10	1.27
A	14	1721.10	1675.70	2.64
T	15	1799.68	1787.00	0.70
B	16	1902.95	1864.40	2.03
B	17	1961.47	1933.30	1.44
T	18	2253.04	2235.30	0.79
B	19	2410.26	2358.00	2.17

A	21	2577.19	2507.70	2.70
T	22	2709.78	2684.40	0.94
B	23	2920.24	2853.10	2.30
B	24	2948.11	2893.70	1.85

Table 3. Comparison between experimental modal analysis and FEM in terms of eigenfrequencies – Type A1 beam. (B, T and A correspond to bending, torsional and axial modes respectively).

Figure 5 and Figure 6 show the percentage difference between experimental and FEM eigenfrequencies for the 26 and 28 mode pairs of beams 2 and 3 respectively.

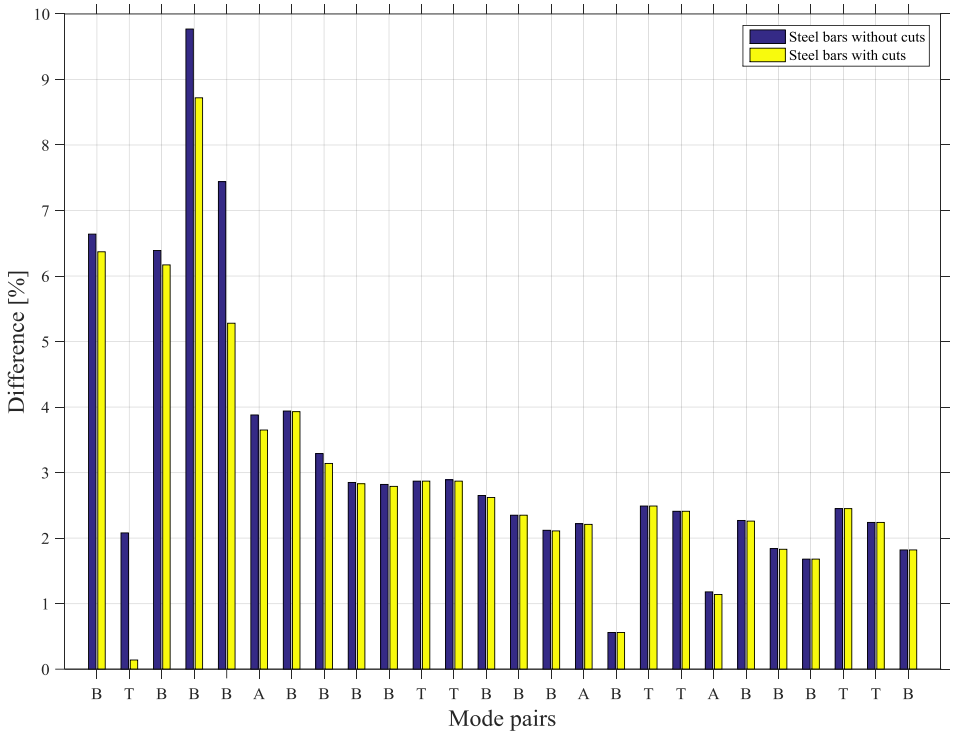

Figure 5. Percentage difference between FEM and experimental eigenfrequencies for beam 2 (B, T and A correspond to bending, torsional and axial modes respectively). Modes are ordered from the lowest to the highest eigenfrequency from left to right.

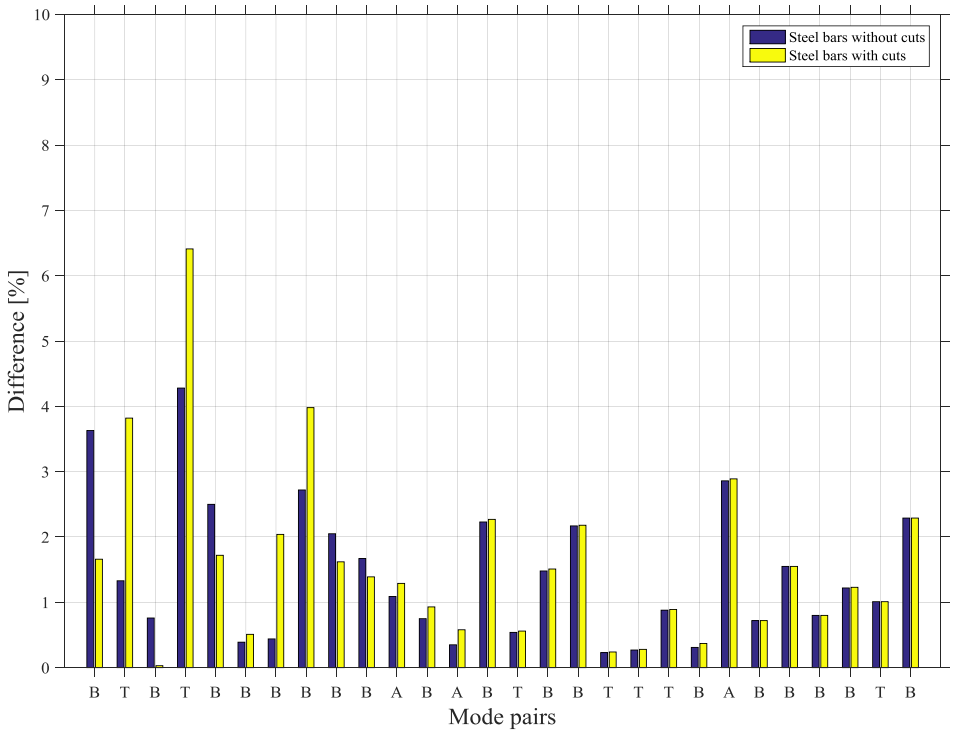

Figure 6. Percentage difference between FEM and experimental eigenfrequencies for beam 3 (B, T and A correspond to bending, torsional and axial modes respectively). Modes are ordered from the lowest to the highest eigenfrequency from left to right.

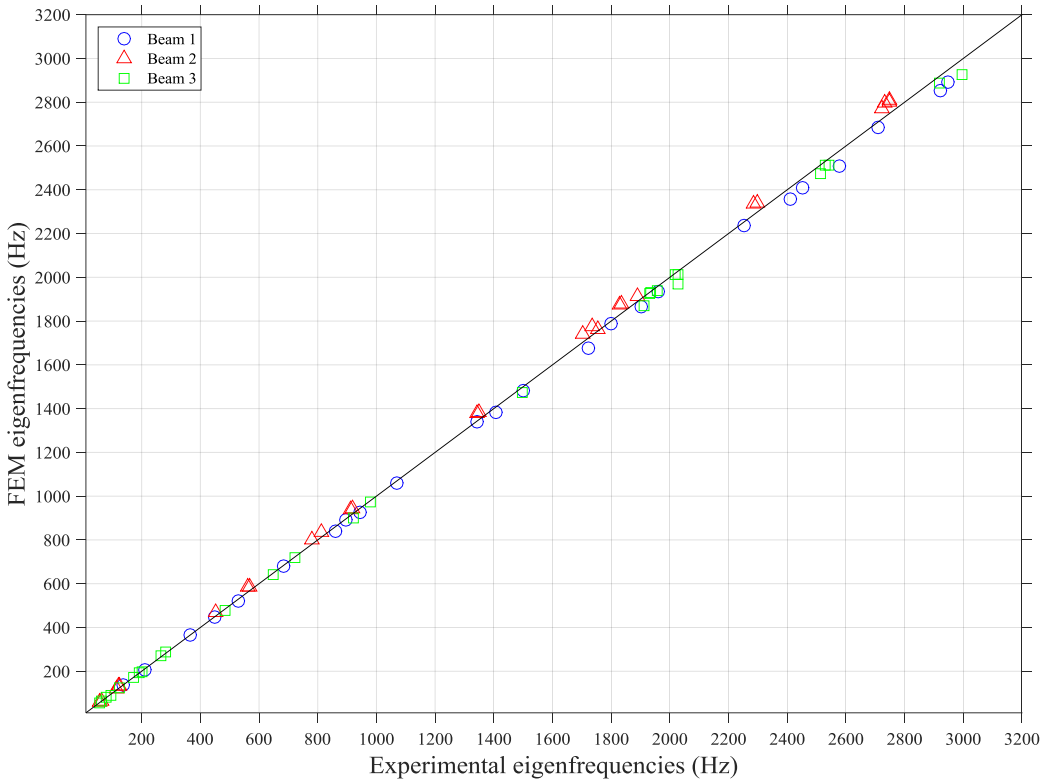

Figure 7. Comparison between experimental and FEM eigenfrequencies for beams 1, 2 and 3.

4 ANALYSIS AND DISCUSSION

In general, close agreement was achieved between FEM and experimental eigenfrequencies for all three reinforced concrete beams as indicated in Figure 7. Therefore the number of discontinuities did not significantly affect the accuracy of the finite element models in terms of their eigenfrequencies.

For beam 1, close agreement was achieved between FEM and experimental results (see Table 3). All the mode pairs in the frequency range from 1 to 3200 Hz had differences less than 3 % in terms of eigenfrequencies.

For beam 2, all the 21 mode pairs above the first axial mode (450.9 Hz) and mode pair 2, showed close agreement between FEM and the experimental results with differences in the eigenfrequencies of less than 4.0 % (see Figure 5). Higher differences occurred with mode pairs 1, 3, 4 and 5 with differences between 6 and 10 %.

For beam 3, close agreement was achieved between FEM and experimental results for all the mode pairs in the frequency range from 1 to 3200 Hz with differences less than 5 % (see Figure 6). Apart from mode pairs 1 and 4 the other pairs all showed differences below 3 %.

The effect of including the diamond saw cuts to the reinforcement bars in the FEM model of beams 2 and 3 was negligible above the first axial mode. Figure 5 and Figure 6 show that in the models with the discontinuities, the steel cuts mainly affect the modes before the first axial mode. Modelling the steel cuts improved the agreement between FEM and experimental results for beam 2 while it is not clear that including the steel cuts had a significant effect for beam 3.

5 CONCLUSIONS

Experimental work has quantified the material properties and the dynamic behavior of three reinforced concrete beams with and without discontinuities. These represent undamaged and damaged beams as might occur in a building after an earthquake.

Finite element models have been successfully validated against experimental modal analysis for these three beams. It was shown that the number of discontinuities did not significantly affect the accuracy of the predicted eigenfrequencies. For the undamaged beams the agreement between the lowest 24 eigenfrequencies from the models and the measurements were within ≈3 %. For the damaged beams, the agreement was within 4 % above the lowest axial mode, whereas the errors were up to 10 % below the lowest axial mode.

An efficient and accurate method of creating discontinuities was experimentally validated. This will inform later stages of the work where numerical experiments will be carried out to assess the influence that various patterns of discontinuities have in the dynamic behavior of one dimensional reinforced concrete members. This will allow Monte Carlo simulations to incorporate aspects of uncertainty that would exist in real fragmented buildings.

ACKNOWLEDGMENT

Keywords: shear-strength models, shear failure, axial load, drift ratio models.

Abstract. *The study reviews the existing methods for estimation of the peak and residual shear strength of columns and the main parameters that affect their shear drift capacity. Shear force effects on the behavior of the columns seem to be significant as shear influences the flexural behavior of columns and encourages failure mechanisms that are more brittle, especially for columns which are shear critical (columns over-reinforced in flexure, short columns). The methods that have been developed up until now for the estimation of shear strength vary, but in all cases contributions from separate mechanisms of resistance, namely the contribution of concrete, web reinforcement and axial load are recognized. In establishing the degradation of shear strength under seismic load reversals the decomposition of concrete cover, the diagonal strut cracking of the element and the yielding or slip of the longitudinal reinforcement are determined. Another important parameter which must be taken into account in experimental results for the calibration of previous methods in establishing the rate of strength degradation as well as the residual strength is the contribution of axial load to the load-carrying capacity loss, with increasing displacement. This phenomenon is shown to be significant and for that reason separation from the other mechanisms of degradation will be essential in revision and refinement of design expressions for shear, necessary in assessment procedures. An analytical investigation of the relationship between shear drift capacity, transverse reinforcement, aspect ratio and axial load is presented in the paper.*

Introduction

Condition assessment of an existing reinforced concrete structure is the first step towards retrofit design and strengthening. Reinforced Concrete (R.C.) columns represent the most critical components in this assessment problem, as their possible failure can place at risk the integrity of the structure and its ability to support gravity loads. Thus, dependable assessment of columns is a prerequisite for the successful redesign of a structure, and requires a good understanding and interpretation of the current condition. A critical part of this procedure is the estimation of the degraded shear strength of reinforced concrete columns after inelastic reserved cyclic displacements such as those occurring during a severe earthquake. In the context of the following investigation, performance assessment makes direct reference to the state of damage attained

by the examined member. Damage is quantified in terms of lateral drift ratio. To facilitate calculations at distinct performance limits, drift capacity is estimated at the point of shear and axial failure on the experimental envelope curve. Current methods used in design codes to estimate the extent of degradation of shear strength with increasing displacement demand are built on previous researches by Aschheim(1992), Lynn(2001), Sezen(2002) and Elwood(2003). However, collective evaluation of the available data identify that certain parameters may have a great than what was thought before effect on the overall mechanism of shear strength degradation and on the deformation capacity of the member at performance limit states; such are, the aspect ratio, the second order effects generated by axial load, and the effect of transverse reinforcement ratio on the value of drift at failure. For this reason this problem is revisited aiming for a better understanding of the relationship between shear strength, P-Δ effects, and the drift ratios at shear and axial load failure.

In particular, evaluation of the residual shear strength of a member after degradation due to excessive displacement has set-in is a focal point of this study. While the displacement increases well beyond the peak point of the resistance curve of the member, the load-carrying capacity decreases owing to a variety of reasons, several of those reflecting implicit shear failure, such as diagonal tension cracking in the web of the member, yielding of longitudinal reinforcement, excessive compressive strains in the compression zone, loss of bond strength of the longitudinal reinforcement and disintegration of the web concrete due to diagonal compression. In some situations other effects may be responsible for what is often interpreted as damage-induced strength degradation – this refers to the influence of second order effects imparted by the axial load while the deformation increases. Especially this phenomenon seems to contribute dramatically to the macroscopically observed loss of lateral resistance, and the confusions caused thereof is occasionally passed-on into the calibrated expressions for shear-strength assessment of columns (the k(μ) factor, see ASCE/SEI 41, 2007). Linked with this is the value of drift at the onset of shear and axial failure. To address this problem from the beginning, a data base of 135 old type R/C columns has been created and an algorithm is followed taking into consideration the second order effects in correcting the experimental resistance envelope curves for some of the specimens. Comparison between the existing calibrated models for the evaluation of shear strength and the results illustrates the significance of second order effects on shear strength degradation. Experimental values of shear and axial drift ratios at the corresponding limit states are compared with values obtained from the proposed models. An investigation of how the values of aspect ratio, transverse reinforcement ratio and axial load influence the values of drift ratio at the reference limit states is also included in the discussion.

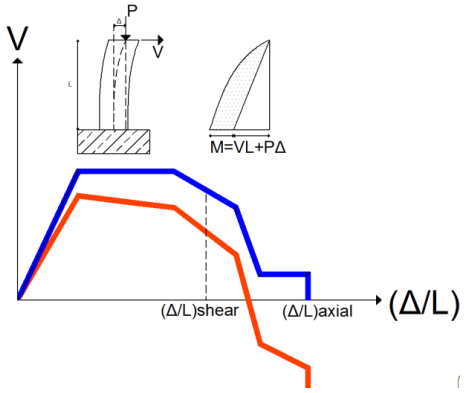

Figure 1 Schematic representation of the effects of P-Δ on the response curve of a member. Vertical axis represents the shear force required to produce a given drift magnitude (horizontal axis coordinate) if axial load is not considered (blue line) and after correction for the P- Δ effects (red line).

1 SHEAR STRENGTH

To investigate the behavior of columns under seismic shear, a data base of column tests was assembled. The data base contains columns of different cross sectional shapes, and tested under cyclic loading in single and double curvature simulating the action of earthquakes. Most of the specimens were observed to exhibit shear failure. Additionally, a small number of spiral columns were selected for study that failed in flexure. Important response parameters selected for the data base were the drift ratios at shear and axial failure, depicted in Fig. 1, and denoted as $(\Delta/L)_{shear}$ and $(\Delta/L)_{axial}$, respectively. According to the established practice in the field, the drift at shear failure is identified as the point where a 20% loss in lateral load carrying capacity is observed, whereas the drift at axial failure is associated with loss of axial load carrying capacity – i.e. collapse (this point sometimes may be identified as the final point of the envelope curve). Parameters used in the investigation were the following: the aspect ratio M/(Vd), the transverse reinforcement ratio ρ'', the average axial load ratio, $v_d=P/A_g f_c'$, the longitudinal reinforcement ratio and the material properties of the specimens. Values of the parameters for all assembled specimens are illustrated in the Table 4 in Appendix A . The specimens are categorized according to cross-section shape.

- Rectangular shaped columns
- Circular shaped columns
- L shaped columns.

The nominal shear strength of a reinforced concrete member, V_n , is estimated from the contribution of various strength components, namely, a contribution of the concrete web, V_C (comprising shear transfer over the compression zone, aggregate interlock and dowel action over the tension zone) and the contribution of transverse (web) reinforcement V_s as illustrated in Figure 3 (Elwood et al 2003). In most cases of design guidelines around the world the contribution of axial load, is either considered separately, or it is embedded in V_C.

$$V_n = V_C + V_s \tag{1}$$

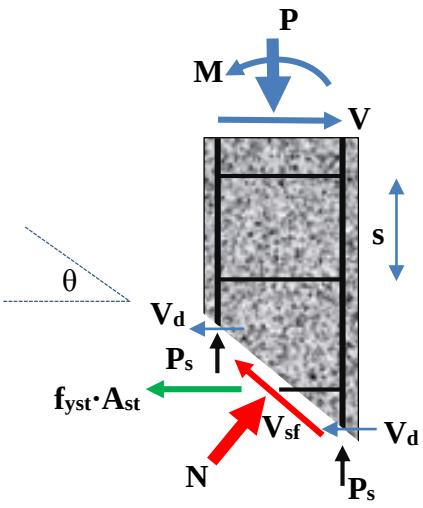

Figure 2 Components of shear force across a diagonal crack near failure (from Elwood 2003).

Because shear failure is a brittle mode of failure it is generally placed higher in the strength hierarchy scheme of capacity design, as compared to flexural failures; in the strength inequality flexural strength defines the demand for shear design of new, or the basis of assessment in existing members. As it is desirable to maintain shear demand below shear strength at least

within the range of design displacements (i.e. up to a displacement ductility of 5), strength is estimated by considering all possible forms of disintegration that may limit its magnitude. Strength reduction is effected by multiplying the nominal strength by a multiplier that accounts for the various effects that are responsible for shear strength loss, originally proposed by Aschheim and Moehle (1992) and later refined by several other researchers. Available proposals to date are listed in the table below:

Researcher	**Shear Strength Proposed Models**
Aschheim (1992), 45° truss angle corresponding to the approximate initial angle typically assumed by shear cracks	$V = V_C + V_s$; $V_C = a'(1+\frac{N_u}{2000A_g})\sqrt{f_c}bd \le 3.5\sqrt{f_c}bd$ For rectangular columns : $V_s = A_v f_{y,tr} d/s$ For spiral columns : $V_s = 2A_{sp} f_{y,tr}(0.8d_s)/s$
Lynn and Moehle (2001), 45° truss angle in this proposal. $\mu_\delta \le 1$ k=1 $1 \le \mu_\delta \le 6$ k varies from 1 and 0.7 $\mu_\delta \ge 6$ k=0.7	$V_n = kV_c + \frac{1}{2}V_c = k\frac{A_g 0.5\sqrt{f_c}}{\frac{a}{d}}\sqrt{1+\frac{P}{0.5A_g\sqrt{f_c}}} + \frac{1}{2}\frac{A_{s,tr} f_{y,tr} d}{s}$
Sezen and Moehle (2002), 45° truss (based on calibration of tests, the average truss angle is found near 55°). Parameter *k* ranges between 1.0 and 0.7 based on average shear crack angle for the test columns in the database (55°) and 45° crack angle, respectively.	$V_n = k(V_c + V_s) = k\frac{A_{s,tr} f_{y,tr} d}{s} + k\left(\frac{0.5\sqrt{f_c}}{\frac{a}{d}}\sqrt{1+\frac{P}{0.5A_g\sqrt{f_c}}}\right)0.80A_g$
Elwood and Moehle (2003), At shear failure (stirrup yielding) the truss angle is equal to **65°** or may be better approximated by $\theta = 55^o + 35^o \cdot (P/P_o)$	$V = \frac{A_{s,tr} f_{y,tr} d_c}{s}\tan\theta - P\left(\frac{25\frac{\Delta}{L}}{1+\tan^2 - \tan\theta\frac{\Delta}{L}}\right)$
Dionysis E. Biskinis, George K. Roupakias, and Michael N. Fardis(2004): from calibration of extensive database of tests. Mean values considered, $\gamma_V = 1$	$V_R = \gamma_V \cdot \left[\frac{b-c}{2L_s} min(N; 0.55A_c f_c) + (1-0.55, min(5; \mu_\Delta^{pl}))\right.$ $\left.\left[(0.16\, max(0.5; 100\rho_{tot})(1-0.16, min(5, \frac{L_s}{b}))\sqrt{f_c}A_c + V_s\right]\right]$
EC8 Part III: same as above, with $\gamma_V = 0.85$	
ASCE/SEI 41 k = 1 for $\mu \le 2$ k= 0.7 for $\mu \ge 6$ k varies linearly for $2 < \mu < 6$ λ= 0.75 for LWA concrete and 1.0 for NWA concrete.	$V_n = k\frac{A_v f_y d}{s} + \lambda k\left(\frac{0.5\sqrt{f_c}}{M/Vd}\sqrt{1+\left(\frac{N_u}{6\sqrt{f_c}A_g}\right)}\right)0.8A_g$

Table 1 Proposed Models for the evaluation of the degraded shear strength.

Notation: L=length of the column; b=column section width; h=column section height; d=depth to centerline of tension reinforcement; a= shear span; s=tie spacing; ρ_l=longitudinal reinforcement ratio ($A_{st}/(b_s)$), ρ''=transverse reinforcement ratio ($A_{st}/(bs)$); f_{yl}=longitudinal steel yield strength; f_{yt}=transverse steel yield strength ; f_c' =concrete strength; $P/(A_g * f_c')$= constant axial load; (M/(Vd))=aspect ratio; Δ/L=drift; c=neutral axis depth; A_c=web cross sectional area; μ_Δ^{pl}=plastic part of ductility demand; ρ_{tot}=total longitudinal reinforcement ratio; V_s=contribution of transverse steel; V_C=concrete web contribution

As is shown in Table 1, the shear strength models include coefficients that estimate the reduced shear strength. The strength reduction is attributed to the degradation of the concrete web which carries the shear through diagonal compressive struts. However, shear force measured in columns while conducting tests to lateral displacement (drift) history, undergoes an apparent loss of magnitude with increasing displacement, even if no web damage could be detected (e.g. in flexural response), and this is due to the second order effects of the column axial load as the longitudinal axis of the member is displaced from the reference point. This apparent reduction of column strength, *dV*, may calculated after consideration of the column in the deformed configuration. Thus, to maintain constant flexural moment at the column base, M_o, the shear force $V(\Delta)$ may be estimated from: $V(\Delta) = (M_o - P\cdot\Delta)/L = V_o - (P\cdot\Delta/L)$, thus $dV = -P\cdot\Delta/L$. Today with the vast number of available column experiments it appears that strength degradation may be overestimated, or may be insensitive to some important relevant parameters. Although behavioral factors such as diagonal cracking of concrete (flexural yielding, splicing of reinforcement in critical regions, compression buckling of longitudinal reinforcement) are the prime culprits, there is no question that second order effects consume a large fraction of the available strength giving the impression that strength loss takes place. It is actually a debated question whether the experiments used to calibrate the expressions for the degradation coefficient were corrected for *dV* before estimating the real strength loss with increasing displacement (Fardis et al.(2004), EC8, ASCE/SEI 41, Elwood and Moehle (2003), Sezen and Moehle (2002), Lynn and Moehle (2001) and Aschheim and Moehle (1992)).

In this paper this problem is revisited by studying strength loss only once after the data were systematically corrected in a uniform manner for the second order effects. The methodology followed in this process is described in detail: In order to understand the degree of influence of second order effects on shear strength, the experimental results will be compared with the results obtained from the proposed models as described in Table 1. As a first step the resistance curve was evaluated for each specimen contained in the database using established sectional analysis software (Response-2000). Next the analytical resistance envelope curve is analyzed and corrected accounting for second order effects; the corrected curve is subsequently compared with the experimental resistance envelope. Any residual difference observed between the experimental curve and the analytical curve after correction for P-Δ may be attributed to other sources of degradation such as compression softening of concrete and disintegration of the web of the member. See the figure below:

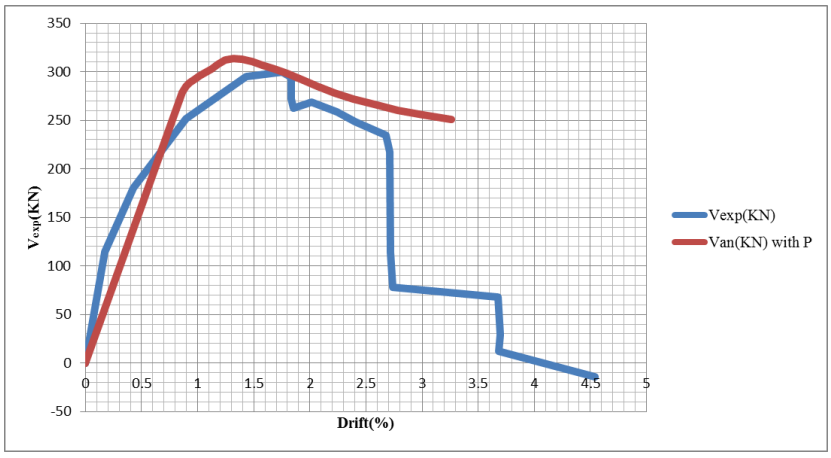

Figure 3 Comparison of the analytical envelope curve after considering the second order effects with the experimental envelope curve.

The background concept of this procedure is as follows: Ideally, a reinforced concrete member that undergoes flexural yielding without any shear degradation, would exhibit a response curve that is either elastoplastic or elastoplastic with hardening. Deviation from this ideal response may be owing to both, disintegration and P-Δ effects. Both of these components increase with deflection, however the latter of the two terms is easy to calculate given the lateral displacement of the column and the shear span length, L_s. The objective is therefore, to separate the contributions of these two sources of apparent strength loss by restructuring the total deviation of the actual response curve from its undegraded flexural response curve. Thus, the total lateral force reduction, ΔV comprises components as:

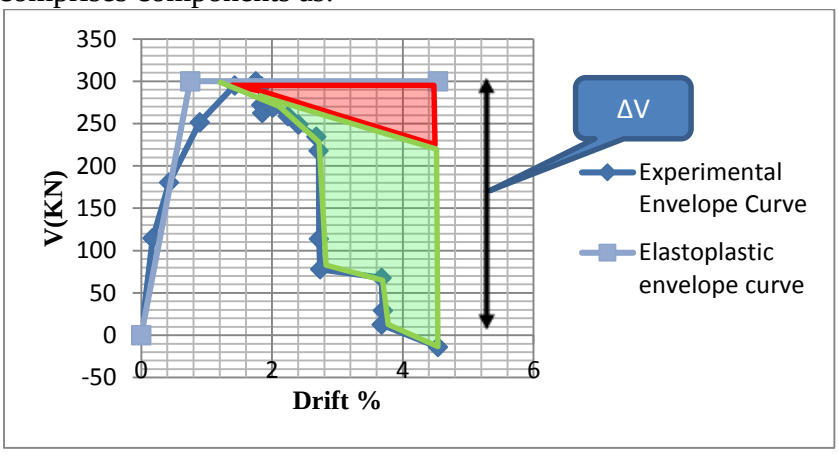

Figure 4 Difference between the elastoplastic and the experimental envelope curve. Red is the load carrying capacity occupied by P-Δ; Green is the load carrying capacity degraded (non-recoverable) due to damage.

$$\Delta V = \Delta V_{red} + \left(\frac{P\Delta}{L_s}\right) \Rightarrow \Delta V_{red} = \Delta V - \left(\frac{P\Delta}{L_s}\right) \quad (2)$$

ΔV= the difference between the elastoplastic and the experimental envelope curve
P= the axial load
Δ= the horizontal displacement
L_s = the span length of the column between the fixed support and the point of zero moment.

Therefore, a relationship is sought between the corrected shear strength degradation term, ΔV_{red}, and the drift ductility μ_θ. Figures 10 in Appendix B illustrates the graph obtained from the experimental results and the results exported from Equation 2. Figure 11 in Appendix B illustrates the comparison between $\Delta V_{red}/V_{max}$, $\Delta V/V_{max}$ with the results for normalized strength degradation as obtained from the available shear strength degradation models proposed by, Aschheim and Moehle (1992), Elwood and Moehle (2003), and Sezen and Moehle (2002). Calculation of ΔV estimated by each of the models was done according to the following procedure:

(1) Calculation of $V_{shear,max}$ for the minimum value of μ_n (ductility).
(2) For the minimum value of drift ductility μ_1 it turns out the following relationship : $V_1 = V_{max} \Rightarrow$ for μ_{v+1} is applicable $V_{n+1} \le V_{max}$
(3)Then $\Delta V = \left(\frac{V_{max} - V_{n+1}}{V_{max}}\right)$

2 SHEAR AND AXIAL DRIFT CAPACITY

Another aspect in the evaluation procedure is deformation capacity. It is established in the literature to refer to deformation capacity at the onset of shear and axial failure. Expressions have been proposed to that effect (Elwood and Moehle, 2003); these were used and the analytical results were compared with the experimental values. Expressions are obtained after empirical evaluation of the experimental database assembled by the investigators. Note that it is possible that this model may not be appropriate (applicable) for columns that were not included in the author's Database, as most of the specimens used to calibrate the expressions for the milestone drift capacities only come from a single research team. The aim of the present investigation is to calculate this shear drift capacity model for different types of columns and to observe the results.

The function used by Elwood and Moehle (2003) to estimate the drift ratio at shear failure of a column under lateral sway is as follows:

$$\left(\frac{\Delta_s}{L}\right) = \frac{3}{100} + 4\rho_t - \frac{1}{500}\frac{\nu}{\sqrt{f_c}} - \frac{1}{40}\frac{P}{A_g f_c} \geq \frac{1}{100} \quad \text{(in psi units)} \tag{3}$$

A comparison between the experimental and analytical results obtained for the shear drift capacity was conducted. The experimental shear force is compared with the value of shear force obtained from Response 2000 analysis taking into account the influence of second order effects and the aspect ratio of the member considered. A parametric investigation between transverse reinforcement ratio, axial load ratio, aspect ratio and experimental shear drift values was conducted.

Another concern is the estimation of the drift ratio at column axial failure. This is an extreme stage where the column is near imminent collapse. At this stage it is assumed that whatever residual shear strength is available to the column, this is owing to the frictional resistance that develops along the failure plane which is inclined at an angle θ from the member cross section (Fig. 2, see term V_{sf}). Based on this frictional concept,

$$V_{sf} = N\mu \tag{3}$$

The equations representing equilibrium of forces along *x* and *y* of the Free-Body Diagram of the column model depicted in Fig. 2 are as follows:

$$\Sigma F\chi \rightarrow \mathrm{N}\sin\theta + V = V_{sf}\cos\theta + \frac{\mathrm{A}_{st} f_{yt} d_c}{s}\tan\theta \tag{4}$$

$$\Sigma Fy \rightarrow P = N\cos\theta + V_{sf}\sin\theta + n_{bar}P_s \tag{5}$$

Since imminent collapse is considered, the external shear resisted, *V* is now taken equal to zero. Thus, Equation (3) will take the following form:

$$\Sigma F\chi \rightarrow N\sin\theta = N\cdot\mu\cos\theta + \frac{A_{st}f_{yt}d_c}{s}\tan\theta, \quad \text{and,} \quad \Sigma Fy \rightarrow P = N(\cos\theta + \mu\sin\theta) + n_{bar}A_b f_y \tag{6}$$

The coefficient of friction and the angle θ of the failure plane are required to perform a calculation; Elwood and Moehle (2003) using the results from their own database and using constant value of shear angle θ= 65^o calculated the coefficient of friction. As a result of this investigation proposed the following relationship between the effective coefficient of friction and the drift ratio at axial failure for the total capacity model.

$$\mu_t = \tan\theta - \frac{100}{3}\left(\frac{\Delta}{L}\right)_{axial} \geq 0 \tag{7}$$

Furthermore the coefficient of friction μ can be calculated from the following equation:

$$\mu = \frac{V}{N} \tag{8}$$

Calibration between the two equations, i.e., (7) and (8) is used to obtain the following expression for the drift at axial failure.

$$\left(\frac{\Delta_a}{L}\right) = \frac{0.5}{5 + \frac{Ps}{A_{tr}f_{yt}d_c}} \tag{9}$$

According to Elwood and Moehle (2003), the precision of such a model is comparable to that for the strength, since the longitudinal reinforcement capacity is not controlled when the drift ratios in the tests are recorded. The model requires information only about the transverse reinforcement and the axial load. In the present study a comparison is carried out between the results from Equation (9) and the independently assembled database of tests, presented herein. A next step investigating the performance of the proposed relationship for the axial drift ratio at failure is the parametric analysis of the effect of aspect ratio, taking into account the transverse reinforcement ratio and the axial load ratio considering collectively all the tests of the database.

4.0 DISCUSSION OF INVESTIGATION RESULTS

To investigate the influence of second order effects on shear strength degradation a bar chart was prepared to check the results for eight selected column specimens obtained from the data base. The specimens are shown in Table 2 and all the geometrical and mechanical properties can be found in Table 4 of Appendix A.The criterion of specimens selection was the same value of displacements ductility μ=4 due to the fact that for high values of displacements, the contribution to shear strength degradation is bigger.Figure 5 compares for a displacement ductility of μ=4 the ratios $\Delta V/V_{max}$, $\Delta V_{red}/V_{max}$ with the corresponding values which are obtained from the shear strength models of Table 1. According with the procedure described in section 2, and as shown in Figure 5, shear strength is decreased with increasing displacement ductility. More specifically, it may be seen in Fig. 8 which compares the ratios $\Delta V/V_{max}$ and $\Delta V_{red}/V_{max}$

for each specimen that a lower strength degradation occurs than previously thought, when the second order effects are accounted for; at the same time, the total strength loss expressed by the $\Delta V/V_{max}$ ratio is underestimated. The first of the models (Ashheim and Moehle 1992) is particularly unconservative. Overall, the model by Elwood and Moehle (2003) gives the closest approximation to the experimental results, although it appears that this too requires improvement (Fig. 8, Table 2) to better match the tests.

Table 3 Comparison of the proposed models results with the experimental results, for displacement ductility μ=4

In the following figures, the experimental results of the database specimens are plotted against the results of the models listed in Table 1.

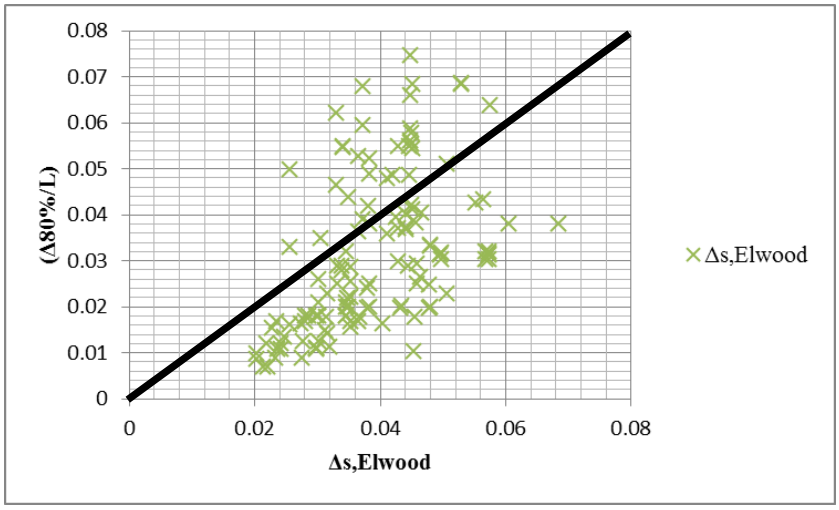

Figure 6 Comparisons between Elwood & Moehle (2003) proposed relationship for shear drift capacity of columns and the experimental values of the data base. The diagonal represents the equal value line.

Figure 7 compares experimental values of shear force with analytical peak lateral force values obtained after sectional analysis of the critical column cross section, using Response 2000 (2001) and considering second order effects; these values corresponding to the onset of shear failure (i.e., at Δ/L_s at a residual post peak strength of 80% of peak.)

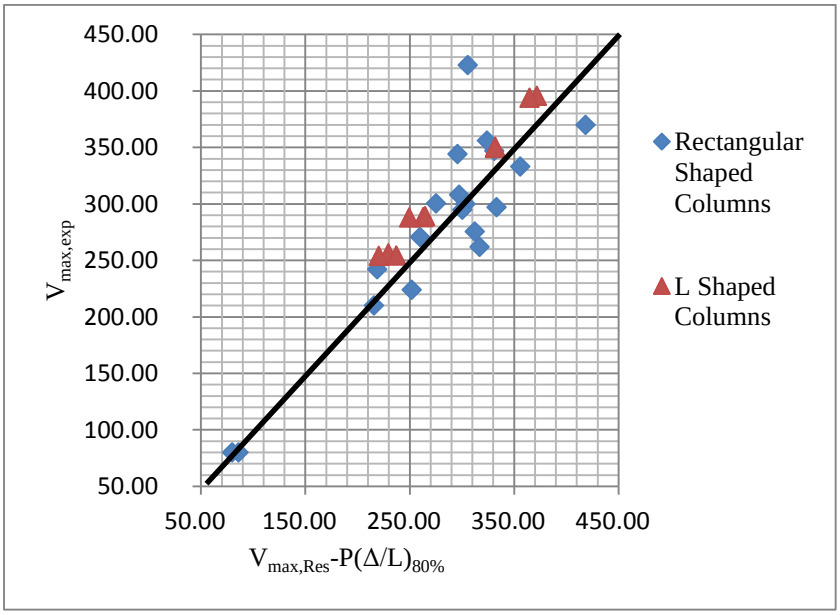

Figure 7 Correlation of $V_{max,exp}$ and $V_{max,Res}$- $P(\Delta/L)_{80\%}$

Results of a parametric investigation of the relationship between transverse reinforcement ratio, axial ratio, aspect ratio and experimental shear drift values are plotted in the following figures. Symbols used in Fig. 8 are color coded to represent the intensity of the axial load ratio (compressive) as follows:

$0 \leq \nu \leq 0.15$

$0.15 \leq \nu \leq 0.3$

$0.3 < \nu \leq 0.6$

Within each group, the rhomboid shape refers to low aspect ratio columns which are predisposed to shear failure; circles correspond to an aspect ratio between 2 and 4, whereas very slender members are plotted with triangles.

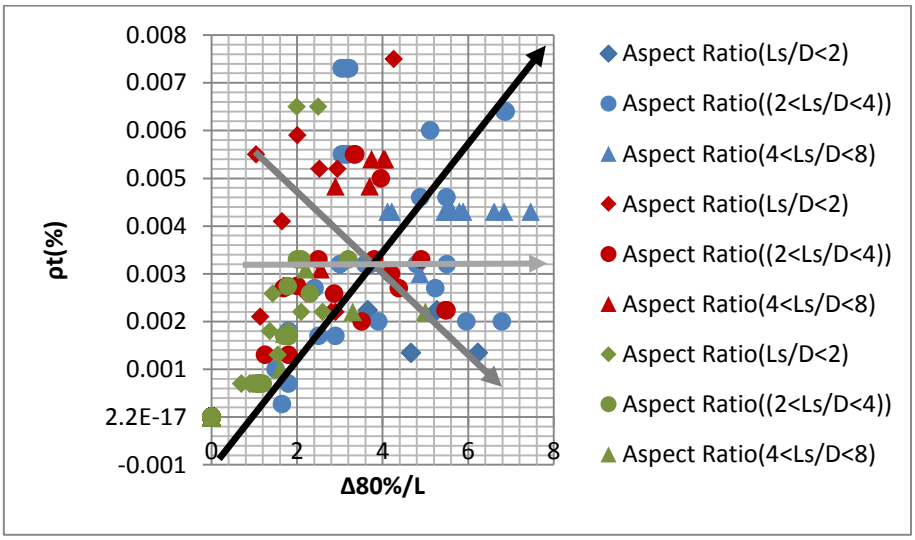

Figure 8 Influence of axial load ratio, transverse reinforcement ratio and aspect ratio, on drift ratio at shear failure.

From Figure 8 it is observed that several trends occur simultaneously: drift capacity at shear failure increases with the amount of transverse reinforcement, since better confinement and better shear reinforcement amounts postpone the occurrence of shear failure; green red and blue points are grouped sequentially in this order on the plot. Thus for the same amount of transverse reinforcement, specimens with higher axial load ratio correspond to lower values of lateral drift at shear failure. Higher drift values are possible as the axial load is reduced. Moreover for values of axial load in the range $0 \leq \nu \leq 0.15$ it may be seen that the drift capacity is proportional to transverse reinforcement ratio. Similar is the effect of the aspect ratio: higher aspect ratios lead to higher values of drift capacity at shear failure. This occurs whether as point of reference equal transverse reinforcement, or equal axial load ratio is considered.

Subsequently the value of drift at axial load failure as calculated by Eq. 9 is compared against its experimental counterpart in Figure 9; clearly the equation assesses the drift capacity at failure quire satisfactorily, however, the scatter is significant. It is possible that by accounting the other two important parameters, namely the aspect ratio and transverse reinforcement ratio the scatter may be reduced and correlation be improved.

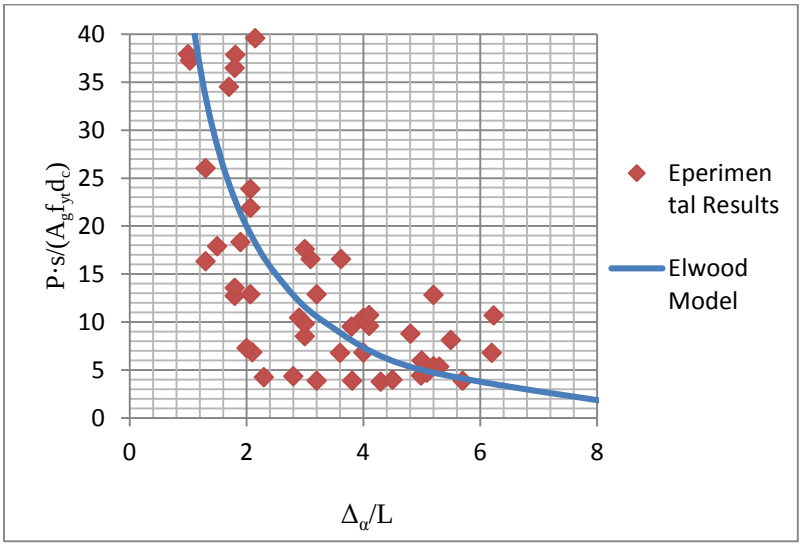

Figure 9 Comparison of experimental values of Δ_α with Elwood and Moehle (2003) proposed model.

6.0 CONCLUSIONS

- The current study aims to recapitulate the current knowledge concerning the estimation of the residual shear strength and pattern of strength degradation, taking into consideration the influence of axial load and the occurrence of second order effects during the lateral displacement history. Furthermore, drift capacities at the point associated with shear and axial load failures were also considered.
- Taking into account the contribution of axial load in estimating the remaining shear strength of a column with increasing displacement, it seems that a large fraction of the macroscopically observed lateral strength loss originally attributed to disintegration of the shear resistance mechanisms is really owing to the contribution of second order effects. This important response aspect accounts for a significant part of the lateral resistance of the column and therefore the coefficient of strength reduction with increasing ductility which has been introduced in assessment codes is found to overestimate the phenomena of strength degradation. Therefore, all the relevant assessment equations need to be reconsidered.
- Drift capacity at the onset of shear failure is defined at the point on the post peak branch associated with 80% residual member strength. After a parametric investigation, the results show that there is an agreement between the expressions by Elwood and Moehle (2003) and an independently assembled experimental database results in that the shear drift value increases almost proportionately with transverse reinforcement ratio, whereas it is inversely proportional to axial load ratio. Higher aspect ratio has the same effect; low shear drift values are observed in the case of shear critical columns.

Keywords: dynamic analysis, slope, spatial variability, kriging, Monte Carlo simulation, probability of failure.

Abstract. *The analysis of earth slopes situated in seismic areas has been extensively investigated in literature using deterministic approaches where average values of the soil properties were used. In this paper, a probabilistic dynamic approach is presented for the slope stability analysis. In this approach, the effect of the soil spatial variability on the dynamic responses was investigated. The soil shear modulus G was modeled as an anisotropic non-Gaussian random field. The deterministic model was based on numerical simulations using the dynamic option of the finite difference code FLAC^{2D}. Notice that when dealing with dynamic problems, the deterministic model becomes very time-consuming. For this reason, one needs to keep to a minimum the number of calls to the deterministic model when performing the probabilistic analyses, the probabilistic method generally employed when considering spatially varying soil properties being the Monte Carlo Simulation (MCS) methodology. This method is known to be not suitable for the computation of the small failure probabilities encountered in practice because it becomes very time-expensive in such cases due to the large number of simulations required. In order to overcome the shortcoming related to the excessive number of calls of the deterministic model when performing Monte Carlo simulations, Echard et al. (2011) proposed an Active learning reliability method (called AK-MCS) combining Kriging and Monte Carlo Simulation. The method was shown to be very efficient as the obtained probability of failure is very accurate needing only a small number of calls to the deterministic model. The probabilistic dynamic analyses presented in this paper were performed using AK-MCS methodology by Echard et al. (2011). The failure probability was computed for the point located on the toe of the slope. For a given realization of the random field, failure is considered to be achieved at the toe if the maximal acceleration A_{max} at this point, as computed bu FLAC^{2D} software, exceeds a prescribed threshold value. Some probabilistic results corresponding to different values of the maximum threshold value are presented and discussed.*

1 INTRODUCTION

The response of a geotechnical structure subjected to a seismic loading has been extensively investigated in literature using deterministic approaches where average values of the soil properties (shear modulus, angle of internal friction, cohesion, etc.) were used. Notice however that the spatial variability of the soil properties may affect the behavior of geotechnical structures. Consequently, reliable responses of a geotechnical system cannot be predicted using a deterministic approach; a probabilistic technique seems to be necessary.

The probabilistic techniques enable the rigorous propagation of the different uncertainties from the input parameters to the system responses. It should be emphasized here that few authors have worked on the analysis of the seismic responses using probabilistic approaches [1-5]. This is because of the significant computation time required per simulation especially when using finite element/finite difference dynamic models.

In this paper, the effect of the soil spatial variability on the seismic response of a geotechnical structure is investigated. The case of an elastic slope subjected to a seismic loading was considered. The effect of the soil spatial variability on the maximal acceleration at the top and/or at the toe of the slope was considered. The objective is the computation of the probability P_f of exceeding a tolerable maximum acceleration A_{max}. The soil shear modulus was considered as a two-dimensional lognormally distributed random field where it is assumed to vary in both vertical and horizontal directions. The deterministic model was based on numerical simulations using the dynamic option of the FLAC^{2D} software. Notice that when dealing with numerical dynamic problems, the deterministic model becomes very time-consuming. For this reason, one needs to keep to a minimum the number of calls to the deterministic model when performing the probabilistic analyses, the probabilistic method generally employed when considering spatially varying soil properties being the Monte Carlo Simulation (MCS) methodology. This method is known to be not suitable for the computation of the small failure probabilities encountered in practice because it becomes very time-expensive in such cases due to the large number of simulations required.

In order to overcome the shortcoming related to the excessive number of calls of the deterministic model when performing Monte Carlo simulations, [6] proposed an Active learning reliability method (called AK-MCS) combining Kriging and Monte Carlo Simulation. The method was shown to be very efficient as the obtained probability of failure is very accurate needing only a small number of calls to the deterministic model. The basic idea of the present approach is to construct a kriging metamodel which is a surrogate (or a substitute) of the real numerical model based only on a few realizations and then, to obtain an estimation of the failure probability and the corresponding coefficient of variation based on this metamodel. The choice of the realizations used in the construction of the metamodel is made in such a manner to focus on the configurations that are close to the limit state surface and that have sufficiently high density of probability so that their contribution on the failure probability is significant. This leads to an accurate value of the failure probability.

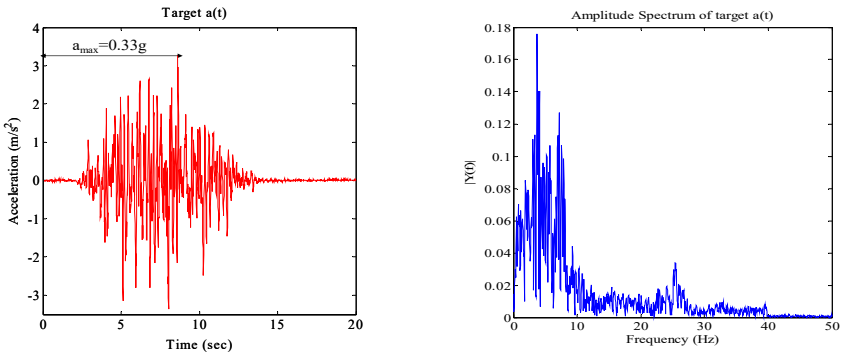
The paper is organized as follows: one first presents the deterministic numerical modeling of the dynamic problem and the corresponding results. Then, the probabilistic analyses and the corresponding probabilistic results are presented and discussed. The paper ends by a conclusion of the main findings.

2 DETERMINISTIC ANALYSIS

In this section, the deterministic numerical model is firstly presented. It is followed by the corresponding deterministic results.

2.1 Numerical modeling

The deterministic model is based on numerical simulations using the dynamic option of the finite difference code FLAC^{2D}. The input seismic signal used in this work is the synthetic signal of Nice for which the corresponding accelerogram is presented in Figure 1(a). This signal is used because it is representative of the French design spectrum [7]. It has a maximum acceleration equal to 0.33g. Its corresponding Fourier amplitude spectrum is shown in Figure 1(b).



(a) (b)

Figure 1. (a) Accelerogram of the synthetic signal of Nice and (b) the corresponding Fourier amplitude spectrum

In the finite difference dynamic analysis by FLAC^{2D}, numerical distortions may occur during the propagation of the seismic waves if the elements size of the mesh is not convenient. The size Δl of an element of the mesh should respect the following condition [8]:

$$\Delta l \leq \frac{V_s}{10 * f_{\max}} \tag{1}$$

where V_s is the shear wave velocity, and f_{max} is the maximum frequency of the incident seismic signal [9]. The shear wave velocity V_s in Equation (1) can be calculated using the values of the soil shear modulus G and the soil density ρ as follows:

$$V_s = \sqrt{\frac{G}{\rho}} \tag{2}$$

Even though an elasto-plastic model would be more realistic to model the soil behavior especially for the cases of medium and high earthquake ground motions GMs, an elastic model was used in this work. The aim is to investigate the effect of the soil spatial variability using a simple model with a reasonable computation time. Concerning the boundary conditions, FLAC^{2D} offers the option of applying absorbing boundary conditions of type "quiet boundaries" or "free field". These boundary conditions absorb the energy of the wave approaching these limits and thus avoid the reflection of these waves. In this paper, the boundary conditions applied to the vertical boundaries are of type "free field". This type of boundary conditions is suitable for vertical surfaces, the boundary conditions of type "quiet boundaries" being generally convenient in the case of horizontal surfaces. Finally, it should be mentioned that in the natural dynamic systems, the internal friction may lead to partial dissipation of the energy of vibration. The software FLAC^{2D} provides a damping of type "Rayleigh damping"

(among other types of damping) which is based on two parameters (i) the natural frequency of the system and (ii) the damping ratio (defined as a percentage of the critical damping).

2.2 Deterministic results

For the dynamic analyses, the values of the shear modulus, bulk modulus and density of the soil were as follows: G=100MPa, K=250MPa and ρ=1800 kg/m^3. In order to avoid the numerical distortion that may occur during the propagation of the seismic waves in the model, the elements size must satisfy Equation (1). By using Equation (2), the shear wave velocity was found to be equal to 235.7m/s. From Figure 1(b), one can see that the maximal frequency f_{max} is equal to 40Hz. Thus, the maximum size of the different elements must be less than or equal to 0.59m. In the studied model, the size Δl of the different elements was taken equal to 0.5m. Concerning the boundary conditions, boundary conditions of type "free field" were applied along the vertical boundaries of the model. The lower horizontal boundary was subjected to the seismic load (i.e. the synthetic accelerogram of Nice). Concerning the damping effect, an undamped system was considered to reduce the number of involved parameters. The effect of damping will be the subject of future work.

The slope geometry considered in the analysis is 10m in height and 45° in inclination angle (see Figure 2). In order to obtain accurate results of the maximum acceleration at the top and at the toe of the slope, one need to position correctly the vertical boundary conditions. For this purpose, the width of the slope L was initially considered to be equal to 60m and was successively increased by 20m (i.e. 10m from each side) until one obtains convergence of the maximum acceleration for the profile presented in figure 2 in red color. Figure 3 presents the maximum acceleration profiles for L=60m, 80m, 100m, 120m, 140m and 160m. From this figure, one can deduce that for L $\geq$ 140m, all the presented profiles coincide. For this reason, a width L=140m was selected for the probabilistic analysis. The corresponding computation time is equal to 50 minutes.

3 PROBABILISTIC ANALYSIS

The aim of this section is to present the probabilistic dynamic analysis. The impact of the soil spatial variability on the dynamic response was investigated. It should be noted here that the dynamic system response considered in this section involves the maximum acceleration (A_{max}) at the toe of the slope. The objective of the probabilistic analysis is the computation of the probability P_f of exceeding a tolerable maximum acceleration A_{max}. The soil shear modulus G was modeled as a two-dimensional log-normal random field. The EOLE methodology [10] was used to discretize the shear modulus random field (i.e. to obtain realizations of the soil shear modulus that respect the correlation structure of this field). For the two-dimensional random field used in this paper, the shear modulus was allowed to vary in both the horizontal and vertical directions. The deterministic model was based on numerical simulations using the finite difference code FLAC^{2D}. As for the probabilistic method used in this paper, the active learning reliability method combining kriging and Monte Carlo Simulation (i.e. AK-MCS) was employed. This method combines both the classical crude Monte Carlo Simulation (MCS) methodology and the Kriging meta-model technique. The performance function used to calculate the probability P_f of exceeding a tolerable maximum acceleration A_{max} was defined as follow:

$$\Gamma = \frac{A_{\max}}{A_{\max}\left(toe\right)} - 1 \tag{3}$$

where A_{max} is a prescribed tolerable maximum acceleration and A_{max}(toe) is the maximum acceleration at the toe of the slope as computed by FLAC^{2D} software due to the applied seismic loading.

In this section, the EOLE method of discretization of random fields is firstly presented. It is followed by a brief presentation of the crude Monte Carlo method, the kriging metamodeling technique and the combined use of the kriging and the Monte Carlo Simulation methodology (called AK-MCS) used for the probabilistic analysis.

3.1 Discretization of a non-isotropic log-normal random field

Consider a 2D non-isotropic log-normal random field Z^{LN} described by: (i) a log-normal marginal cumulative distribution function F_G, and (ii) a square exponential autocorrelation function ρ_Z^{LN} [(x, y), (x', y')] which gives the values of the correlation between two arbitrary points (x, y) and (x', y'). Notice that this function is given as follows:

$$\rho_z^{LN}[(x,\ y),\ (x\ ',\ y\ ')] = \exp\left(-\left(\frac{|x - x\ '|}{a_x} \right)^2 - \left(\frac{|y - y\ '|}{a_y} \right)^2 \right) \tag{4}$$

where a_x and a_y are the autocorrelation distances along x and y respectively. The EOLE method proposed by [10] to discretize a random field is used herein. In this method, one should first define a stochastic grid composed of s grid points (or nodes) and determine the log-normal autocorrelation matrix $\Sigma_{\chi;\chi}^{LN}$ which gives the correlation between each grid point of the stochastic mesh and the other grid points of this mesh using Equation (4). The number of grid points within the stochastic mesh is determined in such a manner that in each direction (x or y), there are five grid points within each autocorraltion distance. The log-normal autocorrelation matrix $\Sigma_{\chi;\chi}^{LN}$ should then be transformed into the Gaussian space using the Nataf transformation [11]. As a result, one obtains a Gaussian autocorrelation matrix $\Sigma_{\chi;\chi}^{G}$ that can be used to discretize the Gaussian random field Z as follows:

$$\tilde{Z}(x\ ,\ y\ ) \cong \mu_{\ln Z} + \sigma_{\ln Z} \sum_{j=1}^{N} \frac{\xi_j}{\sqrt{\lambda_j}} .\phi_j .\Sigma_{Z(x\ ,y\ );\chi} \tag{5}$$

where μ_{lnZ} and σ_{lnZ} are the mean and standard deviation values of the underlying normal distribution (i.e. ln(Z)); (λ_j ,ϕ_j) are the eigenvalues and eigenvectors of the Gaussian autocorrelation matrix $\Sigma_{\chi;\chi}^{G}$; $\Sigma_{Z(x\ ,y\ );\chi}$ is the correlation vector between the value of the field at an arbitrary point (x, y) and its values at the different grid points; ξ_j (j=1, ..., N) is a vector of standard normal random variables; and N is the number of terms (expansion order) retained in EOLE method. This number N is obtained (i) by sorting the eigenvalues λ_j (j=1, …, s) in a descending order and (ii) by choosing the number N of eigenmodes that leads to a variance of the error which is smaller than a prescribed tolerance ε ($\varepsilon \approx 10\%$ in this paper). Notice that the variance of the error for EOLE is given by [10] as follows:

$$Var\left[\ Z(x,\ y) - \tilde{Z}(x,\ y)\ \right] = \sigma_{\ln Z}^2 \left\{ 1 - \sum_{j=1}^{N} \frac{1}{\lambda_j} \left(\left(\phi_j \right)^T \Sigma_{Z(x,y);\chi} \right)^2 \right\} \tag{6}$$

where $Z(x\ ,\ y\ )$ and $\tilde{Z}(x\ ,\ y\ )$ are respectively the exact and the approximate values of the random field at a given point (x, y) and $\left(\phi_j \right)^T$ is the transpose of the eigenvector ϕ_j **.** Once the Gaussian random field is obtained, it should be transformed into the log-normal space by exponentiating the approximated Gaussian random field $\tilde{Z}(x\ ,\ y\ )$ given by Equation (5). Notice finally that Eq. (5) or rather its equivalence for the log-normal random field will be used in this paper to compute the value of the random field at the center of the different elements of the numerical dynamic model to assign values of G to the different elements of this numerical model.

3.2 Monte Carlo method

The Monte Carlo simulation method consists in generating K samples which respect the joint probability density function $f_X(X)$ of the M random variables ($X_1, \ldots, X_M$) gathered in a vector X. For each sample, the system response is calculated. Thus; for the K samples, one obtains K values of the system response gathered in a vector $\Gamma = \left\{\Gamma\left(X^{(1)}\right),\ldots,\Gamma\left(X^{(K)}\right)\right\}$ which may be used to determine the failure probability for a prescribed threshold of this system response. A very large number of samples (i.e. realizations) is required to obtain a rigorous value of the failure probability especially when computing small failure probabilities. It should be noted herein that the random variables considered in the present paper are the standard normal variables ξ_j ($j=1, \ldots, N$) that appear in Eq. (5) for the computation of a given realization of the shear modulus random field.

3.3 Kriging metamodeling technique

The metamodeling technique aims at replacing the response (or the performance function in this paper) of a computationally-expensive mechanical model by a metamodel (i.e. a simple analytical equation). The Kriging metamodeling technique is based on the idea that the performance function $\Gamma(\mathbf{x})$ is seen as a realization of a stochastic field $\delta(\mathbf{x})$ [12]. The first step of kriging consists of defining this stochastic field with its parameters according to an Experimental Design (ED) of length k. This stochastic field is given by:

$$\delta(\mathbf{x}) = F(\mathbf{x},\beta) + Z(\mathbf{x}) \tag{7}$$

Where:

- $F(\mathbf{x},\beta)$ is the deterministic part which gives an approximation of the mean value of the performance function. It corresponds to a regression model that can be written as:

$$F(\mathbf{x},\beta) = \sum_{j=1}^{p} \beta_j f_j(\mathbf{x}^{(i)}) \qquad i=1,\ldots,k \tag{8}$$

  Where $\beta^T = (\beta_j, j = 1, \ldots, p)$ is the vector of coefficients to be determined, $f^T = (f_j, j = 1, \ldots, p)$ is a collection of regression functions (or regressors) and k is the number of observations. The number p of regression functions is assumed to be less than or equal to the number k of observations so that the problem is not underdetermined (i.e. it does not lack equations to compute the unknowns). In this paper, ordinary kriging is selected which means that $F(\mathbf{x},\beta)$ is a scalar to be determined (i.e. $F(\mathbf{x},\beta) = \beta$).

- $Z(\mathbf{x})$ represents the fluctuation around the mean value. It is given by a Gaussian random process (or a random field) with zero mean and covariance between two points of space $\mathbf{x}$ and $\mathbf{x}'$ defined by:

$$COV\left(Z(\mathbf{x}), Z(\mathbf{x}')\right) = \sigma_Z^2 \rho_\theta(\mathbf{x},\mathbf{x}') \tag{9}$$

  Where σ_Z^2 is the process variance and ρ_θ the correlation function defined by its set of parameters θ. Several models exist to define the correlation function. However, in this paper, the anisotropic squared-exponential function is selected. It is given by:

$$\rho_\theta(\mathbf{x},\mathbf{x}') = \prod_{i=1}^{N} exp\left(-\left(\theta_i\left(x_i - x_i'\right)\right)^2\right) \tag{10}$$

Where N is the number of random variables, x_i and x_i' are the i[th] coordinates of the points $\mathbf{x}$ and $\mathbf{x}'$ and θ_i is a scalar which is equal to the inverse of the correlation length in the i[th] direction.

As mentioned above, in order to completely define the kriging model, one has to compute the following parameters: β, σ_Z and the correlation function parameters θ_i. Given an initial Experimental Design (ED) with k samples, $\mathbf{x} = \left\{\mathbf{x}^{(1)},...,\mathbf{x}^{(k)}\right\}$, for which the response values have been computed and stored in $\mathbf{\Gamma} = \left\{\Gamma\left(\mathbf{x}^{(1)}\right),...,\Gamma\left(\mathbf{x}^{(k)}\right)\right\}$, the scalars β and σ_Z^2 are estimated according to [12] by:

$$\hat{\beta} = (\mathbf{1}^T \Sigma_{\Gamma;\Gamma}^{-1} \mathbf{1})^{-1} \mathbf{1}^T \Sigma_{\Gamma;\Gamma}^{-1} \mathbf{\Gamma} \tag{11}$$

$$\hat{\sigma}_Z^2 = \frac{1}{k}(\mathbf{\Gamma} - \hat{\beta}\mathbf{1})^T \Sigma_{\Gamma;\Gamma}^{-1} (\mathbf{\Gamma} - \hat{\beta}\mathbf{1}) \tag{12}$$

Where $\mathbf{1}$ is the vector of length k filled with $\mathbf{1}$, $\Sigma_{\Gamma;\Gamma}^{-1}$ is the inverse of the correlation matrix $\Sigma_{\Gamma;\Gamma}$. It should be mentioned that a row i of the correlation matrix gives the values of the correlation between the value of the response at the sampled point $\Gamma\left(\mathbf{x}^{(i)}\right)$ and all the values of the response at the sampled points $\mathbf{\Gamma} = \left\{\Gamma\left(\mathbf{x}^{(1)}\right),...,\Gamma\left(\mathbf{x}^{(k)}\right)\right\}$ as follows:

$$\left(\Sigma_{\Gamma;\Gamma}\right)_{i,j} = \rho_\theta\left(\mathbf{x}_i, \mathbf{x}_j\right) \qquad i=1,...,k \text{ and } j=1,...,k \tag{13}$$

However, as $\hat{\beta}$ and $\hat{\sigma}_\Gamma^2$ in Eqs. (11) and (12) depend on the correlation parameters θ_i through the matrix $\Sigma_{\Gamma;\Gamma}$, it is first required to obtain them using maximum likelihood estimation:

$$\theta = \arg\min_\theta \left(\det \Sigma_{\Gamma;\Gamma}\right)^{\frac{1}{k}} \hat{\sigma}_Z^2 \tag{14}$$

The next step consists of predicting the response of $\Gamma(\mathbf{x})$ in a given unknown point $\mathbf{x}$. At such a point, the Best Linear Unbiased Predictor (BLUP) $\hat{\Gamma}(\mathbf{x})$ of $\delta(\mathbf{x})$ is computed as [12]:

$$\hat{\Gamma}(\mathbf{x}) = \beta + \sum_{\Gamma(\mathbf{x});\Gamma} \sum_{\Gamma;\Gamma}^{-1} (\mathbf{\Gamma} - \beta\mathbf{1}) \tag{15}$$

Where $\Sigma_{\Gamma(\mathbf{x});\Gamma}$ is the correlation vector whose elements provide the correlation between the value of the response at the unsampled point $\Gamma(\mathbf{x})$ and the values of the response at the sampled points gathered in the vector $\mathbf{\Gamma} = \left\{\Gamma\left(\mathbf{x}^{(1)}\right),...,\Gamma\left(\mathbf{x}^{(k)}\right)\right\}$ as follows:

$$\left(\Sigma_{\Gamma(\mathbf{x});\Gamma}\right)_i = \rho_\theta\left(\mathbf{x}_i, \mathbf{x}\right) \qquad i=1,...,k \tag{16}$$

The kriging variance is defined as the minimum of the mean squared error between $\Gamma(\mathbf{x})$ and $\hat{\Gamma}(\mathbf{x})$. It can be expressed as the following analytical function:

$$\sigma_{\hat{\Gamma}}^2(\mathbf{x}) = \sigma_Z^2\left(\mathbf{1} + u(\mathbf{x})^t \left(\mathbf{1}^t \Sigma_{\Gamma;\Gamma}^{-1} \mathbf{1}\right) u(\mathbf{x}) - \Sigma_{\Gamma(\mathbf{x});\Gamma}^T \Sigma_{\Gamma;\Gamma}^{-1} \Sigma_{\Gamma(\mathbf{x});\Gamma}\right) \tag{17}$$

Where:

$$u\left(\mathbf{x}\right)=\mathbf{1}^{t}\Sigma_{\Gamma;\Gamma}^{-1}\Sigma_{\Gamma(\mathbf{x});\Gamma}-\mathbf{1} \tag{18}$$

Kriging is an exact interpolation method. The prediction of $\hat{\Gamma}\left(\mathbf{x}^{(i)}\right)$ in a point $\mathbf{x}^{(i)}$ of the design of experiments is exact (i.e. $\hat{\Gamma}\left(\mathbf{x}^{(i)}\right)=\Gamma\left(\mathbf{x}^{(i)}\right)$). Therefore, the kriging variance is null in these points and it becomes important in unexplored areas. These properties are interesting in reliability studies and metamodels as the Kriging variance represents a good index to improve a design of experiments.

3.4 AK-MCS methodology

The active learning reliability method called AK-MCS combines both the Kriging metamodeling technique and Monte Carlo Simulation. The iterative procedure suggested by [6] for computing the probability of failure P_f using this approach can be described as follows:

1. Generate a population S of n_{MC} (say 1,000,000) realizations of the spatially varying soil shear modulus using Monte Carlo Simulation. It should be emphasized here that the computation of the performance function for these realizations (as defined in equation 3 based on the computationally-expensive FLAC^{2D} model) is not required at this stage.
2. Randomly select from the S population a small number of realizations (called initial Design of Experiments DoE) containing N_1 realizations (say 20). For those N_1 realizations, one should evaluate the performance function given by equation (3) based on the computationally-expensive FLAC^{2D} model. The required initial DoE may be greater than 20 for a great number of random variables (i.e. for a spatially varying soil property with small values of the autocorrelation distances). This is because for high dimensional problems (i.e. when a large number of random variables is needed to discretize the shear modulus random field), the kriging model needs more points (i.e. realizations) in order to compute correlation parameters θ_i given by equation (15).
3. Compute the kriging model according to the small initial DoE containing the N_1 realizations. This kriging model is given by equation (16). It should be mentioned here that this stage was performed using the Matlab toolbox DACE [7]. In this paper, ordinary kriging model was used (i.e. the regression model is considered to be constant) and a square exponential correlation function was adopted in the analysis.
4. By using DACE toolbox, compute (for the whole population S containing the n_{MC} realizations of the random field) both the kriging predictor values $\hat{\Gamma}$ of the performance function (based on equation 16) and their corresponding kriging variance values $\sigma_{\hat{\Gamma}}^2$ (based on equation 18). From the obtained values of the kriging predictors $\hat{\Gamma}$, obtain an estimation of the probability of failure $\hat{P}_f$ by counting the number of negative predictors $N_{\hat{\Gamma}\leq 0}$ and dividing it by the total number of samples in S as follows:

$$\hat{P}_f=\frac{N_{\hat{\Gamma}\leq 0}}{n_{MC}} \tag{19}$$

Also compute the coefficient of variation of $\hat{P}_f$ as follows:

$$C\hat{O}V(\hat{P}_f)=\sqrt{\frac{1-\hat{P}_f}{\hat{P}_f n_{MC}}} \tag{20}$$

5. Identify the best next realization in S for which one will compute the performance function using FLAC^{2D}. This is performed by evaluating a learning function U for each realization in S. The learning function U is given by:

$$U\left(\mathbf{x}^{(i)}\right)=\frac{\left|\hat{\Gamma}\left(\mathbf{x}^{(i)}\right)\right|}{\sigma_{\hat{\Gamma}}\left(\mathbf{x}^{(i)}\right)} \qquad i=1,...,n_{MC} \tag{21}$$

The best next candidate realization is the one with minimum value of U. If this minimum value of U is smaller than 2, the performance function based on FLAC^{2D} is evaluated for the best candidate and the initial DoE is updated. Thus one should go back to step 3 and evaluate a new kriging model based on the updated DoE. Steps 3, 4 and 5 are repeated until the minimum value of U become larger than 2. At this stage the learning stops and the metamodel is considered accurate enough based on the n_{MC} realizations.

6. When the learning stops, one must compute the estimated values of both the probability of failure $\hat{P}_f$ and the coefficient of variation $C\hat{O}V\left(\hat{P}_f\right)$. The obtained value of $\hat{P}_f$ is considered to be accurate if $C\hat{O}V\left(\hat{P}_f\right)\leq 5\%$. If the estimated coefficient of variation is larger than 5%, one must increase the population S in step 1 and repeat the procedure.

It should be emphasized herein that a small initial DoE is chosen within the present approach (see step 2) in order to keep to a minimum the number of calls to the deterministic model. This initial DoE is successively increased by a single realization at each time (see step 5). The chosen realization is the one that is improving the most the metamodel because equation (22) searches for the realization that has a small kriging predictor (i.e. a realization that is close to the limit state surface) and/or a high kriging variance (i.e. a high uncertainty in the sign of its performance function value). Notice that the realizations with high uncertainties in the sign of their performance function values (positive or negative) are those that are close to the limit state surface. Finally, notice that the stopping criterion min(U)>2 corresponds to a maximal probability of making a mistake on the sign of the performance function of $\Phi(-2)=0.023$. This means that the stopping criterion is relevant making use of the realizations with a small uncertainty in making a mistake in their performance functions' signs, the probability of making a mistake in the signs of their performance function values being negligible.

3.5 Probabilistic dynamic results

The aim of this section is to present the probabilistic dynamic results of a soil slope exhibiting a spatially varying shear modulus. The objective is the computation of the probability P_f of exceeding a tolerable maximum acceleration A_{max}. The shear modulus G was modeled by a random field and it was assumed to follow a log-normal probability density function. The mean value and the coefficient of variation of G were respectively μ_G=100MPa and COV_G=25%. A square exponential autocorrelation function was used in this study to represent the correlation structure of the random field. The random field was discretized using EOLE method. Although an isotropic random field is often assumed in literature [13, 14], the vertical autocorrelation length tends to be shorter than the horizontal one due to the geological soil formation process for most natural soil deposits [15]. A common ratio of about 1 to 10 for these autocorrelation lengths can be used [16]. Notice that in this paper, only one configuration of the autocorrelation distances (a_x=50m and a_y=5m) was considered. An extension to this work may consider other configurations of a_x and a_y. The present study was performed in order to explore some interesting features related to the values of P_f for different values of the tolerable maximum acceleration A_{max}.

3.6 AK-MCS results for different values of the tolerable acceleration

In this section, the results obtained based on AK-MCS methodology are presented and discussed for the case where a_x=50m and a_y=5m. It should be mentioned here that a population S containing a total number of simulations n_{MC} equal to one million was selected. Then, a small initial design of experiment (DoE) of N_1=20 realizations among the whole population S was randomly selected. The performance function given by equation (3) was evaluated for this DoE. Thus, the computationally-expensive dynamic model based on finite difference code FLAC^{2D} was only called 20 times before evaluating the kriging model. The Kriging model was thus built based on this DoE. A simple analytical equation is then obtained and the performance function can be evaluated for the whole population S with no time: Both the kriging predictor and the kriging variance for the whole S population were evaluated based on equations (15) and (17) of the kriging model using the DACE Matlab toolbox [17]. The probability of failure $\hat{P}_f$ and the corresponding coefficient of variation $C\hat{O}V(\hat{P}_f)$ were computed using equations (19) and (20). Notice finally that several points (realizations) were added based on the evaluation of the learning function U given by equation (21) until reaching convergence.

Table 1 present the evolution of $\hat{P}_f$ and $C\hat{O}V(\hat{P}_f)$ as a function of the number of added points (realizations) for four different values of the tolerable maximum acceleration A_{max} (A_{max}=15, 25, 30 and 35m/s^2). From this table, one may conclude that for small value of A_{max} (A_{max}=15m/s^2) one obtains a large value of $\hat{P}_f$. Figure 4 presents the variation of $\hat{P}_f$ and $C\hat{O}V(\hat{P}_f)$ as function of the number of added points using the AK-MCS algorithm. This figure shows that the values of $\hat{P}_f$ and $C\hat{O}V(\hat{P}_f)$ stabilized when the algorithm has added 100 extra points to the initial DoE containing 20 points. In the present paper extra points were added to show the efficiently of the algorithm and to demonstrate that no further modifications on the obtained values of $\hat{P}_f$ and $C\hat{O}V(\hat{P}_f)$ may occur.

A_{max}(m/s^2)	$\hat{P}_f$	$C\hat{O}V(\hat{P}_f)$ (%)	Number of added points
15	170 x10^{-3}	0.21%	248
25	50 x10^{-3}	0.41%	185
30	12 x10^{-3}	0.1%	270
35	2.5x10^{-3}	0.1%	248

Table 1: Variation of $\hat{P}_f$ and $C\hat{O}V(\hat{P}_f)$ together with the number of added points for different values of A_{max}.

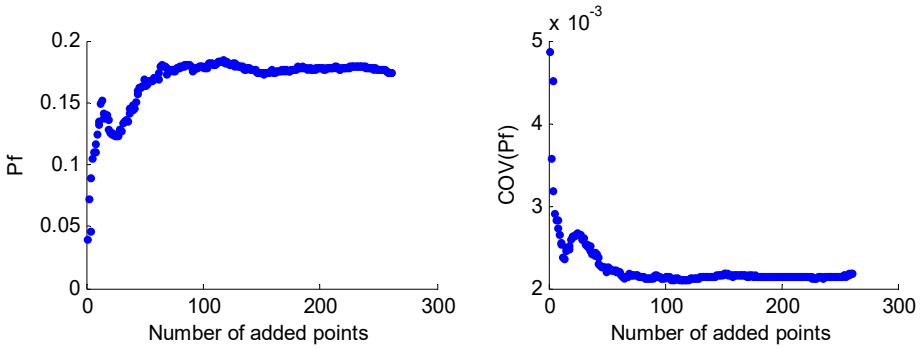

Figure 4. Variation of $\hat{P}_f$ and $C\hat{O}V(\hat{P}_f)$ as function of the number of added points for A_{max} =15m/s^2

4 CONCLUSION

The probabilistic dynamic analyses presented in this paper were performed using AK-MCS methodology. In a first stage (step 1), a significant number of realizations (about 1 million) of the spatially varying soil medium were generated by MCS using EOLE method. In a second stage (step 2), an initial design of experiments (DoE) based on a random selection of some realizations among the MCS population was determined and employed to compute the Kriging model. In a third stage (steps 3-5), a kriging model is constructed and a learning function U was employed to choose the best next realization to be used for the computation of the system response from the original deterministic model and to update the kriging model with this new response value. Notice that steps 3-5 were repeated several times until reaching the adopted stopping condition. At the end, the surrogate kriging model was considered to be enough accurate for the estimation of the failure probability and the corresponding value of the coefficient of variation, for the prescribed number of simulations (step 6). The probabilistic results have shown that for small value of the tolerable maximum acceleration A_{max} one obtains a large value of $\widehat{P}_f$. One the other hand, one can notice that number of realizations required by the AK-MCS algorithm (to obtain accurate values of $\hat{P}_f$ and $\widehat{COV}(\hat{P}_f)$) is relatively small. This is very interesting for computationally expensive dynamic problems.

Keywords: Corotational formulation; energy-momentum method; conserving energy; nonlinear dynamic; 2D Beam

Abstract. *This paper presents an energy-momentum method for nonlinear dynamics of 2D Bernoulli corotational beams. It is shown that the time stepping algorithm conserves energy, linear momentum and angular momentum. To be consistent in the corotational approach, cubic interpolations of Bernoulli element are employed to derive both inertia and elastic terms. The shallow arch strain definition is used to get an element which produce accurate results for less number of elements. To avoid membrane locking, we use a constant and average value of the axial strains. In addition, the energy-momentum method is used to preserve the conserving properties, which is able to maintain the stability and accuracy in a non-dissipative system for a long period. The midpoint velocities of kinematic fields and strains are used to tackle any non-linear form of strain displacement relations. Finally, two examples including large overall displacement are presented to illustrate the stability and efficiency of the proposed algorithms.*

1 INTRODUCTION

The corotational method is an attractive approach to derive non-linear finite beam elements [1, 2, 3, 4, 5, 6, 7, 8] . The idea is to decompose the large motion of the element into rigid body and pure deformational parts through the use of a local system which continuously rotates and translates with the element. The deformational response is captured at the level of the local reference frame, whereas the geometric non-linearity induced by the large rigid-body motion, is incorporated in the transformation matrices relating local and global quantities. The main interest is that the pure deformation part can be assumed as small and can be represented by a linear or a low order non-linear theory.

Regarding corotational dynamic formulations, constant Timoshenko mass matrices [1, 2, 5] are often used to express the dynamic terms. However, such an approach assumes that the in-plane local displacements are zero, which is not accurate. For this reason, Le et al. [3] used the Interpolation Interdependent Element formulation [9], and hence cubic functions, to derive both the elastic and inertia terms. They show that this formulation is more efficient than using constant mass matrices.

Implicit time stepping methods are often used together with non-linear finite elements to study dynamic problems. The Newmark family of algorithms [10] is one of the most commonly employed. However, these methods present instabilities in non-linear analyses [4, 5]. To avoid these instabilities, Geradin and Cardona [11] introduced numerical dissipations (Alpha method [12]) in order to damp the high frequencies. However, by doing that, the energy in the system is not conserved [13, 14].

A different integration scheme, called Energy-Momentum Method, was developed from the standard midpoint rule. Simo and Tarnow [14] were the first authors to use this method that is unconditional stable in non-linear dynamics of three-dimensional elastic bodies. However, their formulation was only valid for quadratic-nonlinearities in the displacement field. In the corotational context, Crisfield and Shi [4] used a mid-point configuration combined to average strains in order to conserve the energy. Galvanetto and Crisfield [5] developed an energy-conserving time-integration procedure for implicit non-linear dynamic analysis of planar beam structures. They used the constant Timoshenko mass matrix for the inertia term.

In this paper, an energy-momentum method for corotational 2D Bernoulli beam elements is proposed. The main advantage of this scheme is that it preserves the total energy and the linear and angular momenta. Besides, this scheme maintains stability and accuracy in long term analyses. Regarding the element, Hermitian shape functions are used to derive both the inertia and elastic terms. A shallow arch strain definition is used for the local formulation. The element formulation is obtained by applying midpoint velocities to both the kinematic quantities and the strains.

2 BEAM KINEMATICS AND STRAIN

2.1 Beam kinematics

The kinematic of the beam and all the notations used in this section are shown in Figure 1. The vector of global displacements is defined by

$$\boldsymbol{q} = \left[\begin{array}{cccccc} u_1 & w_1 & \theta_1 & u_2 & w_2 & \theta_2 \end{array} \right]^{\mathrm{T}} \tag{1}$$

The vector of local displacements is defined by

$$\bar{\boldsymbol{q}} = \left[\begin{array}{ccc} \bar{u} & \bar{\theta}_1 & \bar{\theta}_2 \end{array} \right]^{\mathrm{T}} \tag{2}$$

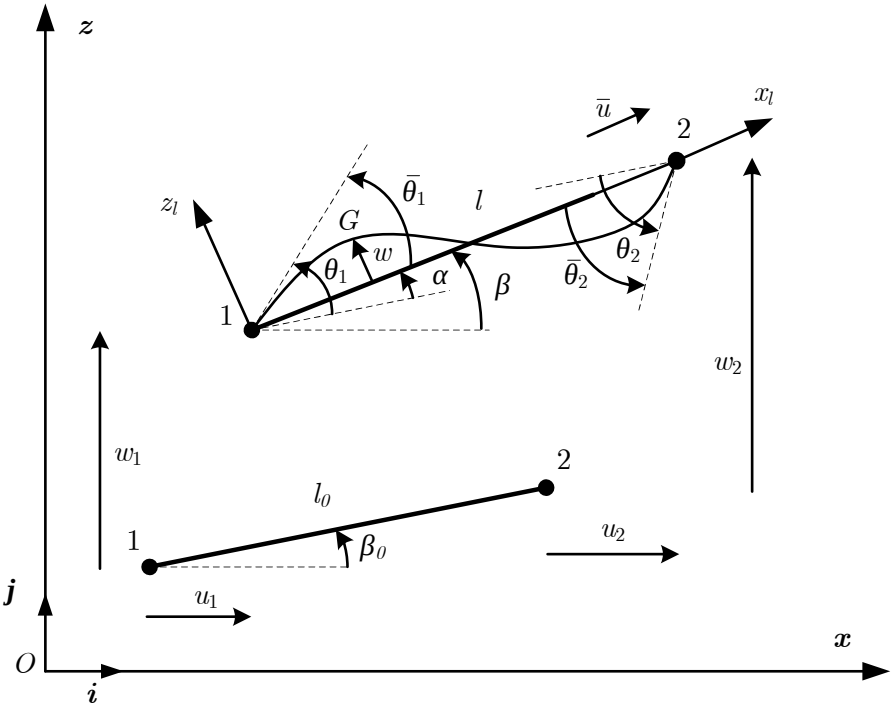

Figure 1: Beam kinematics.

The components of $\bar{\boldsymbol{q}}$ are computed according to

$$\bar{u} = l - l_0 \tag{3}$$
$$\bar{\theta}_1 = \theta_1 - \alpha \tag{4}$$
$$\bar{\theta}_2 = \theta_2 - \alpha \tag{5}$$

where l_0 and l denote the initial and current lengths of the element. The current angle of the local system with respect to the global system is denoted as β and is given by

$$c = \cos\beta = \frac{1}{l}(x_2 + u_2 - x_1 - u_1) \tag{6}$$
$$s = \sin\beta = \frac{1}{l}(z_2 + w_2 - z_1 - w_1) \tag{7}$$

The global position of the centroid G of the cross-section is given by

$$\boldsymbol{OG} = (x_1 + u_1)\,\mathbf{i} + (z_1 + w_1)\,\mathbf{j} + \frac{l_n}{l_0} x\,\boldsymbol{a} + w\,\boldsymbol{b} \tag{8}$$

with

$$\boldsymbol{a} = \cos\beta\,\mathbf{i} + \sin\beta\,\mathbf{j} \tag{9}$$
$$\boldsymbol{b} = -\sin\beta\,\mathbf{i} + \cos\beta\,\mathbf{j} \tag{10}$$

and w is the local transversal displacement of G. By using Eqs.(6) and (7), the components of the global displacements are obtained as

$$u_G = N_1(x_1 + u_1) + N_2(x_2 + u_2) - w\sin\beta \tag{11}$$
$$w_G = N_1(z_1 + w_1) + N_2(z_2 + w_2) + w\cos\beta \tag{12}$$

with

$$N_1 = 1 - \frac{x}{l_0} \tag{13}$$

$$N_2 = \frac{x}{l_0} \tag{14}$$

The global rotation of the cross-section is given by

$$\theta_G = \vartheta + \alpha \tag{15}$$

where ϑ is the local rotation of the cross-section.

2.2 Strain

The Bernoulli assumption is adopted for the local formulation. Hence, a linear interpolation is taken for the axial displacement u and a cubic one for the vertical displacement w.

The local strain is given by

$$\varepsilon_{11} = \varepsilon - \kappa\, z \tag{16}$$

in which the axial strain ε and the curvature κ are defined by

$$\varepsilon = \frac{1}{l_0}\int_{l_0}\left[\frac{\partial u}{\partial x} + \frac{1}{2}\left(\frac{\partial w}{\partial x}\right)^2\right]\mathrm{d}x \tag{17}$$

$$\kappa = \frac{\partial^2 w}{\partial x^2} \tag{18}$$

In Eq.(17), a shallow arch strain definition is taken. The purpose of introducing a low order of geometrical non-linearity in the local formulation is to obtain a more efficient formulation compared to a linear strain definition. The same level of accuracy is obtained with fewer elements. Besides, an average axial strain is taken in order to avoid membrane locking.

3 HAMILTON'S PRINCIPLE AND ENERGY-MOMENTUM METHOD

3.1 Hamilton's principle

Hamilton's principle states that the time integral of the Lagrangian at two specified states between two specified times t_1 and t_2 of a conservative mechanical system is stationary

$$\delta\int_{t_1}^{t_2}\mathcal{L}\,\mathrm{d}t = 0 \tag{19}$$

The integrand $\mathcal{L}$ is called Lagrange function

$$\mathcal{L} = \mathcal{K} - \mathcal{U}_{int} - \mathcal{U}_{ext} \tag{20}$$

$\mathcal{K}$ is the kinetic energy. $\mathcal{U}_{int}$ and $\mathcal{U}_{ext}$ are respectively the internal and the external potential energies. The body is non-conducting linear elastic solid and thermodynamic effects are not included in the system. The kinetic energy is the sum of the translational and rotational kinetic energies:

$$\mathcal{K} = \frac{1}{2}\int_{l_0}\rho A\,\dot{u}_G^2\,\mathrm{d}x + \frac{1}{2}\int_{l_0}\rho A\,\dot{w}_G^2\,\mathrm{d}x + \frac{1}{2}\int_{l_0}\rho I\,\dot{\theta}_G^2\,\mathrm{d}x \tag{21}$$

The elastic potential energy is defined as

$$\mathcal{U}_{int} = \frac{1}{2}\int_{l_0} EA\,\varepsilon^2 \mathrm{d}x + \frac{1}{2}\int_{l_0} EI\,\kappa^2 \mathrm{d}x \tag{22}$$

The external potential energy is defined as

$$\mathcal{U}_{ext} = -\int_{l_0} p_u\,u_G\,\mathrm{d}x - \int_{l_0} p_w\,w_G\,\mathrm{d}x - \int_{l_0} p_\theta\,\theta_G\,\mathrm{d}x - \sum_{i=1}^{6} P_i\,q_i \tag{23}$$

E is Young's modulus of the material, A is the area of the cross-section, I is the inertia moment of the cross-section, p_u and p_w are the distributed horizontal and the vertical loads, p_θ is the distributed external moment, P_i is the vector of concentrated forces and moments at the nodes.

By introducing Eqs.(21) to (23), the variation of Eq.(19) can be written as

$$\begin{aligned}
&\int_{t_1}^{t_2}\left(\int_{l_0}\rho A\,\ddot{u}_G\,\delta u_G\,\mathrm{d}x + \int_{l_0}\rho A\,\ddot{w}_G\,\delta w_G\,\mathrm{d}x + \int_{l_0}\rho I\,\ddot{\theta}_G\,\delta\theta_G\,\mathrm{d}x\right)\mathrm{d}t\\
-\;&\int_{t_1}^{t_2}\left(\int_{l_0} EA\,\varepsilon\,\delta\varepsilon\,\mathrm{d}x + \int_{l_0} EI\,\kappa\,\delta\kappa\,\mathrm{d}x - \int_{l_0} p_u\,\delta u_G\,\mathrm{d}x - \int_{l_0} p_w\,\delta w_G\,\mathrm{d}x\right)\mathrm{d}t\\
+\;&\int_{t_1}^{t_2}\left(\int_{l_0} p_\theta\,\delta\theta_G\,\mathrm{d}x + \sum_{i=1}^{6} P_i\,\delta q_i\right)\mathrm{d}t = 0
\end{aligned} \tag{24}$$

By using part integration for the first three terms of (24), the previous equation can be reformulated

$$\begin{aligned}
&\int_{t_1}^{t_2}\left(\int_{l_0}\rho A\,\ddot{u}_G\,\delta u_G\,\mathrm{d}x + \int_{l_0}\rho A\,\ddot{w}_G\,\delta w_G\,\mathrm{d}x + \int_{l_0}\rho I\,\ddot{\theta}_G\,\delta\theta_G\,\mathrm{d}x\right)\mathrm{d}t\\
+\;&\int_{t_1}^{t_2}\left(\int_{l_0} EA\,\varepsilon\,\delta\varepsilon\,\mathrm{d}x + \int_{l_0} EI\,\kappa\,\delta\kappa\,\mathrm{d}x - \int_{l_0} p_u\,\delta u_G\,\mathrm{d}x - \int_{l_0} p_w\,\delta w_G\,\mathrm{d}x\right)\mathrm{d}t\\
+\;&\int_{t_1}^{t_2}\left(-\int_{l_0} p_\theta\,\delta\theta_G\,\mathrm{d}x - \sum_{i=1}^{6} P_i\,\delta q_i\right)\mathrm{d}t = 0
\end{aligned} \tag{25}$$

3.2 Energy-momentum integration scheme

The classical midpoint time integration scheme is defined by the following equations:

$$\boldsymbol{q}_{n+\frac{1}{2}} = \frac{\boldsymbol{q}_{n+1}+\boldsymbol{q}_n}{2} = \boldsymbol{q}_n + \frac{1}{2}\Delta\boldsymbol{q} \tag{26}$$

$$\dot{\boldsymbol{q}}_{n+\frac{1}{2}} = \frac{\dot{\boldsymbol{q}}_{n+1}+\dot{\boldsymbol{q}}_n}{2} = \frac{\boldsymbol{q}_{n+1}-\boldsymbol{q}_n}{\Delta t} = \frac{\Delta\boldsymbol{q}}{\Delta t} \tag{27}$$

$$\ddot{\boldsymbol{q}}_{n+\frac{1}{2}} = \frac{\ddot{\boldsymbol{q}}_{n+1}+\ddot{\boldsymbol{q}}_n}{2} = \frac{\dot{\boldsymbol{q}}_{n+1}-\dot{\boldsymbol{q}}_n}{\Delta t} = \frac{2}{\Delta t^2}\Delta\boldsymbol{q} - \frac{2}{\Delta t}\dot{\boldsymbol{q}}_n \tag{28}$$

By extension of the classical midpoint rule, the average midpoint strains are developed in the context of energy-momentum method. This idea has been introduced in [16, 17]. The midpoint velocities are applied to both the kinematic fields and the strains because the nonlinear terms arise from both fields. This gives:

$$\int_{t_n}^{t_{n+1}} f(t)dt = f(t_{n+\frac{1}{2}})\Delta t = f_{n+\frac{1}{2}}\Delta t \tag{29}$$

$$f_{n+\frac{1}{2}} = f_n + \frac{\Delta t}{2}\dot{f}_{n+\frac{1}{2}} \tag{30}$$

where the function f can represent both the kinematic (u_G, w_G, θ_G) and deformational quantities (ε, κ).

The application of the midpoint rule (29) to the Hamilton's principle (25) gives

$$\begin{aligned}\Delta t \quad & \Big(\int_{l_0} \rho A\, \ddot{u}_{G,n+\frac{1}{2}}\, \delta u_{G,n+\frac{1}{2}}\, \mathrm{d}x + \int_{l_0} \rho A\, \ddot{w}_{G,n+\frac{1}{2}}\, \delta w_{G,n+\frac{1}{2}}\, \mathrm{d}x + \int_{l_0} \rho I\, \ddot{\theta}_{G,n+\frac{1}{2}}\, \delta \theta_{G,n+\frac{1}{2}}\, \mathrm{d}x \\ + \quad & \int_{l_0} EA\, \varepsilon_{n+\frac{1}{2}}\, \delta \varepsilon_{n+\frac{1}{2}}\, \mathrm{d}x + \int_{l_0} EI\, \kappa_{n+\frac{1}{2}}\, \delta \kappa_{n+\frac{1}{2}}\, \mathrm{d}x - \int_{l_0} p_{u,n+\frac{1}{2}}\, \delta u_{G,n+\frac{1}{2}}\, \mathrm{d}x \\ - \quad & \int_{l_0} p_{w,n+\frac{1}{2}}\, \delta w_{G,n+\frac{1}{2}}\, \mathrm{d}x - \int_{l_0} p_{\theta,n+\frac{1}{2}}\, \delta \theta_{G,n+\frac{1}{2}}\, \mathrm{d}x - \sum_{i=1}^{6} P_{i,n+\frac{1}{2}}\, \delta q_{i,n+\frac{1}{2}} \Big) = 0 \end{aligned} \tag{31}$$

As the variation $\delta \boldsymbol{q}$ is arbitrary, the dynamic equilibrium at time $n+\frac{1}{2}$ is obtained from the previous equation

$$\begin{aligned} & \int_{l_0} \rho A\, \ddot{u}_{G,n+\frac{1}{2}} \frac{\partial u_{G,n+\frac{1}{2}}}{\partial \boldsymbol{q}_{n+\frac{1}{2}}}\, \mathrm{d}x + \int_{l_0} \rho A\, \ddot{w}_{G,n+\frac{1}{2}} \frac{\partial w_{G,n+\frac{1}{2}}}{\partial \boldsymbol{q}_{n+\frac{1}{2}}}\, \mathrm{d}x + \int_{l_0} \rho I\, \ddot{\theta}_{G,n+\frac{1}{2}} \frac{\partial \theta_{G,n+\frac{1}{2}}}{\partial \boldsymbol{q}_{n+\frac{1}{2}}}\, \mathrm{d}x \\ + \quad & \int_{l_0} EA\, \varepsilon_{n+\frac{1}{2}} \frac{\partial \varepsilon_{n+\frac{1}{2}}}{\partial \boldsymbol{q}_{n+\frac{1}{2}}}\, \mathrm{d}x + \int_{l_0} EI\, \kappa_{n+\frac{1}{2}} \frac{\partial \kappa_{n+\frac{1}{2}}}{\partial \boldsymbol{q}_{n+\frac{1}{2}}}\, \mathrm{d}x - \int_{l_0} p_{u,n+\frac{1}{2}} \frac{\partial u_{G,n+\frac{1}{2}}}{\partial \boldsymbol{q}_{n+\frac{1}{2}}}\, \mathrm{d}x \\ - \quad & \int_{l_0} p_{w,n+\frac{1}{2}} \frac{\partial w_{G,n+\frac{1}{2}}}{\partial \boldsymbol{q}_{n+\frac{1}{2}}}\, \mathrm{d}x - \int_{l_0} p_{\theta,n+\frac{1}{2}} \frac{\partial \theta_{G,n+\frac{1}{2}}}{\partial \boldsymbol{q}_{n+\frac{1}{2}}}\, \mathrm{d}x - P_{i,n+\frac{1}{2}} = 0 \end{aligned} \tag{32}$$

4 NUMERICAL EXAMPLES

Two numerical applications are presented in this section. The first purpose of these examples is to verify numerically that the proposed energy-momentum algorithm conserves the total energy of the system and remains stable even if a very large number of time steps are applied. The second purpose is to show that in the absence of applied external loads, the proposed algorithm conserves the linear and angular momenta.

4.1 Cantilever beam

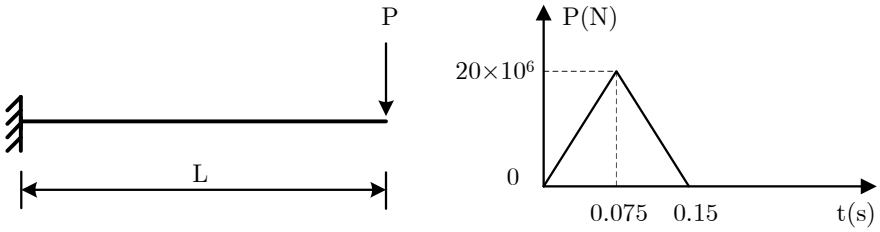

Figure 2: Geometry and load history.

The first example, see Figure 2, is a cantilever beam loaded by a triangular force at its end. The parameters of the problem are:

$$\begin{aligned} L &= 3\ m, A = 1000\ cm^2, I = 8330\ cm^4 \\ E &= 200\ GPa, \rho = 48831\ kg/m^3 \\ \Delta t &= 10^{-3}\ s, \text{Number of elements} = 4 \end{aligned}$$

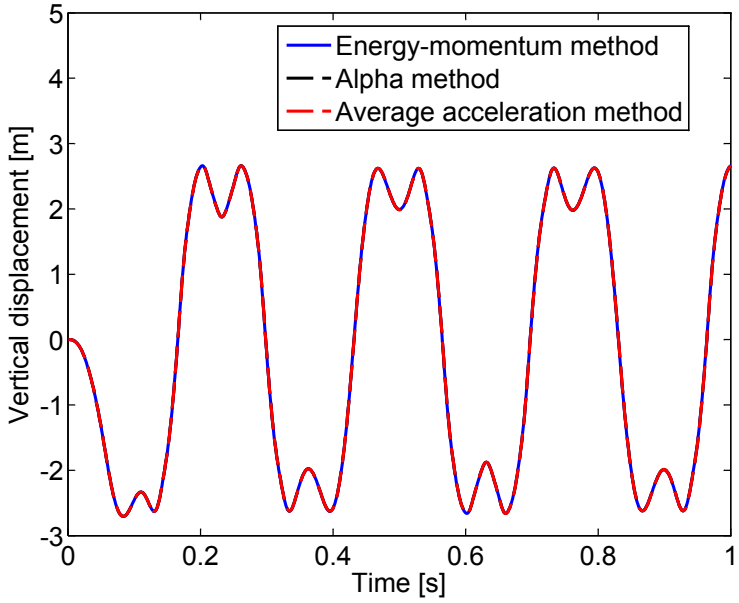

Figure 3: Comparison the displacements at the end of the tip.

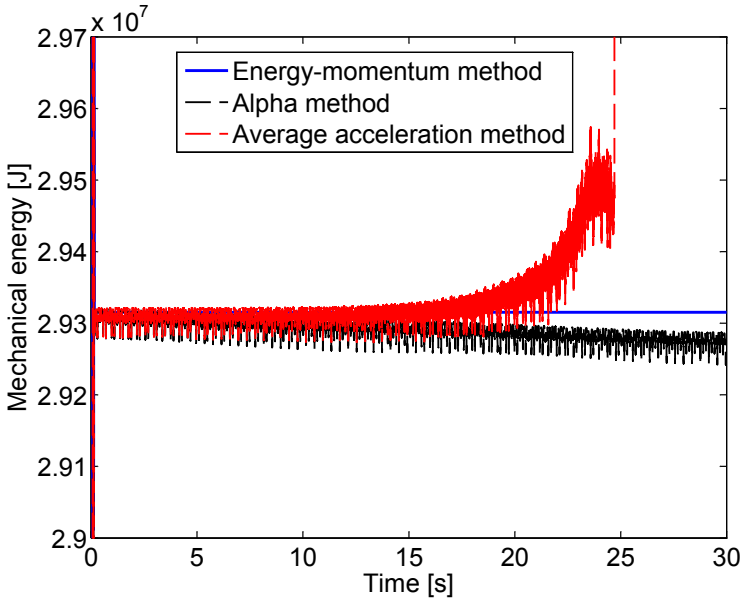

Figure 4: Comparison of mechanical energy from 0s to 30s.

The results obtained with the present energy-momentum formulation are compared to the ones obtained with the corotational formulation proposed by Le et al. [3]. In this previous formulation, the alpha method is used to solve the equations of motion. Two cases are considered here, $\alpha = 0$, which corresponds to the classical average acceleration method and $\alpha = -0.01$ which gives a small numerical damping that limits the influence of higher modes on the response.

The results presented in Figure 3 show that at the beginning the three approaches give exactly the same results. The results in Figures 4 and 5 show clearly that with the average acceleration

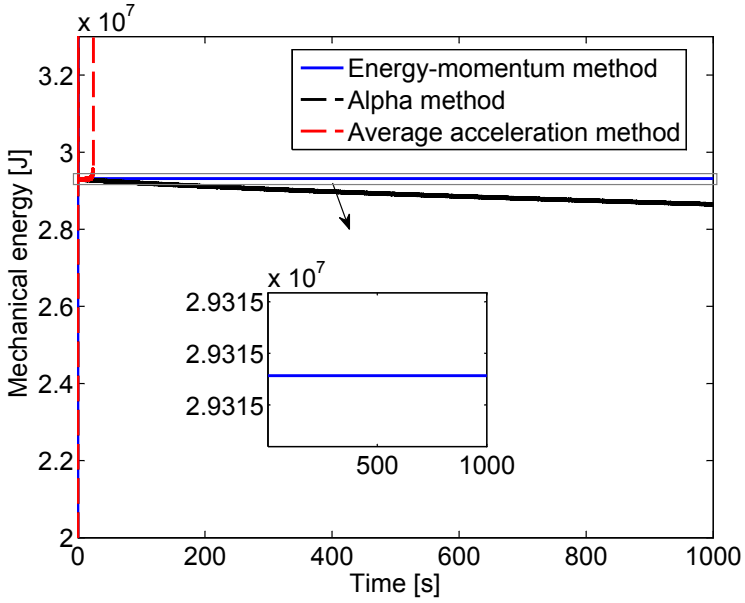

Figure 5: Comparison of mechanical energy from 0s to 1000s.

method, the mechanical energy (sum of kinetic energy and internal energy) blows up after about $24s$ and the solution diverges. With the alpha method, the solution does not diverge, but as expected, there is a loss of the mechanical energy due to the numerical damping. However, with the present energy-momentum approach, the mechanical energy is constant and the solution remains stable even if a very large number of steps (one million) is applied.

4.2 Free fly beam

The second example is a free flying beam, see Figure 6. The parameters of the problems are

$$\begin{aligned} L &= 3\ m, A = 200\ cm^2, I = 66.67\ cm^4 \\ E &= 200\ GPa, \rho = 48831\ kg/m^3 \\ \Delta t &= 10^{-4}\ s, \text{Number of elements} = 4 \end{aligned}$$

The interest of this problem is that after 0.4s, no forces and moments are applied to the beam. Consequently, this problem is suitable to study the conservation of the linear and angular momenta. Figures 7, 8 and 9 show the conservation of energy and momenta for one million time steps. The relative error is about 10^{-8} for the energy. We present here the two momenta on two different figures 8 and 9 with appropriate scale. The figures show that all the moments are constant.

5 CONCLUSION

This paper has presented an energy-momentum dynamic integration scheme in the context of corotational 2D beam elements. The main idea is to use the classical midpoint rules for both the kinematic and strain quantities. The advantage of the propose algorithm is that it conserves the total energy of the system and remains stable and accurate even if a very large number of time steps are applied. Besides, in the absence of applied external loads, the linear and angular momenta are constant. These characteristics have been proved numerically by using two numerical applications.

Keywords: Structures with dampers, fractional models of dampers, uncertainty of design parameters.

Abstract. *In this paper, the influence of the uncertainty of design parameters on the dynamic characteristics of structures with viscoelastic dampers mounted on them is considered. The fractional derivatives are used to describe the models of dampers. The uncertainty of their design parameters is introduced as an interval value. The lower and upper bounds of objective dynamic characteristics are obtained using the first- and second-order Taylor series expansion. Typical calculations are presented and compared with the results obtained using the vertex method.*

1 INTRODUCTION

In many practical situations, design parameters are uncertain. The uncertainty of parameters is caused by the inaccuracy of measurements, assembly errors, defect of material, temperature dependence, etc. The problem of uncertain parameters is widely described in numerous research papers. For issues with an unknown variability of the parameters, the interval analysis is often used. In this method, it suffices to know that the parameter values change within certain limits. Moore [1] did a pioneering work of interval analysis. In the last two decades, many methods which enable this theory to be used in engineering problems have been developed. In paper [2], the vertex method is presented. The method is based on the theorem of "inclusion monotonic". It assumes that the lower and upper bounds of the objective function should be calculated as the end-point combination of the design interval parameters. The method is also used in [3]. However, when the number of interval design parameters is large, the computational cost of the combination of all the parameters is very high. In this approach, the number of the required combinations equals 2^r, where r denotes the number of the interval parameters.

Alternative methods are required for non-monotonic problems. In papers [4,5], optimization-based interval analysis methods are presented. The lower and upper bounds of the objective function are obtained as the minimization and maximization of calculation using the interval parameters as constraints for the optimization problem.

For dynamic issues with uncertain design parameters, the lower and upper bounds of the objective function are often obtained using the Taylor series expansion. The method was extended in paper [6] and its application to optimization was shown. In [3, 7], the authors improved the method using the second-order Taylor series expansion. In [7], Fujita and Takewaki introduced an application of the method to the analysis of structures with passive dampers. A similar analysis of the structures with uncertain parameters was presented in [8] using the robustness analysis.

In this paper, the Taylor series expansion of the first- and second-order is used for determination of the lower and upper bounds of dynamic characteristics, such as natural frequencies, non-dimensional damping factors, and eigenvectors. The structure is modeled as a shear frame with dampers described by fractional derivatives. In the numerical example, the uncertainties of dampers' parameters are taken into consideration. The obtained results are compared with the vertex method of which the results are close to the exact solution. Such analysis is carried out for structures with dampers described by fractional derivatives for the first time.

2 DESCRIPTION OF STRUCTURES WITH DAMPERS

2.1 Models of dampers

Many rheological models of dampers have been proposed in the literature. The most frequently used models are the Kelvin and the Maxwell models. The first one consists of a spring and a dashpot connected in parallel whereas the second one is built of a serially connected spring and dashpot (Fig. 1).

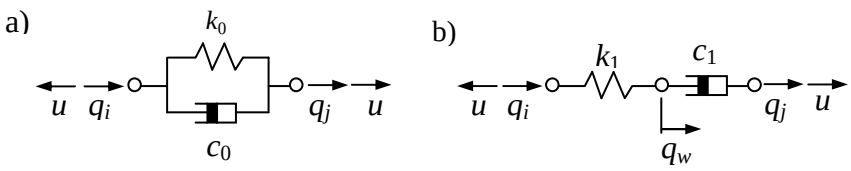

Figure 1. Classical models of dampers a) Kelvin model, b) Maxwell model.

In many instances, it is difficult to describe the rheological properties of viscoelastic dampers by basic classical models and it is necessary to use the generalized models which consist of numerous Kelvin or Maxwell elements. The number of parameters which are required for the description of the properties of dampers is rather high and sometimes it is more efficient to use the fractional models [9]. A damping element (called "a springpot element") is described by two constants, c and α, where α denotes the order of the fractional derivative. The fractional Kelvin and Maxwell models are shown in Fig. 2.

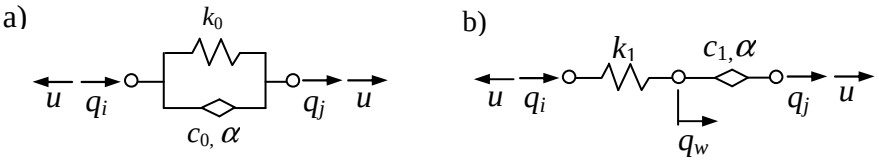

Figure 2. Fractional models of dampers a) Kelvin model, b) Maxwell model.

The equation of motion for the fractional Kelvin model can be written in the following way:

$$u(t) = k_0 \Delta q(t) + c_0 D_t^{\alpha} \Delta q(t) \tag{1}$$

and for the fractional Maxwell model, it could be described as follows:

$$u(t) + \frac{c_1}{k_1} D_t^{\alpha} u(t) = c_1 D_t^{\alpha} \Delta q(t) \tag{2}$$

where k_0 and k_1 denote stiffnesses, c_0 and c_1 denote damping factors, $\Delta q(t) = q_j(t) - q_i(t)$ is relative displacement of nodes of damper and the symbol D_t^{α} denotes the Riemann-Liouville fractional derivative of the order α with respect to time [10, 11].

After taking the Laplace transform, Equations (1) and (2) can be written in the forms:

$$\bar{u}(s) = k_0 \Delta \bar{q}(s) + c_0 s^{\alpha} \Delta \bar{q}(s) \tag{3}$$

$$\bar{u}(s) + \frac{c_1}{k_1} s^{\alpha} \bar{u}(s) = c_1 s^{\alpha} \Delta \bar{q}(s) \tag{4}$$

where: $\Delta \bar{q}(s) = L[\Delta q(t)]$, $\bar{u}(s) = L[u(t)]$, $s^{\alpha} \bar{u}(s) = L[D_t^{\alpha} u(t)]$, and s – Laplace variable. Finally, it is possible to write the general relationship:

$$\bar{u}(s) = G(s) \Delta \bar{q}(s) \tag{5}$$

where:

$$G(s) = k_0 + c_0 s^{\alpha} \tag{6}$$

for the fractional Kelvin model (see Fig. 2a) and

$$G(s) = k_1 \frac{c_1 s^{\alpha}}{k_1 + c_1 s^{\alpha}} \tag{7}$$

for the fractional Maxwell model (see Fig. 2b).

2.2 Equation of motion for structures with dampers

The equation of motion for structures with viscoelastic dampers can be written in the following form [12]:

$$\mathbf{M}_s\ddot{\mathbf{q}}(t)+\mathbf{C}_s\dot{\mathbf{q}}(t)+\mathbf{K}_s\mathbf{q}(t)=\mathbf{p}(t)+\mathbf{f}(t) \tag{8}$$

where: $\mathbf{M}_s$, $\mathbf{C}_s$ and $\mathbf{K}_s$ denote the mass, the damping and the stiffness matrix of structure, respectively. The structure is modeled as a shear frame with mass lumped at the storey level. $\mathbf{q}(t)=[q_1 \quad ... \quad q_n]^T$ is the vector of displacements of the structure, $\mathbf{p}(t)=[p_1 \quad ... \quad p_n]^T$ is the vector of excitation forces, $\mathbf{f}(t)=[f_1 \quad ... \quad f_n]^T$ is the vector of the interaction forces between the frame and the dampers (see Fig. 3) and *n* is the number of the degrees of freedom of the considered system.

Vector $\mathbf{f}(t)$ is a sum of the vectors $\mathbf{f}_k(t)$. Each of them is formed if damper *k* only is located on the frame, i.e.:

$$\mathbf{f}(t)=\sum_{k=1}^{m}\mathbf{f}_k(t)\,. \tag{9}$$

where *m* is the number of dampers.

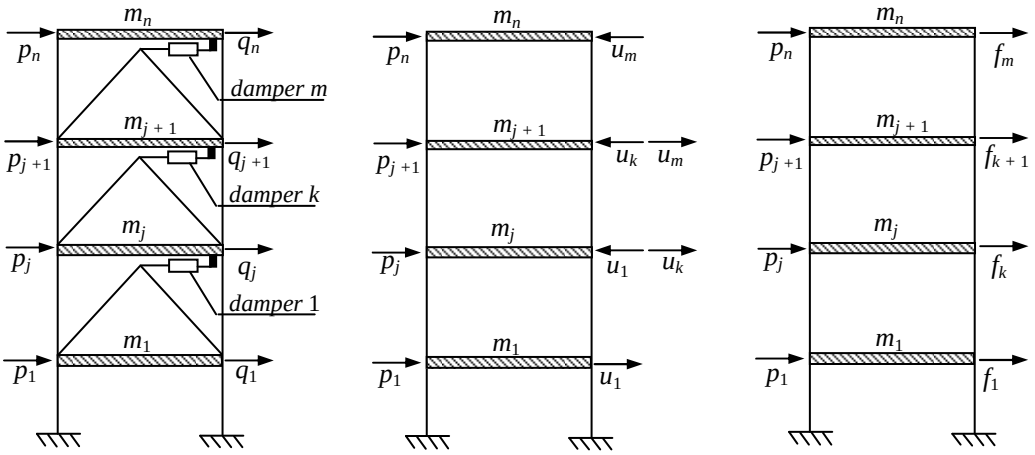

Figure 3. Diagram of frame with dampers.

For the damper located between the floors *j* and *j* + 1 (see Fig. 3), it is possible to write:

$$\mathbf{f}_k(t)=\mathbf{e}_k u_k(t), \qquad \mathbf{e}_k=[0 \quad ... \quad e_j=1 \quad e_{j+1}=-1 \quad ... \quad 0]^T\,. \tag{10}$$

After taking the Laplace transform, the equation of motion can be written as:

$$\left(s^2\mathbf{M}_s+s\mathbf{C}_s+\mathbf{K}_s\right)\bar{\mathbf{q}}(s)=\bar{\mathbf{p}}(s)+\bar{\mathbf{f}}(s) \tag{11}$$

where: $\bar{\mathbf{q}}(s)=L[\mathbf{q}(t)]$, $\bar{\mathbf{p}}(s)=L[\mathbf{p}(t)]$ and $\bar{\mathbf{f}}(s)=L[\mathbf{f}(t)]$.
The vector $\bar{\mathbf{f}}(s)$ is in the following form:

$$\bar{\mathbf{f}}(s)=\sum_{k=1}^{m}\bar{\mathbf{f}}_k(s)=\sum_{k=1}^{m}G_k(s)\mathbf{L}_k\bar{\mathbf{q}}(s) \tag{12}$$

and $\mathbf{L}_k=\mathbf{e}_k\mathbf{e}_k^{\mathrm{T}}$ is the matrix of the location of dampers.

After substituting Equation (12) to (11), the equation of the motion of structure with viscoelastic dampers is:

$$\mathbf{D}(s)\overline{\mathbf{q}}(s) = \overline{\mathbf{p}}(s) \tag{13}$$

where:

$$\mathbf{D}(s) = s^2\mathbf{M}_s + s\mathbf{C}_s + \mathbf{K}_s + \sum_{k=1}^{m}\mathbf{G}_k\,, \qquad \mathbf{G}_k(s) = G_k(s)\mathbf{L}_k\,. \tag{14}$$

If the vector of external forces equals zero ($\overline{\mathbf{p}}(s) = \mathbf{0}$), then Equation (13) leads to the following nonlinear eigenproblem:

$$\mathbf{D}(s)\,\overline{\mathbf{q}}(s) = \mathbf{0}\,. \tag{15}$$

Methods to solve a nonlinear eigenproblem for a structure with damping forces described using fractional derivatives were proposed in [13-15]. In this paper, the nonlinear eigenproblem was solved by the continuation method, described in detail in paper [15].

After determination of eigenvalues (s_i) and eigenvectors ($\mathbf{q}_i$), it is possible to calculate natural frequencies (ω_i) and non-dimensional damping factors (γ_i) according to the formulae:

$$\begin{aligned} \omega_i^2 &= \mu_i^2 + \eta_i^2 \\ \gamma_i &= -\mu_i / \omega_i \end{aligned} \tag{16}$$

where $\mu_i = \mathrm{Re}(s_i)$, $\eta_i = \mathrm{Im}(s_i)$.

3 UNCERTAIN PARAMETERS

3.1 Interval analysis - definition

Let us assume some design parameters have changed, though only within a specified range. These variations can be written as interval parameters in the form:

$$\mathbf{p}^I = \left[\mathbf{p}^c - \Delta\mathbf{p},\ \mathbf{p}^c + \Delta\mathbf{p}\right] \tag{17}$$

or as follows:

$$\mathbf{p}^I = \left[\underline{\mathbf{p}}, \overline{\mathbf{p}}\right] \tag{18}$$

where $\mathbf{p}^I = \left[p_1^I, p_2^I, ..., p_r^I\right]$ denotes the values of interval parameters, r denotes the number of interval design parameters, $\mathbf{p}^c$ denotes middle values of interval parameters:

$$\mathbf{p}^c = \frac{\overline{p} + \underline{p}}{2}\,, \tag{19}$$

$\Delta\mathbf{p}$ denotes half of the varied range of interval parameters (radius value):

$$\Delta\mathbf{p} = \frac{\overline{p} - \underline{p}}{2}\,, \tag{20}$$

$\underline{\mathbf{p}}$ and $\overline{\mathbf{p}}$ denote the lower and upper bounds of the interval parameters, respectively.

Let us consider an objective function $F(\mathbf{p})$ which depends on the design parameters. If the parameters' values change within a specified range, the considered function can be written in the form $F^I(\mathbf{p}^I)$. The interval analysis leads us to find the lower and upper bounds of the ob-

jective function in a feasible domain of the interval parameters $(-\Delta\mathbf{p}, \Delta\mathbf{p})$. The interval problem can be described as:

$$F^I(\mathbf{p}^I) = \left[\min_{\mathbf{p}\in\mathbf{p}^I} F(\mathbf{p}),\ \max_{\mathbf{p}\in\mathbf{p}^I} F(\mathbf{p})\right] \tag{21}$$

3.2 Interval analysis based on approximation of Taylor series expansion

An approximation of the objective function $\widetilde{F}(\mathbf{p})$ using the first-order Taylor series expansion around the middle values of parameters $\mathbf{p}^C$ is defined in the following form:

$$\widetilde{F}(\mathbf{p}) = F(\mathbf{p}^C) + \sum_{i=1}^{r} \frac{\partial F(\mathbf{p}^C)}{\partial p_i} \Delta p_i \tag{22}$$

where $\Delta p_i = p_i - p_i^C$ and $\partial F(\mathbf{p}^C)/\partial p_i$ denotes a first-order differentiation of the function $F(\mathbf{p}^C)$ at middle values of design parameters with respect to the changing parameter p_i.

From Equation (22), it is possible to write the increment of the objective function calculated using the first-order Taylor series expansion

$$\Delta F(\mathbf{p}) = \sum_{i=1}^{r} \frac{\partial F(\mathbf{p}^C)}{\partial p_i} \Delta p_i \tag{23}$$

as a sum of increments of the objective function for each one-dimensional perturbation. Hence, the increment of the objective function for the variation of parameter p_1 can be evaluated from:

$$\Delta F_1(p_1^I, p_2^C, ..., p_n^C) = \frac{\partial F(\mathbf{p}^C)}{\partial p_1}(p_1 - p_1^C). \tag{24}$$

According to an interval analysis, the following formula can be written:

$$\Delta F_1^I(p_1^I, p_2^C, ..., p_n^C) = \begin{bmatrix} \min\left[\Delta F_1(\underline{p}_1, p_2^C, ..., p_n^C), \Delta F_1(\overline{p}_1, p_2^C, ..., p_n^C)\right] \\ \max\left[\Delta F_1(\underline{p}_1, p_2^C, ..., p_n^C), \Delta F_1(\overline{p}_1, p_2^C, ..., p_n^C)\right] \end{bmatrix} \tag{25}$$

It is possible to write a similar relationship for each interval design parameter. Finally, substituting $\Delta F_i(p_i^I)$ to Equation (22) leads us to the equation:

$$F^I(\mathbf{p}^I) = \left[F(\mathbf{p}^C) + \sum_{i=1}^{r} \Delta\underline{F}_i(p_i^I),\ \ F(\mathbf{p}^C) + \sum_{i=1}^{r} \Delta\overline{F}_i(p_i^I)\right] \tag{26}$$

According to formula (26), the lower and upper bounds of the objective interval function, approximated using the first-order Taylor series expansion, can be written as:

$$\begin{aligned} \underline{F}(\mathbf{p}^I) &= F(\mathbf{p}^C) - \sum_{i=1}^{r} \left|\frac{\partial F(\mathbf{p}^C)}{\partial p_i} \Delta p_i\right| \\ \overline{F}(\mathbf{p}^I) &= F(\mathbf{p}^C) + \sum_{i=1}^{r} \left|\frac{\partial F(\mathbf{p}^C)}{\partial p_i} \Delta p_i\right| \end{aligned} \tag{27}$$

Some researchers [3,7] proposed an approximation of the objective function $\tilde{\tilde{F}}(\mathbf{p})$ using the second-order Taylor series expansion around the middle values of parameters $\mathbf{p}^C$:

$$\tilde{\tilde{F}}(\mathbf{p}) = F(\mathbf{p}^C) + \sum_{i=1}^{r} \frac{\partial F(\mathbf{p}^C)}{\partial p_i} \Delta p_i + \frac{1}{2} \sum_{i=1}^{r} \sum_{j=1}^{r} \frac{\partial^2 F(\mathbf{p}^C)}{\partial p_i \partial p_j} \Delta p_i \Delta p_j \tag{28}$$

where $\partial^2 F(\mathbf{p}^C) / (\partial p_i \partial p_j)$ build the Hessian matrix of the function $F(\mathbf{p}^C)$ with respect to the changing parameters p_i and p_j. The matrix consists of a second-order differentiation of the function $F(\mathbf{p}^C)$ at middle values of the design parameters. The increment of the objective function can be written in the following form:

$$\Delta F(\mathbf{p}) = \sum_{i=1}^{r} \frac{\partial F(\mathbf{p}^C)}{\partial p_i} \Delta p_i + \frac{1}{2} \sum_{i=1}^{r} \sum_{j=1}^{r} \frac{\partial^2 F(\mathbf{p}^C)}{\partial p_i \partial p_j} \Delta p_i \Delta p_j . \tag{29}$$

Based on inclusion monotonic, in order to find the lower and upper bounds of the objective function $\tilde{\tilde{F}}(\mathbf{p})$, it is necessary to calculate all end-point combinations of the interval parameters p_i and p_j. The number of combinations is the same as the number of combinations using the vertex method and it equals 2^r. The computational cost in this approach is very high, especially for high numbers of the interval parameters. Therefore, a simplification of the above method was proposed in [3]. In that paper, the non-diagonal elements of the Hessian matrix are neglected.

An approximation of the objective function $\tilde{\tilde{\tilde{F}}}(\mathbf{p})$ using the second-order Taylor series expansion with only the diagonal elements of the Hessian matrix is as follows:

$$\tilde{\tilde{\tilde{F}}}(\mathbf{p}) = F(\mathbf{p}^C) + \sum_{i=1}^{r} \left(\frac{\partial F(\mathbf{p}^C)}{\partial p_i} \Delta p_i + \frac{1}{2} \frac{\partial^2 F(\mathbf{p}^C)}{\partial p_i^2} \Delta p_i^2 \right). \tag{30}$$

The increment of the objective function can be written in the following form:

$$\Delta F(\mathbf{p}) = \sum_{i=1}^{r} \left(\frac{\partial F(\mathbf{p}^C)}{\partial p_i} \Delta p_i + \frac{1}{2} \frac{\partial^2 F(\mathbf{p}^C)}{\partial p_i^2} \Delta p_i^2 \right). \tag{31}$$

For variability of parameter p_1, Equation (31) is as follows:

$$\Delta F_1(\mathbf{p}) = \frac{\partial F(\mathbf{p}^C)}{\partial p_1} (p_1 - p^C) + \frac{1}{2} \frac{\partial^2 F(\mathbf{p}^C)}{\partial p_1^2} (p_1 - p^C)^2 . \tag{32}$$

It should be noted that, when using relationship (25) for calculating the lower and upper bounds of the objective function, the number of combinations is reduced to $2r$.

3.3 Dynamic characteristics of structures with uncertain design parameters

In this section, formulae describing the lower and upper bounds of the chosen dynamic characteristics are determined. The natural frequency (ω), non-dimensional damping factor (γ), and eigenvectors ($\mathbf{q}$) are taken into consideration. According the formula (26), it is possible to write:

$$\omega^I(\mathbf{p}^I)=\left[\omega(\mathbf{p}^C)+\sum_{i=1}^{r}\Delta\underline{\omega}_i(p_i^I),\quad \omega(\mathbf{p}^C)+\sum_{i=1}^{r}\Delta\overline{\omega}_i(p_i^I)\right] \tag{33}$$

for the natural frequency,

$$\gamma^I(\mathbf{p}^I)=\left[\gamma(\mathbf{p}^C)+\sum_{i=1}^{r}\Delta\underline{\gamma}_i(p_i^I),\quad \gamma(\mathbf{p}^C)+\sum_{i=1}^{r}\Delta\overline{\gamma}_i(p_i^I)\right] \tag{34}$$

for the non-dimensional damping factor and

$$\mathbf{q}^I(\mathbf{p}^I)=\left[\mathbf{q}(\mathbf{p}^C)+\sum_{i=1}^{r}\Delta\underline{\mathbf{q}}_i(p_i^I),\quad \mathbf{q}(\mathbf{p}^C)+\sum_{i=1}^{r}\Delta\overline{\mathbf{q}}_i(p_i^I)\right] \tag{35}$$

for the eigenvector.

When the objective function is approximated using the first-order Taylor series expansion, the increments can be written as:

$$\Delta\omega(\mathbf{p})=\sum_{i=1}^{r}\frac{\partial\omega(\mathbf{p}^C)}{\partial p_i}\Delta p_i\,, \tag{36}$$

$$\Delta\gamma(\mathbf{p})=\sum_{i=1}^{r}\frac{\partial\gamma(\mathbf{p}^C)}{\partial p_i}\Delta p_i\,, \tag{37}$$

$$\Delta\mathbf{q}(\mathbf{p})=\sum_{i=1}^{r}\frac{\partial\mathbf{q}(\mathbf{p}^C)}{\partial p_i}\Delta p_i\,. \tag{38}$$

When the objective function is approximated using the second-order Taylor series expansion, the increments are as follows:

$$\Delta\omega(\mathbf{p})=\sum_{i=1}^{r}\frac{\partial\omega(\mathbf{p}^C)}{\partial p_i}\Delta p_i+\frac{1}{2}\sum_{i=1}^{r}\sum_{j=1}^{r}\frac{\partial^2\omega(\mathbf{p}^C)}{\partial p_i\partial p_j}\Delta p_i\Delta p_j\,, \tag{39}$$

$$\Delta\gamma(\mathbf{p})=\sum_{i=1}^{r}\frac{\partial\gamma(\mathbf{p}^C)}{\partial p_i}\Delta p_i+\frac{1}{2}\sum_{i=1}^{r}\sum_{j=1}^{r}\frac{\partial^2\gamma(\mathbf{p}^C)}{\partial p_i\partial p_j}\Delta p_i\Delta p_j\,, \tag{40}$$

$$\Delta\mathbf{q}(\mathbf{p})=\sum_{i=1}^{r}\frac{\partial\mathbf{q}(\mathbf{p}^C)}{\partial p_i}\Delta p_i+\frac{1}{2}\sum_{i=1}^{r}\sum_{j=1}^{r}\frac{\partial^2\mathbf{q}(\mathbf{p}^C)}{\partial p_i\partial p_j}\Delta p_i\Delta p_j\,. \tag{41}$$

And when the objective function is approximated using the second-order Taylor series expansion with only the diagonal elements of the Hessian matrix, the increments are described as:

$$\Delta\omega(\mathbf{p})=\sum_{i=1}^{r}\left(\frac{\partial\omega(\mathbf{p}^C)}{\partial p_i}\Delta p_i+\frac{1}{2}\frac{\partial^2\omega(\mathbf{p}^C)}{\partial p_i^2}\Delta p_i^2\right), \tag{42}$$

$$\Delta\gamma(\mathbf{p})=\sum_{i=1}^{r}\left(\frac{\partial\gamma(\mathbf{p}^C)}{\partial p_i}\Delta p_i+\frac{1}{2}\frac{\partial^2\gamma(\mathbf{p}^C)}{\partial p_i^2}\Delta p_i^2\right), \tag{43}$$

$$\Delta\mathbf{q}(\mathbf{p})=\sum_{i=1}^{r}\left(\frac{\partial\mathbf{q}(\mathbf{p}^C)}{\partial p_i}\Delta p_i+\frac{1}{2}\frac{\partial^2\mathbf{q}(\mathbf{p}^C)}{\partial p_i^2}\Delta p_i^2\right). \tag{44}$$

The calculation of the lower and upper bounds of the dynamic characteristics requires the sensitivities of the first- and the second-order of the objective function $\left(\partial F\left(\mathbf{p}^C\right)/\partial p_i\,,\partial^2 F\left(\mathbf{p}^C\right)/\left(\partial p_i \partial p_j\right)\right)$ with respect to the design parameters. These sensitivities are obtained by the direct differentiation method, which is described in detail in [16]. The formulae for sensitivities with respect to the parameters of the Kelvin damper model are shown in Appendix A.

4 EXAMPLE

In the example, an eight-storey frame with three bays is considered (see Fig. 4). The frame is designed according to the EC8 Part 1. Construction data, with the exception of the unit mass of the floor, were adopted on the basis of [17]. The height of the columns is 3m and the span of the beams is 5m. Young's modulus (E) for concrete is 31GPa. Dimensions of columns and their replacement stiffnesses are shown in Table 1.

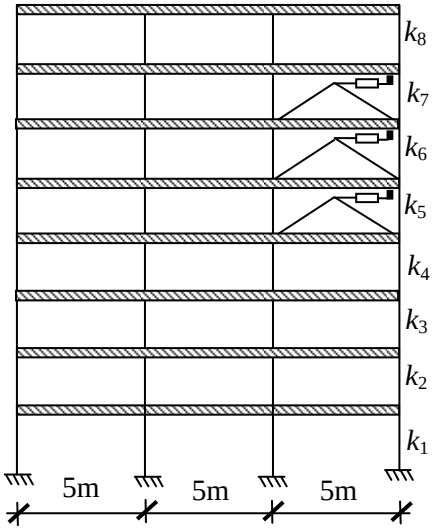

Figure 4. Diagram of the considered frame.

Storey level	Lateral column [cm]	Central column [cm]	Replacement stiffness [kN/m]
1,2	50x50	60x60	441119
3,4	45x45	53x53	275351
5,6	40x40	45x45	152948
7,8	35x35	40x40	93244

Table 1. Dimensions and replacement stiffness columns.

The mass per unit length of every floor equals 60000 kg/m. The dampers are attached on the fifth, sixth and seventh floors of the structure. Such locations were chosen according to paper [17]. A fractional Kelvin model of damper is taken into consideration (see Fig. 2a). The dampers‘ parameters were adopted in such a way that the first non-dimensional damping factor was $\gamma_1 \geq 0.04$. The following parameters are adopted for the dampers:

$k_0 = 20000\text{kN/m}$, $c_0 = 27000\text{kNs}^{\alpha}/\text{m}$ and $\alpha = 0.6$. The values of first natural frequencies ω_1 and the non-dimensional damping factor γ_1 for the structure without dampers and for the structure with the fractional Kelvin model are shown in Table 2. Damping in the structure is neglected.

The uncertainties of dampers' parameters are considered. They are shown in Table 3. The damper parameters are marked k_{0i} and c_{0i}, where i denotes the damper number. The order of the fractional derivative remains constant.

Structure without dampers	Structure with fractional dampers	
natural frequency ω_1 [rad/s]	natural frequency ω_1 [rad/s]	non-dimensional damping factor γ_1
3.10396	3.34162	0.04045

Table 2. First natural frequencies and non-dimensional damping factor without and with fractional dampers.

damper parameter	uncertainty [%]
c_{01}	10
c_{02}	15
c_{03}	15
k_{01}	15
k_{02}	20
k_{03}	15

Table 3. Uncertainties of damper parameters.

The parameters are assumed to vary independently. The interval parameters for dampers are listed in Tables 4-5.

bounded value	middle value	radius value
$c_{01}^I = [24300, 29700]$	$c_{01}^C = 27000$	$\Delta c_{01} = 2700$
$c_{02}^I = [22950, 31050]$	$c_{02}^C = 27000$	$\Delta c_{02} = 4050$
$c_{03}^I = [22950, 31050]$	$c_{03}^C = 27000$	$\Delta c_{03} = 4050$

Table 4. Interval parameters of damping factor [kNs$^{\alpha}$/m].

bounded value	middle value	radius value
$k_{01}^I = [17000, 2300]$	$k_{01}^C = 20000$	$\Delta k_{01} = 2000$
$k_{02}^I = [16000, 2400]$	$k_{02}^C = 20000$	$\Delta k_{02} = 1000$
$k_{03}^I = [17000, 2300]$	$k_{03}^C = 20000$	$\Delta k_{03} = 2000$

Table 5. Interval parameters of stiffness [kN/m].

The parameters' middle values are taken to find the solutions given in Table 2. In Table 6, the results of interval analysis are presented. The results obtained by the vertex method, first-order Taylor series expansion, second-order Taylor series expansion and second-order Taylor

series expansion with only the diagonal element of the Hessian matrix are compared. The critical combinations of the interval parameters are shown for each case. The solution of the vertex method is assumed as a comparative solution and the error is calculated in relation to that.

Table 7. Lower and upper bounds of γ_1.

Based on the obtained results, it should be noted that the solutions using the first-order Taylor series expansion and the second-order Taylor series expansion are close to the solution

calculated with the use of the vertex method. In each of the four cases, the critical combination of the interval parameters is the same.

The lower and upper bounds of the first eigenvector are also calculated. The middle values of the eigenvector's elements are evaluated for the middle values of dampers' parameters. The lower and upper values of the eigenvector obtained by the vertex method $[\underline{\mathbf{q}}_1, \overline{\mathbf{q}}_1]$ are calculated for the relevant natural frequencies $[\underline{\omega}_1, \overline{\omega}_1]$ obtained by this method (solid lines). The obtained results are compared with the values calculated using the first-order Taylor series expansion (dashed line). The comparison is shown in Figures 6-7.

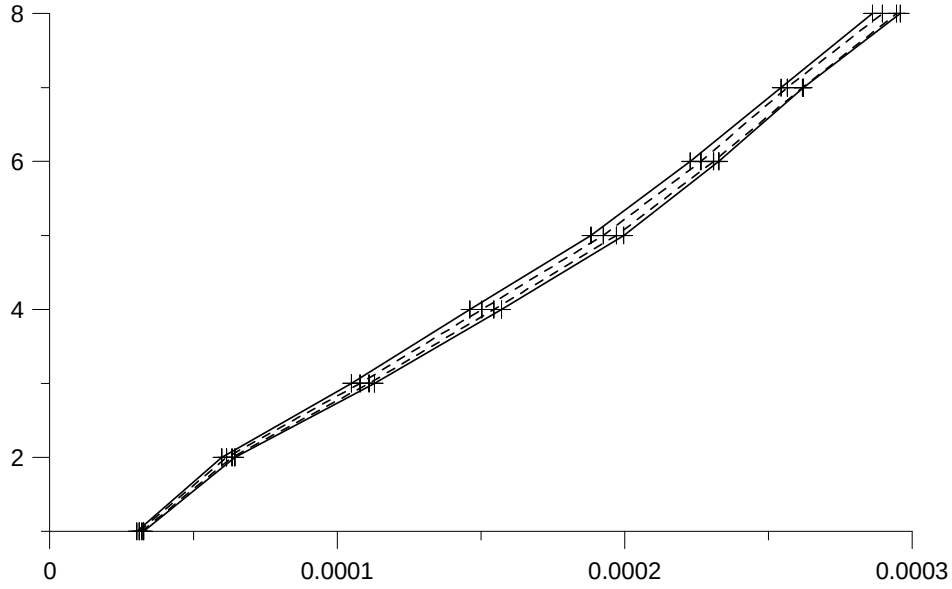

Figure 6. Lower and upper bounds of the real part of eigenvector $\mathbf{q}_1$.

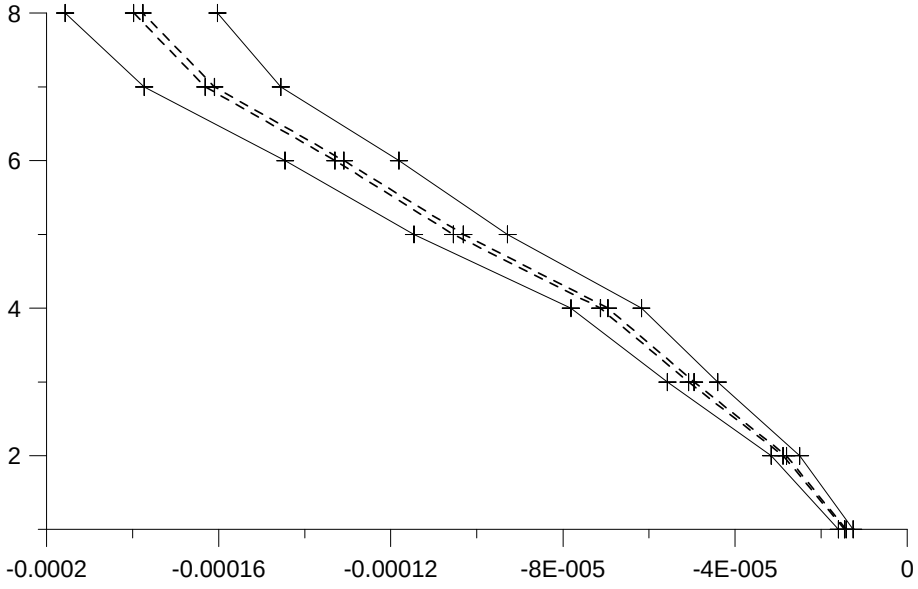

Figure 7. Lower and upper bounds of the imaginary part of eigenvector $\mathbf{q}_1$.

Evaluations of the lower and upper bounds of the eigenvector, carried out using the vertex method and the first-order Taylor series expansion differ by about 2-3% in the case of the real parts and 9-13% in the case of the imaginary parts.

5 CONCLUSIONS

The influence of uncertainties of the design parameters on the dynamic characteristics of structures with viscoelastic dampers are investigated. The presented formulae enable determination of the lower and upper bounds of the objective function. The different methods of evaluation of the lower and upper bounds are shown. The bounds are determined using the vertex method, first order Taylor series expansion, second-order Taylor series expansion and simplified second-order Taylor series expansion. The vertex method was chosen as a comparative solution but it should be noted that the exact solution in the form of a critical combination of the interval parameters can be obtained for values of parameters between the limit values. The methods based on the Taylor series expansion provide results which are close to those obtained by the vertex method. Errors of the calculations performed are similar in each of the three presented approximating functions but the second-order Taylor series expansion requires high computational costs, especially if all the elements of the Hessian matrix are taken into account.

APPENDIX A

In order to calculate the sensitivities of dynamic characteristics with respect to the design parameter, the following sets of equations can be solved [16]:

$$\begin{bmatrix} \mathbf{D}(s) & \dfrac{\partial \mathbf{D}(s)}{\partial s}\overline{\mathbf{q}}(s) \\ \overline{\mathbf{q}}^T(s)\dfrac{\partial \mathbf{D}(s)}{\partial s} & \dfrac{1}{2}\overline{\mathbf{q}}^T(s)\dfrac{\partial^2 \mathbf{D}(s)}{\partial s^2}\overline{\mathbf{q}}(s) \end{bmatrix} \begin{Bmatrix} \dfrac{\partial \overline{\mathbf{q}}(s)}{\partial p_i} \\ \dfrac{\partial s}{\partial p_i} \end{Bmatrix} = \begin{Bmatrix} \mathbf{h}_1(s) \\ h_2(s) \end{Bmatrix} \tag{A.1}$$

for the first-order sensitivities and

$$\begin{bmatrix} \mathbf{D}(s) & \dfrac{\partial \mathbf{D}(s)}{\partial s}\overline{\mathbf{q}}(s) \\ \overline{\mathbf{q}}^T(s)\dfrac{\partial \mathbf{D}(s)}{\partial s} & \dfrac{1}{2}\overline{\mathbf{q}}^T(s)\dfrac{\partial^2 \mathbf{D}(s)}{\partial s^2}\overline{\mathbf{q}}(s) \end{bmatrix} \begin{Bmatrix} \dfrac{\partial^2 \overline{\mathbf{q}}(s)}{\partial p_i \partial p_j} \\ \dfrac{\partial^2 s}{\partial p_i \partial p_j} \end{Bmatrix} = \begin{Bmatrix} \mathbf{h}_3(s) \\ h_4(s) \end{Bmatrix} \tag{A.2}$$

for the second-order sensitivities.
The right-hand sides of the above equations are as follows:

$$\mathbf{h}_1(s) = -\mathbf{R}_1(s)\overline{\mathbf{q}}(s), \tag{A.3}$$

$$h_2(s) = -\frac{1}{2}\overline{\mathbf{q}}^T(s)\mathbf{R}_2(s)\overline{\mathbf{q}}(s), \tag{A.4}$$

$$\mathbf{h}_3(s) = -\left[\mathbf{R}_{31}(s)\overline{\mathbf{q}}(s) + \mathbf{R}_{32}(s)\frac{\partial \overline{\mathbf{q}}(s)}{\partial p_i} + \mathbf{R}_{33}(s)\frac{\partial \overline{\mathbf{q}}(s)}{\partial p_j}\right], \tag{A.5}$$

$$h_4(s)=-\left[\overline{\mathbf{q}}(s)^T\mathbf{R}_{41}(s)\overline{\mathbf{q}}(s)+\overline{\mathbf{q}}(s)^T\mathbf{R}_{42}(s)\frac{\partial\overline{\mathbf{q}}(s)}{\partial p_i}+\overline{\mathbf{q}}(s)^T\mathbf{R}_{43}(s)\frac{\partial\overline{\mathbf{q}}(s)}{\partial p_j}+\frac{\partial\overline{\mathbf{q}}(s)}{\partial p_i}^T\frac{\partial\mathbf{D}(s)}{\partial s}\frac{\partial\overline{\mathbf{q}}(s)}{\partial p_j}\right] \quad \text{(A.6)}$$

where:

$$\mathbf{R}_1(s)=\frac{\partial\mathbf{D}(s)}{\partial p_i},\qquad \mathbf{R}_2(s)=\frac{\partial^2\mathbf{D}(s)}{\partial p_i\partial s}, \quad \text{(A.7)}$$

$$\mathbf{R}_{31}(s)=\frac{\partial^2\mathbf{D}(s)}{\partial p_i\partial p_j}+\frac{\partial^2\mathbf{D}(s)}{\partial p_i\partial s}\frac{\partial s}{\partial p_j}+\frac{\partial^2\mathbf{D}(s)}{\partial p_j\partial s}\frac{\partial s}{\partial p_i}+\frac{\partial^2\mathbf{D}(s)}{\partial s^2}\frac{\partial s}{\partial p_i}\frac{\partial s}{\partial p_j}, \quad \text{(A.8)}$$

$$\mathbf{R}_{32}(s)=\frac{\partial\mathbf{D}(s)}{\partial p_j}+\frac{\partial\mathbf{D}(s)}{\partial s}\frac{\partial s}{\partial p_j},\qquad \mathbf{R}_{33}(s)=\frac{\partial\mathbf{D}(s)}{\partial p_i}+\frac{\partial\mathbf{D}(s)}{\partial s}\frac{\partial s}{\partial p_i} \quad \text{(A.9)}$$

$$\mathbf{R}_{41}(s)=\frac{1}{2}\left[\frac{\partial^3\mathbf{D}(s)}{\partial s^3}\frac{\partial s}{\partial p_i}\frac{\partial s}{\partial p_j}+\frac{\partial^3\mathbf{D}(s)}{\partial s^2\partial p_j}\frac{\partial s}{\partial p_i}+\frac{\partial^3\mathbf{D}(s)}{\partial s^2\partial p_i}\frac{\partial s}{\partial p_j}+\frac{\partial^3\mathbf{D}(s)}{\partial s\partial p_i\partial p_j}\right], \quad \text{(A.10)}$$

$$\mathbf{R}_{42}(s)=\frac{\partial^2\mathbf{D}(s)}{\partial s\partial p_j}+\frac{\partial^2\mathbf{D}(s)}{\partial s^2}\frac{\partial s}{\partial p_j},\qquad \mathbf{R}_{43}(s)=\frac{\partial^2\mathbf{D}(s)}{\partial s\partial p_i}+\frac{\partial^2\mathbf{D}(s)}{\partial s^2}\frac{\partial s}{\partial p_i}. \quad \text{(A.11)}$$

In the case of the Kelvin model of damper, the matrices $\mathbf{R}_1(s)$ and $\mathbf{R}_2(s)$ which are required for solving the first-order sensitivities, are as follows:

$$\mathbf{R}_1(s)=s^{\alpha_i}\mathbf{L}_i,\qquad \mathbf{R}_2(s)=\alpha_i s^{\alpha_i-1}\mathbf{L}_i \quad \text{(A.12)}$$

when the design parameter p_i is c_{0i} and

$$\mathbf{R}_1(s)=\mathbf{L}_i,\qquad \mathbf{R}_2(s)=\mathbf{0} \quad \text{(A.13)}$$

when the design parameter p_i is k_{0i}.

When the second-order sensitivities is of interest, the matrices $\mathbf{R}_{31}(s)$, $\mathbf{R}_{32}(s)$, $\mathbf{R}_{33}(s)$, $\mathbf{R}_{41}(s)$, $\mathbf{R}_{42}(s)$ and $\mathbf{R}_{43}(s)$ can be written as:

$$\mathbf{R}_{31}(s)=\frac{\partial^2\mathbf{D}}{\partial s^2}\frac{\partial s}{\partial c_{0i}}\frac{\partial s}{\partial c_{0j}}+\alpha_j s^{\alpha_j-1}\mathbf{L}_j\frac{\partial s}{\partial c_{0i}}+\alpha_i s^{\alpha_i-1}\mathbf{L}_i\frac{\partial s}{\partial c_{0j}}, \quad \text{(A.14)}$$

$$\mathbf{R}_{32}(s)=s^{\alpha_j}\mathbf{L}_j+\frac{\partial\mathbf{D}(s)}{\partial s}\frac{\partial s}{\partial c_{0j}},\qquad \mathbf{R}_{33}(s)=s^{\alpha_i}\mathbf{L}_i+\frac{\partial\mathbf{D}(s)}{\partial s}\frac{\partial s}{\partial c_{0i}}, \quad \text{(A.15)}$$

$$\mathbf{R}_{41}(s)=\frac{1}{2}\left[\alpha_j(\alpha_j-1)s^{\alpha_j-2}\mathbf{L}_j\frac{\partial s}{\partial c_{0i}}+\alpha_i(\alpha_i-1)s^{\alpha_i-2}\mathbf{L}_i\frac{\partial s}{\partial c_{0j}}+\frac{\partial^3\mathbf{D}}{\partial s^3}\frac{\partial s}{\partial c_{0i}}\frac{\partial s}{\partial c_{0j}}\right], \quad \text{(A.16)}$$

$$\mathbf{R}_{42}(s)=\alpha_j s^{\alpha_j-1}\mathbf{L}_j+\frac{\partial^2\mathbf{D}(s)}{\partial s^2}\frac{\partial s}{\partial c_{0j}},\qquad \mathbf{R}_{43}(s)=\alpha_i s^{\alpha_i-1}\mathbf{L}_i+\frac{\partial^2\mathbf{D}(s)}{\partial s^2}\frac{\partial s}{\partial c_{0i}} \quad \text{(A.17)}$$

when the design parameters p_i and p_j are c_{0i} and c_{0j}, respectively, and

$$\mathbf{R}_{31}(s)=\frac{\partial^2\mathbf{D}}{\partial s^2}\frac{\partial s}{\partial c_{0i}}\frac{\partial s}{\partial k_{0j}}+\alpha_i s^{\alpha_i-1}\mathbf{L}_i\frac{\partial s}{\partial k_{0j}}, \quad \text{(A.18)}$$

$$\mathbf{R}_{32}(s)=\mathbf{L}_j+\frac{\partial\mathbf{D}(s)}{\partial s}\frac{\partial s}{\partial k_{0j}},\qquad \mathbf{R}_{33}(s)=s^{\alpha_i}\mathbf{L}_i+\frac{\partial\mathbf{D}(s)}{\partial s}\frac{\partial s}{\partial c_{0i}}, \tag{A.19}$$

$$\mathbf{R}_{41}(s)=\frac{1}{2}\left[\alpha_i(\alpha_i-1)s^{\alpha_i-2}\mathbf{L}_i\frac{\partial s}{\partial k_{0j}}+\frac{\partial^3\mathbf{D}}{\partial s^3}\frac{\partial s}{\partial c_{0i}}\frac{\partial s}{\partial k_{0j}}\right], \tag{A.20}$$

$$\mathbf{R}_{42}(s)=\frac{\partial^2\mathbf{D}(s)}{\partial s^2}\frac{\partial s}{\partial k_{0j}},\qquad \mathbf{R}_{43}(s)=\alpha_i s^{\alpha_i-1}\mathbf{L}_i+\frac{\partial^2\mathbf{D}(s)}{\partial s^2}\frac{\partial s}{\partial c_{0i}} \tag{A.21}$$

when the design parameters p_i and p_j are c_{0i} and k_{0j}, respectively, and

$$\mathbf{R}_{31}(s)=\frac{\partial^2\mathbf{D}}{\partial s^2}\frac{\partial s}{\partial k_{0i}}\frac{\partial s}{\partial k_{0j}},\quad \mathbf{R}_{32}(s)=\mathbf{L}_j+\frac{\partial\mathbf{D}(s)}{\partial s}\frac{\partial s}{\partial k_{0j}},\quad \mathbf{R}_{33}(s)=\mathbf{L}_i+\frac{\partial\mathbf{D}(s)}{\partial s}\frac{\partial s}{\partial k_{0i}} \tag{A.22}$$

$$\mathbf{R}_{41}(s)=\frac{1}{2}\left[\frac{\partial^3\mathbf{D}}{\partial s^3}\frac{\partial s}{\partial k_{0i}}\frac{\partial s}{\partial k_{0j}}\right],\quad \mathbf{R}_{42}(s)=\frac{\partial^2\mathbf{D}(s)}{\partial s^2}\frac{\partial s}{\partial k_{0j}},\quad \mathbf{R}_{43}(s)=\frac{\partial^2\mathbf{D}(s)}{\partial s^2}\frac{\partial s}{\partial k_{0i}} \tag{A.23}$$

when the design parameters p_i and p_j are k_{0i} and k_{0j}, respectively.

The derivatives of matrix $\mathbf{D}(s)$ with respect to s in the case of the Kelvin model of damper are as follows:

$$\frac{\partial\mathbf{D}(s)}{\partial s}=2s\mathbf{M}+\mathbf{C}+\sum_{k=1}^{m}c_{0k}\alpha_k s^{\alpha_k-1}\mathbf{L}_k, \tag{A.24}$$

$$\frac{\partial^2\mathbf{D}(s)}{\partial s^2}=2\mathbf{M}+\sum_{k=1}^{m}c_{0k}\alpha_k(\alpha_k-1)s^{\alpha_k-2}\mathbf{L}_k, \tag{A.25}$$

$$\frac{\partial^3\mathbf{D}(s)}{\partial s^3}=\sum_{k=1}^{m}c_{0k}\alpha_k(\alpha_k-1)(\alpha_k-2)s^{\alpha_k-3}\mathbf{L}_k. \tag{A.26}$$

The derived formulae enable determination of all the elements of the Hessian matrix of dynamic characteristics with respect to the chosen design parameters.

Keywords: Numerical Modelling, Reinforced Concrete Structures, Finite-Discrete Element Method, Static Load, Dynamic Load.

Abstract. *Crack opening is one of the dominant causes of nonlinearity in brittle and quasi-brittle structures which leads to localized failure and stands out as a serious challenge in numerical modelling. Therefore, a realistic modelling of crack initiation and propagation is one of the key factors that affect the reliability of the model for analysing the structures, especially those subjected to earthquakes. The largest number of structures in the world's most populated seismic areas is made of materials such as reinforced concrete, stone and masonry, in which localized failure dominantly influences the structural collapse. Sophisticated numerical models based on time dependent and incremental dynamic analysis can play an important role in simulating the behaviour of such structures. In this work 2D and 3D numerical modelling for analysis of reinforced concrete structures under static and dynamic load is presented. The model uses the finite-discrete element method; thus taking into account the discontinuous nature of the concrete at the failure stages. This approach considers the structure as a deformable continuum until the opening of the cracks. The transition from the continuum to the discontinuum is a result of the crack initiations which are modelled through the contact elements implemented between finite elements. The interaction between discrete elements is considered through the contact interaction algorithm based on the principle of potential contact forces which are computed using penalty function method and the Coulomb friction law. The non-linear behaviour of the concrete in tension and shear takes into account strain-hardening, strain-softening and cyclic behaviour during dynamic loading. The model for reinforcing bars is based on an approximation of the experimental curves for the bar strain in the crack. The developed numerical model includes interaction effects between reinforcement and concrete as well as cyclic behaviour of concrete and steel during dynamic loading. Thus, it is possible to describe the crack initiation and propagation, collapse mechanism, energy dissipation by non-linear effects, inertial effects and contact interaction which are very important in the analysis of RC structures, especially those subjected to seismic load.*

1 INTRODUCTION

The development of the numerical models for simulation of the response of reinforced concrete structures under static and dynamic load, taking into consideration non-linear behavior of the concrete and reinforcement, makes possible the results of high accuracy. One of the main causes of concrete non-linear behavior is cracking. A reliable model for simulation of the opening and closing the cracks is especially important in the structures under dynamic load. The most of the models described in literature is based on finite element method where the cracking is described with smeared crack models or with embedded models where the cracks are modelled as discontinuity within the elements by enriching interpolation function. In contrast to the finite elements, in discrete models cracks are simulated as discontinuities of displacement between two elements.

A numerical model for analysis of reinforced concrete structures under static and cyclic load developed in this work is based on combined finite-discrete element method [1]. Transition from continua to discontinua in this method occurs through fracture and fragmentation processes. A typical combined finite discrete element method based simulation may start with a few discrete elements and finished with very large number of discrete elements. Fracture occurs through alteration, damage, yielding or failure of micro structural elements of the material.

There has been a number of fracture models proposed in the context of both discrete element methods and combined finite discrete element method. Some of the models are based on a global approach applied to each individual body, while others used a local smeared crack approach or local single-crack approach. In this work a model for plane and spatial crack initiation and crack propagation in concrete is used [2]. The model combines standard finite element formulation for the hardening part of the constitutive law with the single-crack model for the softening part of stress-strain curve. Finite elements are used to model behavior of the material up to the ultimate tensile strength while a discrete crack model is used for modelling of the crack opening and separation along edges of finite elements.

In this work cracking of the concrete in plane and space are enabled by a combined single and smeared crack model. An embedded model of reinforcing bars [3, 4] is implemented in finite-discrete element code [1]. The concrete and reinforcing bars are analyzed separately, but they are connected by the relation between the size of the concrete crack and strain of the reinforcing bar [5, 6]. Cyclic behavior of the steel during the cyclic load is modelled with improved Kato's model [7].

2 MODELLING OF THE REINFORCED CONCRETE STRUCTURE

The concrete structure in plane is discretized on triangular finite elements, while in the space it is discretized by tetrahedron finite elements. Reinforcing bars are modelled with linear one-dimensional elements which can be placed in arbitrary position inside the concrete finite elements. The model of the reinforced concrete structure with the embedded reinforcing bars in 2D and 3D concrete structure is presented in Fig. 1.

The structure behaves as continuum until opening of the crack. The deformation of the finite triangular element influence to the deformation of the reinforcing bars. When the crack in concrete appears, joint element in concrete as well as joint element in reinforcing bars is occurred. The concrete and reinforcing bars are analyzed separately, but they are connected by the relationship between the size of the concrete crack and strain of the reinforcing bar.

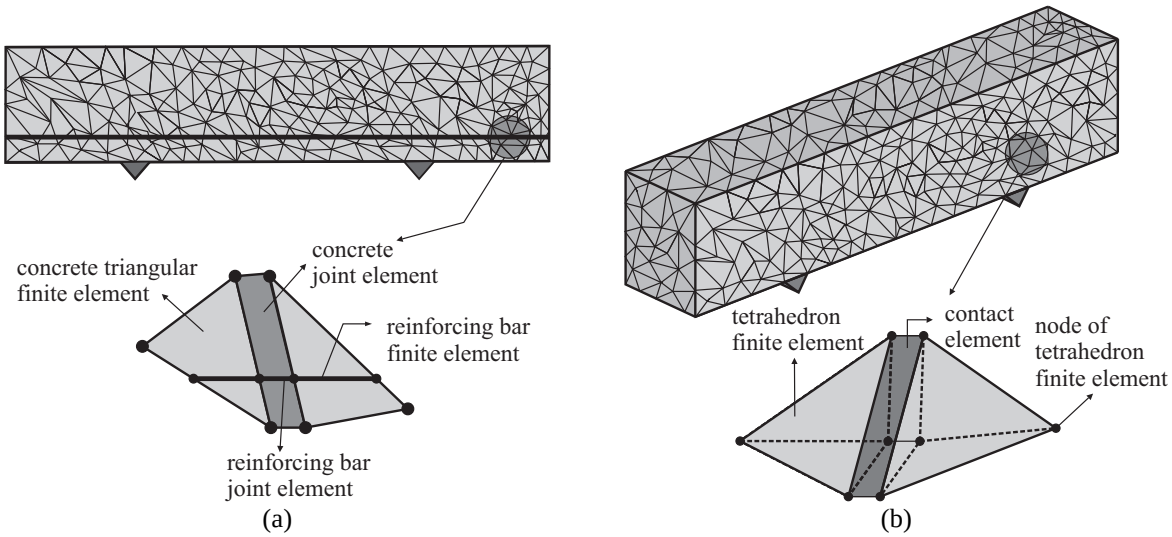

Figure 1: Discretization of reinforced concrete structure: (a) 2D model; (b) 3D model.

3 NON-LINEAR MATERIAL MODEL IN JOINT ELEMENTS

3.1 Concrete model in joint element

The concrete model is based on crack initiation and crack propagation in tension and shear [2]. It is developed on the basis of experimental stress-strain curves for concrete in tension.

The area under the stress-strain curve consists of two parts (Fig. 2), part for modelling of the concrete behavior up to the crack opening [2] and part which represents strain softening after the tensile strength is exceeded [8]. The assumption of the discrete crack model is that the cracks coincide with the finite element edges. The total number of nodes for each of the finite element meshes is doubled and the continuity between elements is realized through the penalty method [9]. Separation of the edges induces a bonding stress, which is a function of the size separation δ (Fig. 2).

The area under the stress-displacement curve represents the energy release rate $G_f = 2\gamma$, where γ is the surface energy, i.e. the energy needed to extend the crack surface by a unit area.

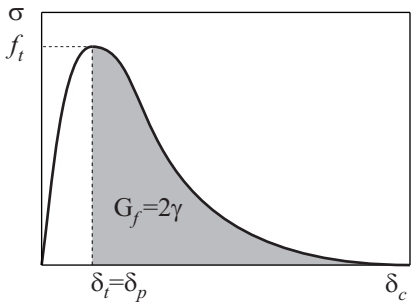

Figure 2: Strain softening stress-strain and stress-displacement curves.

No separation of the adjacent elements occurs before the tensile strength is reached, i.e. the edges of two adjacent elements are held together by normal and shear springs (Fig. 3). Procedure of the separation of the elements and complete relationship for the normal and shear bonding stress are given in [2].

3.2 Steel material model in reinforcement joint element

In this work a model of the relationship between the concrete crack size and strain of the reinforcing bar developed by Shima [5] and Shin [6] is applied. The model is based on experimental strain-slip curves and represents well approximation of the behavior of reinforcing bar with the expressed plastic strain caused by cyclic loading.

The steel strain-slip relation before the yielding of reinforcing bar is given by expressions:

$$s = \varepsilon_s (6 + 3500\varepsilon_s) \tag{1}$$

$$s = \left(\frac{S}{D}\right) \cdot K_{fc}, \quad K_{fc} = \left(\frac{f_c'}{20}\right)^{2/3} \tag{2}$$

where $s = s(\varepsilon_s)$ is normalized steel slip, D is bar diameter and f_c' is concrete strength.

Normalized slip in the post-yield range is given by expression:

$$s = s_{pl} + s_e \tag{3}$$

where s_e is slip in the elastic region and s_{pl} is slip in the yield region. A strain distribution along the reinforcing bar in the post-yield region is shown in Fig. 4, where ε_{se} a strain at the yield boundary point on the elastic region is and ε_{sp} is a strain at the yield boundary point on the yield region.

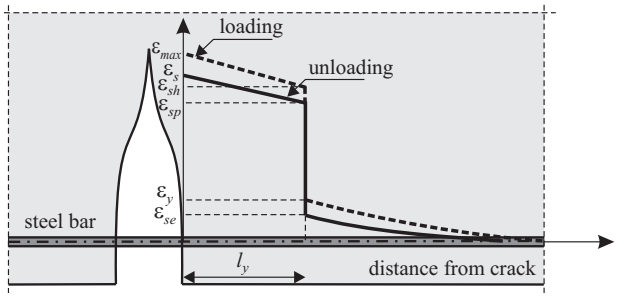

Figure 4: Strain distribution along the reinforcing bar in the post-yield range.

Normalized plastic steel slip in the yield region is given by an expression [5, 6]:

$$s_{pl} = \frac{(1+\beta)\varepsilon_s + \varepsilon_{sh} - \beta\varepsilon_{\max}}{\varepsilon_{\max} + \varepsilon_{sh}}(s_{\max} - s_y^*) \tag{4}$$

where $\beta = \sigma_{\max}/\sigma_y$ represents the gradient of the line shown in Figure 4, $\sigma_{\max}$ is the maximum stress in reinforcing bar under tensile loads, $s_{\max}$ is a function of $\varepsilon_{\max}$ and $s_y^* = \varepsilon_s(2+3500\varepsilon_s)$.

Non-linear material model for steel is based on experimental stress-strain curve and it is shown in Fig. 5a. Cyclic behavior of the steel during the cyclic load (Fig. 5b) is modelled with improved Kato's model [7].

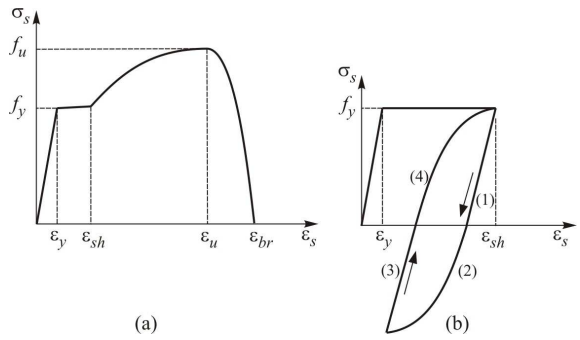

Figure 5: Material model for steel: (a) Stress-strain relation for steel, (b) Cyclic behavior of steel.

4 EXAMPLES

4.1 Sensitivity of the 3D model to the mesh refinement and penalty parameter

This example was chosen to analyse the sensitivity of the 3D numerical model to the mesh refinement and penalty parameter. Analysis was performed on concrete cantilever exposed to monotonic increasing tension load. Geometry and cross section of structure are shown in Fig. 6. Modulus of elasticity of concrete is E=30 GPa.

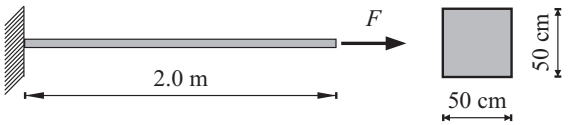

Figure 6: Geometry and load of structure.

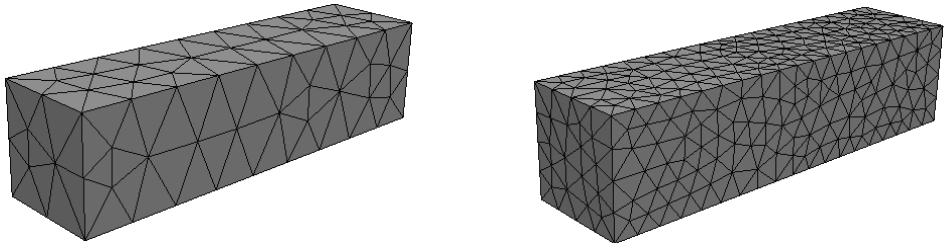
The analyses were performed without and with contact elements using two different finite elements meshes refinement (mesh A, mesh B) as shown in Fig. 7.



(a) (b)

Figure 7: Discretization of structure: (a) mesh A, (a) mesh B.

Mesh A was comprised of 320, while mesh B was comprised of 3102 finite elements. In analyses performed with contact elements, penalty term p was 20 times higher than E_c.

Fig. 8 shows the comparison of the analytical and numerical results obtained by the presented model. It can be seen that for homogeneous state of stress the numerical 3D model is not sensitive to the mesh refinement regardless of the presence of the contact elements. It can be also seen when analyses were performed without contact elements, the numerical results correspond to analytical solution while the introduction of contact elements leads to relative error of numerical results in comparison to analytical solution.

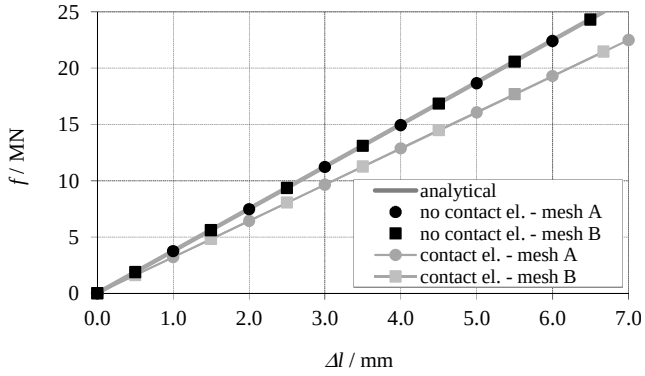


Figure 8: Force-displacement relations.

The sensitivity of the numerical model in linear elastic stage to the penalty parameter p was performed on concrete cantilever with finite element mesh shown in Fig. 7(a). The analyses were performed for three values of penalty parameter p. The comparison of the analytical and numerical results obtained by the presented model is shown in Fig. 9.

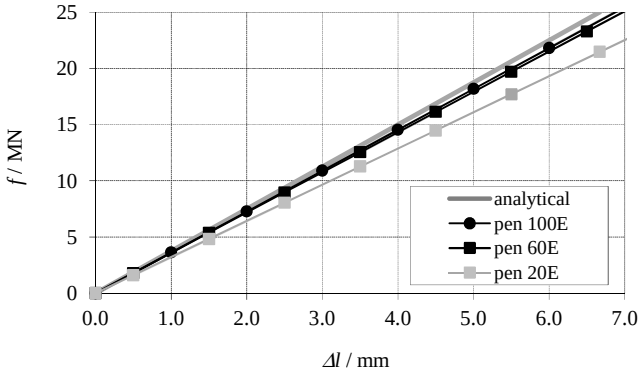

Figure 9: Force-displacement relations.

The influence of the penalty parameter p to the relative error is shown in table 1. It can be seen that for values of penalty term higher than $100E$ relative error is less than 2%. Similar conclusions have been obtained for 2D analysis [4].

Penalty parameter	Relative error
20Ec	14.1
60Ec	4.4
100Ec	1.9

Table 1: Influence of penalty parameter to the solution error.

4.2 Seismic analysis of coupled RC wall structure

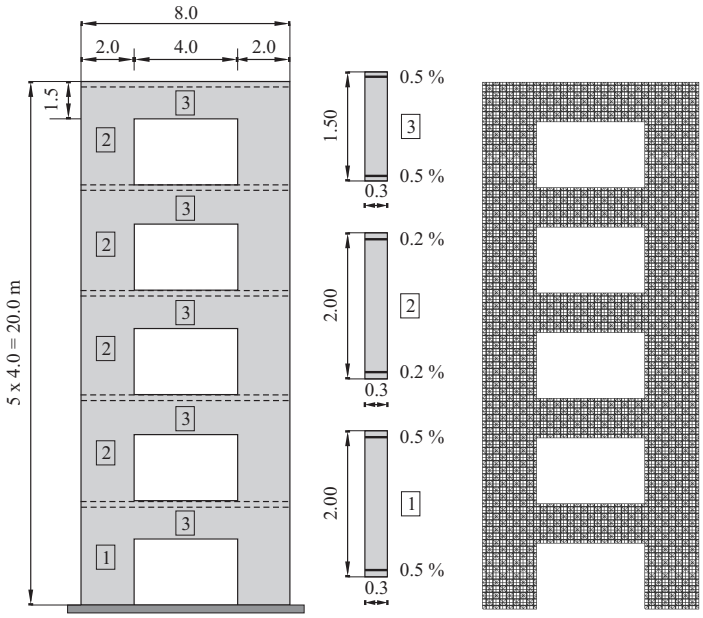
The application of the presented finite-discrete numerical model of reinforced concrete structures was shown on five-storey reinforced concrete building with coupled wall system. The vertical load of the building consists of the own weight of structural elements, an additional dead load of 2.5 kN/m^2 and impose load of 4.0 kN/m^2 at floor slabs.

Material characteristics of concrete and steel used in a numerical analysis are shown in Table 1.

Concrete					
E_c / MPa	v	f_t / MPa	f_c / MPa	G_f/ N/m	ρ / kN/m^3
32800	0.2	3.80	38	150	25
Steel					
E_s / MPa	f_y / MPa	f_u / MPa	ε_{sh}	ε_u	
210000	500	600	0.02	0.1	

Table 2: Material characteristics of the RC wall.

The application of the presented model in incremental dynamic analysis [10] of RC structure was performed for the boundary coupled RC wall with geometry, reinforcement and discretisation shown in Fig. 10.



(a) (b)

Figure 10: Coupled RC wall: (a) Geometry and reinforcement of the cross-sections, (b) Discretisation.

Seismic loading is represented by a time function of the horizontal ground acceleration recorded during real earthquakes. The earthquake accelerograms were taken from the European Strong-Motion Database [11]. The selected earthquakes are Petrovac (Montenegro)-1979, South Iceland (Iceland)-2000 and Campano Lucano (Italy)-1980, as shown in Fig. 11.

The observed five-storey RC wall structure is exposed to the horizontal ground acceleration of selected three earthquakes. The amplitudes were gradually increased until the collapse of the structure. The relation between the ratio of peak ground acceleration and gravity con-

stant a and the ratio of maximum top displacement u and the height of structure H (u/H) obtained by incremental dynamic analysis is shown in Fig. 12.

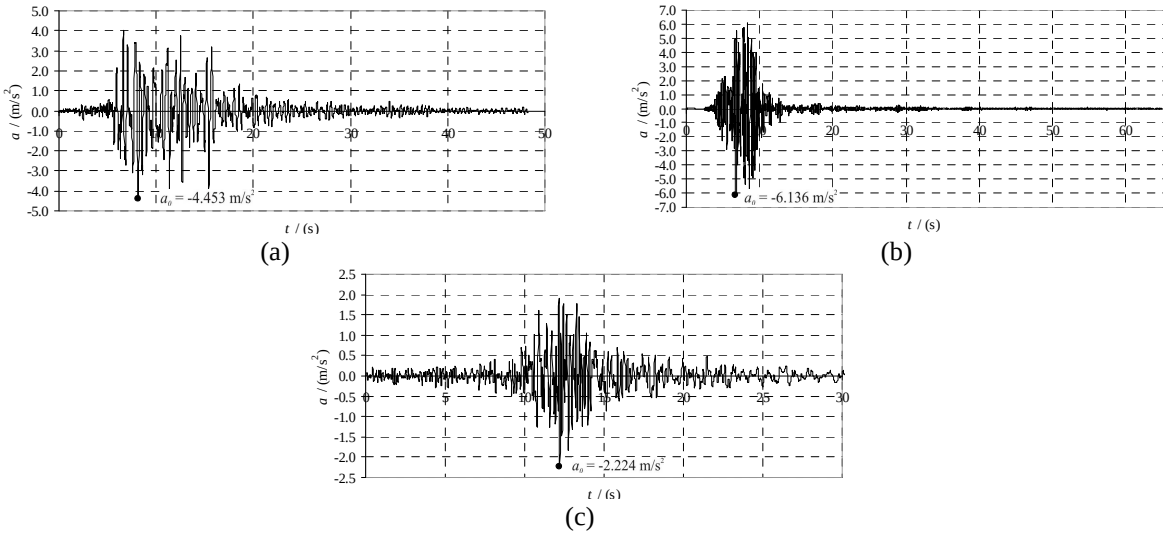


Figure 11: Accelerograms of three real earthquakes: (a) Petrovac (1979.), (b) South Iceland (2000.), (c) Campano Lucano (1980.)

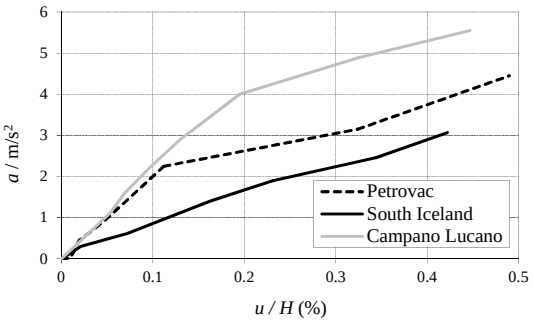

Figure 12: The ratio between the maximum roof displacement u and the height of structure H for coupled RC wall structure in dependence to the peak ground acceleration.

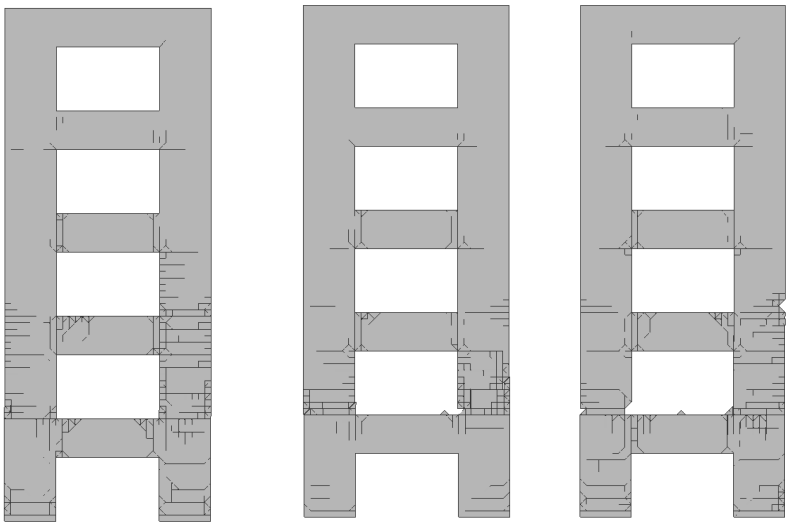

Figure 13: Crack pattern for the coupled RC wall structure exposed to the failure peak ground acceleration of earthquake: (a) Petrovac, (b) South Iceland, (c) Campano Lucano.

Finite-discrete numerical model based on discrete cracks presented in this paper can simulate opening and closing the cracks as well as realistic crack patterns for different intensity of accelerations. Crack pattern for the coupled RC wall structure exposed to the failure peak ground acceleration of three earthquakes is shown in Figure 13.

This example highlights the ability of the developed model based on discrete cracks for simulation of opening and closing the cracks during the earthquake loading as well as obtaining of the ultimate acceleration, which is very important in the estimation of the safety of RC structures under the seismic loading.

5 CONCLUSIONS

- This paper presents numerical model for analysis of reinforced concrete structures under static and dynamic load.
- Simple numerical model of reinforcement which is implemented in combined finite discrete element code is presented. Model based on approximation of the experimental curves for behaviour of the concrete and steel in crack, is primarily aimed for monitoring of the behaviour of reinforced concrete structure subjected to static and dynamic load up to failure.
- Cracking of the structure is enabled by discrete model of cracks where the cyclic behaviour of concrete and steel was successfully implemented.
- Interaction between reinforcement and concrete was not directly considered, but it was taken into consideration by defining the average spacing between the cracks.
- The model provides quite realistic description of cracking in the reinforced concrete structures under the seismic loading until the collapse.

Keywords: Beam on elastic foundation, partial damage to the foundation, sudden structural changes, transient dynamic processes, the dynamic increments of strain and stress.

Abstract. *One of the major problems of modern structural mechanics is sensitivity analysis of actual and projected designs to various effects not provided for under normal operating conditions, arising in particular in emergency situations, as a result of wear and damage accumulation, etc. The paper presents a physical and mathematical model of the transient dynamical processes initiated in a beam on an elastic foundation with a sudden partial or fully destruction of the foundation. Mathematical models are the differential equations of the static bending of initial and damaged beam, equations of the free and forced vibrations of sections beams formed after damage foundation, with the initial and boundary conditions, conjugations conditions of the beam's parts, assumptions and limitations. Exact solution of the problem of forced vibrations loaded beam on an elastic foundation (partially or fully destroyed) was obtained, using the Fourier method of separation of variables, the expansion of dynamic movements on the modes of free vibrations of the damaged beams and Duhamel integral.*

1 INTRODUCTION

An important problem in structural mechanics is a sensitivity analysis of load-bearing systems in structural rearrangements under load such as a sudden turn off the links, cracks, partial damage, etc. Obtaining this information for real structures requires the development of special methods, because the problem can not be solved by universal methods. From the viewpoint of structural mechanics in these problems there is a need for calculating such systems as a constructively nonlinear with dynamic increments of strain and stress caused by sudden impacts beyond design basis. And if the design accidental situations are analyzed and regulated by the relevant documents, the situation is not beyond design basis and classified as responses to specific impacts on structural elements are insufficiently investigated. Engineering design and calculation methods that take into account the sudden restructuring and sudden damage to the structural systems, are few and far from being perfect. Absence and lack of knowledge about deformation and stress state of structural elements during dynamic processes initiated by a sudden damage, constrain the development of the theory and design techniques that take into account the possibility and potential consequences of beyond design impacts and ensure a high level of safety of their maintenance. As an example of work performed in the discussed direction, we note a number of publications [1-4] containing the results of the modeling of transient dynamic processes that occur in stressed beams at the sudden breakage of the support links, formation of transverse and longitudinal cracks, delamination and exfoliation, change conditions interfaces parts construction and others. All these works are made in relation to the free beams, that are not supported by solid foundations. It is of theoretical interest and practical importance of the spread of similar approaches to the beams on an elastic foundation.

Beams on elastic foundation, columns, piles, supported by length – widely used building blocks are long and detailed study of objects in many fields of mechanics and construction. However, despite the abundance of books, articles and reports related to the dynamic problems of structural elements resting on all sorts of grounds, in the scientific literature insufficiently investigated cases where structure simply supported partly initially or lost some (or all) of the foundation during exploitation. The problem of vibration of a homogeneous beam, partially supported by the Winkler foundation, first staged by Doyle and Pavlovic in [5], which investigated with two cases of symmetrical bearing beam ends: hinges and free ends. The authors identified three cases occurring in different ranges of values of the natural vibration frequencies, associated with the mechanical characteristics of the beam and foundation. Solutions are obtained analytically. Numerical results are presented for the first five modes of natural vibrations. Further development of the problem was in Eisenberger's at al work [6], in relation to arbitrary boundary conditions. The paper deduced the precise mass and stiffness matrix, developed by special finite elements, the displacement functions which are the solutions of the equations for the static beam on an elastic foundation. Dynamic solution produced a finite element procedure. These results take the form of generalized frequency dependency of rigidity generalized system of "beam-foundation" for the first four forms of eigenfunction. Later, the results of [5] extended to partially embedded piles [7]. The paper Kukla [8] investigated the free vibrations of a homogeneous beam, supported by the Winkler foundation with areas of piecewise constant stiffness which is given by the Heaviside function. The frequency equation was obtained by standard procedure satisfying the boundary conditions and the conditions of conjugation parts. As a special case, one of the numerical examples describes the vibration of a cantilever beam, consisting of two sections, one of which is not supported by the elastic foundation. It is shown an effect of the partial support on the first four natural frequencies. The paper Motaghian et al [9] provides a method for the analysis of natural vibra-

tions of the beam, in part supported by the Winkler foundation. The approach is to provide a foundation reactions as a some "external load", distributed along the length and depending on the desired deflection. Next eigenfunctions and "load" are expanded in Fourier series. The coefficients of the series are calculated by successive approximations by definite integrals, which bounds are the coordinates of the beginning and the end of the foundation part. The method is illustrated by calculations of natural frequencies of the beams with different boundary conditions, location and length of the supported part. In Cazzani work [10] studied in detail the natural vibrations of the beams, partially supported by an elastic foundation. Presents a number of exact solutions of the problem on the eigenvalues, in particular, the transcendental equations for the eigenfrequencies and their solutions. Analyzed three types of vibration modes, depending on the combination of the stiffness of the beam and the foundation. It is shown possibility of transfer of vibrations from one type to another with increasing number of forms of natural vibrations.

Thus, the vast majority of work on the dynamics of interaction between the beam and the grounds devoted to the analysis of natural vibrations. Forced vibrations caused by various external forces are considered in cases where the calculated scheme of the system "beam-foundation" in the process of loading is not changed.

In this paper, it is assumed that static load applied to the beam, fully supported by the elastic foundation, and only at some point part (or all) of the foundation suddenly collapses and the beam is set in motion, in which getting additional dynamic strain and stress. The aim of this study is to construct a mathematical model of transient dynamic processes in a loaded beam on an elastic foundation with the sudden occurrence of the defect foundation – total or partial destruction of it.

The structure of the paper is as follows: in the first part is given an analysis of the stress-strain state of the loaded beam with quasi-static fracture supporting its elastic foundation. Decisions of static problems are used in the second part to form the initial conditions of dynamic tasks and for comparison with the stress-strain state of the beam during the dynamic process initiated by the sudden damage to the foundation.

2 STATIC STRESS – STRAIN STATE OF THE BEAM SUPPORTED ON THE ELASTIC FOUNDATION

2.1 Beam fully supported on the elastic foundation

Consider the bending of the beam with stiffness *EI*, resting on the Winkler foundation with stiffness k, rigid clamped at both ends, under the action of uniformly distributed load of intensity q (Figure 1 *a*). The solution of the problem is carried out in Cartesian coordinates related to the beam axis. All movements and linear dimensions attributed to the length of the beam *L*. The deflection of the beam of the beam in the dimensionless variables and parameters described by the equation

$$\frac{d^4 w_{cm}}{d\xi^4} + 4\alpha^4 w_{cm} = \bar{q}, \tag{2.1}$$

where $\xi = \frac{x}{L}$, $w_{cm} = \frac{w}{L}$, $\alpha = \sqrt[4]{\frac{kL^4}{4EI}}$, $\bar{q} = \frac{qL^3}{EI}$.

The general solution of the inhomogeneous equation (2.1) in the case of clamped of the ends

$$w_{cm}(\xi)=\bar{q}\left\{\frac{1-R_4(\alpha\xi)}{4\alpha^4}+C_1(\alpha)R_2(\alpha\xi)+C_2(\alpha)R_1(\alpha\xi)\right\}, \tag{2.2}$$

where

$$C_1(\alpha)=\frac{(R_4(\alpha)-1)R_2(\alpha)+4\alpha^4R_1^2(\alpha)}{R_5(\alpha)},\quad C_2(\alpha)=\frac{(R_4(\alpha)-1)R_3(\alpha)+4\alpha^4R_1(\alpha)R_2(\alpha)}{R_5(\alpha)};$$

$$R_1(\alpha\xi)=\frac{\sin\alpha\xi ch\alpha\xi-\cos\alpha\xi sh\alpha\xi}{4\alpha^3},\quad R_2(\alpha\xi)=\frac{\sin\alpha\xi sh\alpha\xi}{2\alpha^2},$$

$$R_3(\alpha\xi)=\frac{\sin\alpha\xi ch\alpha\xi+\cos\alpha\xi sh\alpha\xi}{2\alpha},\quad R_4(\alpha\xi)=\cos\alpha\xi ch\alpha\xi,\quad R_5(\alpha\xi)=\frac{sh^2(\alpha\xi)-\sin^2(\alpha\xi)}{2}.$$

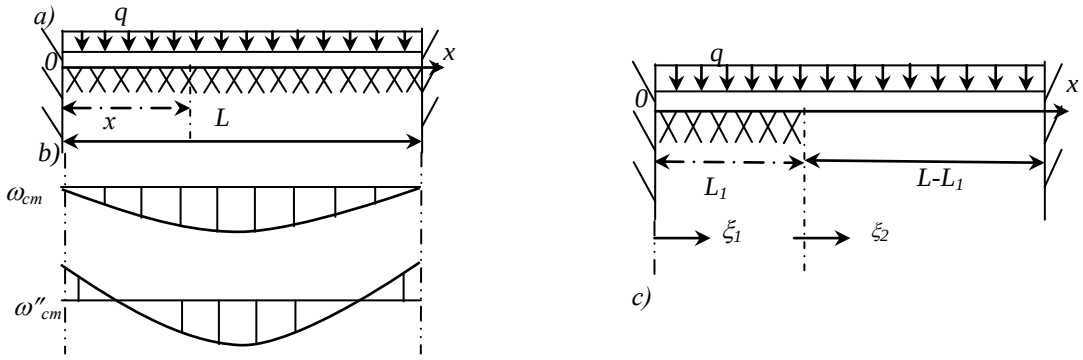

Figure 1: Beam on elastic foundation: *a)* completely simply supported on a foundation, *b)* diagrams of deflections and bending moments, *c)* simply supported on the part of foundation.

The function (2.2) is then used as the initial condition of the dynamic process resulting from the total or partial destruction of the foundation.

2.2 Beam partly supported on an elastic base

It is assumed that the formation of a defect – the removal a part of foundation of the loaded beams – was slowly (quasi-statically), i.e. without inertial forces. In this case, there is the problem of calculating the beam consisting of two coupled segments one of which is supported by an elastic foundation, the other – free (Figure 1 *c*).

Local coordinates are entered for each segment

$$\xi_1=\xi \quad \text{and} \quad \xi_2=\xi-v,\quad v=\frac{L_1}{L}.$$

Let us consider each segment bend sequence.

1) 1st segment bend described by the equation

$$\frac{d^4w_1}{d\xi_1^4}+4\alpha^4w_1=\bar{q},\qquad w_1=\frac{v_1}{L}, \tag{2.3}$$

the general solution (2.3) has the form

$$w_1(\xi_1)=\frac{\bar{q}}{4\alpha^4}(1-R_4(\alpha\xi_1))+w_{10}R_4(\alpha\xi_1)+w'_{10}R_3(\alpha\xi_1)+w''_{10}R_2(\alpha\xi_1)+w'''_{10}R_1(\alpha\xi_1), \tag{2.4}$$

where $w_{10}=w_1(0)$, $w'_{10}=w'_1(0)$, $w''_{10}=w''_1(0)$, $w'''_{10}=w'''_1(0)$ – the initial parameters.

We introduce:

– the vector of state of the 1st segment $\overline{W}_1(\xi_1)$

$$\overline{W_1}(\xi_1) = \{w_1(\xi_1) \quad w_1'(\xi_1) \quad w_1''(\xi_1) \quad w_1'''(\xi_1)\};$$

– the vector of initial parameters $\overline{W}_{10}$

$$\overline{W}_{10} = \{w_{10} \; w_{10}' \; w_{10}'' \; w_{10}'''\};$$

– functional matrix $V_1(\xi_1)$

$$\underset{4\times4}{V_1}(\xi_1) = \begin{pmatrix} R_4(\alpha\xi_1) & R_3(\alpha\xi_1) & R_2(\alpha\xi_1) & R_1(\alpha\xi_1) \\ -4\alpha^4 R_1(\alpha\xi_1) & R_4(\alpha\xi_1) & R_3(\alpha\xi_1) & R_2(\alpha\xi_1) \\ -4\alpha^4 R_2(\alpha\xi_1) & -4\alpha^4 R_1(\alpha\xi_1) & R_4(\alpha\xi_1) & R_3(\alpha\xi_1) \\ -4\alpha^4 R_3(\alpha\xi_1) & -4\alpha^4 R_2(\alpha\xi_1) & -4\alpha^4 R_1(\alpha\xi_1) & R_4(\alpha\xi_1) \end{pmatrix}$$

– load vector $\overline{\bar{q}V}_{1q}(\xi_1)$

$$\overline{\bar{q}V}_{1q}(\xi_1) = \bar{q}\left\{\frac{1-R_4(\alpha\xi_1)}{4\alpha^4} \; R_1(\alpha\xi_1) \; R_2(\alpha\xi_1) \; R_3(\alpha\xi_1)\right\}.$$

Then the state in an arbitrary section of the 1st segment describes the matrix equation

$$\overline{W}_1(\xi_1) = V_1(\xi_1)\overline{W}_{10} + \overline{\bar{q}V}_{1q}(\xi_1). \tag{2.5}$$

The state vector of the end 1st segment, with $\xi_1 = \nu$

$$\overline{W}_1(\nu) = V_1(\nu)\overline{W}_{10} + \overline{\bar{q}V}_{1q}(\nu). \tag{2.6}$$

2) 2nd segment bend described by the equation

$$\frac{d^4 w_2}{d\xi_2^4} = \bar{q}, \quad w_2 = \frac{v_2}{L}. \tag{2.7}$$

The general solution of equation (1.7) has the form

$$w_2(\xi_2) = w_{20}T_4(\xi_2) + w_{20}'T_3(\xi_2) + w_{20}''T_2(\xi_2) + w_{20}'''T_1(\xi_2) + \bar{q}_0 T_0(\xi_2), \tag{2.8}$$

where $T_0(\xi_2) = \frac{\xi_2^4}{24}$, $T_1(\xi_2) = \frac{\xi_2^3}{6}$, $T_2(\xi_2) = \frac{\xi_2^2}{2}$, $T_3(\xi_2) = \xi_2$, $T_4 = 1$; $w_{20} = w_1(\nu)$, $w_{20}' = w_1'(\nu)$, $w_{20}'' = w_1''(\nu)$, $w_{20}''' = w_1'''(\nu)$ – the initial parameters of the 2nd segment. These equations are also conditions of conjugation segments.

We introduce:

– the vector of state of the 2nd segment $\overline{W}_2(\xi_2)$

$$\overline{W_2}(\xi_2) = \{w_2(\xi_2) \quad w_2'(\xi_2) \quad w_2''(\xi_2) \quad w_2'''(\xi_2)\};$$

– the vector of initial parameters, the components of which are expressed through the components of the vector of initial parameters of the previous one, the 1st segment $\overline{W}_1(\nu)$

$$\overline{W}_{20} = \overline{W}_1(\nu) = V_1(\nu)\overline{W}_{10} + \overline{\bar{q}V}_{1q}(\nu). \tag{2.9}$$

– functional matrix $V_2(\xi_2)$

$$\underset{4\times4}{V_2(\xi_2)}=\begin{pmatrix}1 & T_3(\xi_2) & T_2(\xi_2) & T_1(\xi_2)\\ 0 & 1 & T_3(\xi_2) & T_2(\xi_2)\\ 0 & 0 & 1 & T_3(\xi_2)\\ 0 & 0 & 0 & 1\end{pmatrix};$$

– load vector $\bar{q}\overline{V}_{2q}(\xi_2)$

$$\bar{q}\overline{V}_{2q}(\xi_2)=\bar{q}\{T_0(\xi_2)\ T_1(\xi_2)\ T_2(\xi_2)\ T_3(\xi_2)\}.$$

Then the state of the 2nd segment described by the matrix equation

$$\overline{W}_2(\xi_2)=V_{21}(\xi_2,\nu)\overline{W}_{10}+\bar{q}(\overline{V}_{21}(\xi_2,\nu)+\overline{V}_{2q}(\xi_2)), \tag{2.10}$$

where the matrix $\underset{4\times4}{V_{21}(\xi_2,\nu)}=\underset{4\times4}{V_2(\xi_2)}\underset{4\times4}{V_1(\nu)}$ and vector $\underset{4\times1}{\overline{V}_{21}(\xi_2,\nu)}=\underset{4\times4}{V_2(\xi_2)}\underset{4\times1}{\overline{V}_{1q}(\nu)}$.

Thus, the state of the beam at both segment is expressed through the initial parameters of the 1st segment at $\xi_1=0$. In this case, two parameters known

$$w_{10}=w'_{10}=0.$$

The remaining two parameters w''_{10} and w'''_{10} are determined from boundary conditions at the end of $2^{\underline{\text{nd}}}$ segment with $\xi_2=1-\nu$. Denoted the elements of matrix $V_{21}(\xi_2,\nu)$ and vector $\bar{q}(\overline{V}_{21}(\xi_2,\nu)+\overline{V}_{2q}(\xi_2))$ as $a_{ij}(\xi_2,\nu)$ and $b_i(\xi_2,\nu)$ $(i,j=1\div4)$, respectively, and write the equation (2.10) in expanded form for $\xi_2=1-\nu$ taking into account the known boundary conditions

$$w_{10}=w'_{10}=w_2(1-\nu)=w'_2(1-\nu)=0$$

$$\begin{pmatrix}0\\0\\w''_2(1-\nu)\\w'''_2(1-\nu)\end{pmatrix}=\begin{pmatrix}a_{11}(1-\nu) & a_{12}(1-\nu) & a_{13}(1-\nu) & a_{14}(1-\nu)\\ a_{21}(1-\nu) & a_{22}(1-\nu) & a_{23}(1-\nu) & a_{24}(1-\nu)\\ a_{31}(1-\nu) & a_{32}(1-\nu) & a_{33}(1-\nu) & a_{34}(1-\nu)\\ a_{41}(1-\nu) & a_{42}(1-\nu) & a_{43}(1-\nu) & a_{44}(1-\nu)\end{pmatrix}\begin{pmatrix}0\\0\\w''_{10}\\w'''_{10}\end{pmatrix}+\bar{q}\begin{pmatrix}b_1(1-\nu)\\b_2(1-\nu)\\b_3(1-\nu)\\b_4(1-\nu)\end{pmatrix} \tag{2.11}$$

where, in particular

$$a_{13}(\xi_2,\nu)=R_2(\alpha\nu)+R_3(\alpha\nu)\xi_2+R_4(\alpha\nu)\frac{\xi_2^2}{2}-4\alpha^4R_1(\alpha\nu)\frac{\xi_2^3}{6};$$

$$a_{14}(\xi_2,\nu)=R_1(\alpha\nu)+R_2(\alpha\nu)\xi_2+R_3(\alpha\nu)\frac{\xi_2^2}{2}+R_4(\alpha\nu)\frac{\xi_2^3}{6};$$

$$a_{23}(\xi_2,\nu)=R_3(\alpha\nu)+R_4(\alpha\nu)\xi_2+4\alpha^4R_1(\alpha\nu)\frac{\xi_2^2}{2};$$

$$a_{24}(\xi_2,\nu)=R_2(\alpha\nu)+R_3(\alpha\nu)\xi_2+R_4(\alpha\nu)\frac{\xi_2^2}{2};$$

$$b_1(\xi_2,\nu)=\frac{1-R_4(\alpha\nu)}{4\alpha^4}+R_1(\alpha\nu)\xi_2+R_2(\alpha\nu)\frac{\xi_2^2}{2}+R_3(\alpha\nu)\frac{\xi_2^3}{6}+\frac{\xi_2^4}{24};$$

$$b_2(\xi_2,\nu)=R_1(\alpha\nu)+R_2(\alpha\nu)\xi_2+R_3(\alpha\nu)\frac{\xi_2^2}{2}+\frac{\xi_2^3}{6}.$$

From the matrix equation (2.11) we obtain a system of two algebraic equations for the un-

known w''_{10} and w'''_{10}

$$\begin{pmatrix} a_{13}(1-\nu) & a_{14}(1-\nu) \\ a_{23}(1-\nu) & a_{24}(1-\nu) \end{pmatrix} \begin{pmatrix} w''_{10} \\ w'''_{10} \end{pmatrix} + \bar{q} \begin{pmatrix} b_1(1-\nu) \\ b_2(1-\nu) \end{pmatrix} = 0,$$

where by Cramer method obtain

$$w''_{10} = \frac{\Delta_1}{\Delta}, \quad w'''_{10} = \frac{\Delta_2}{\Delta}, \tag{2.12}$$

where determinants Δ, Δ_1 and Δ_2 have the form

$$\Delta = \begin{vmatrix} a_{13}(1-\nu) & a_{14}(1-\nu) \\ a_{23}(1-\nu) & a_{24}(1-\nu) \end{vmatrix}, \quad \Delta_1 = \begin{vmatrix} -\bar{q}b_1(1-\nu) & a_{14}(1-\nu) \\ -\bar{q}b_2(1-\nu) & a_{24}(1-\nu) \end{vmatrix}, \quad \Delta_2 = \begin{vmatrix} a_{13}(1-\nu) & -\bar{q}b_1(1-\nu) \\ a_{23}(1-\nu) & -qb_2(1-\nu) \end{vmatrix}.$$

Now dimensionless deflections and bending moments on the areas determined by dependencies

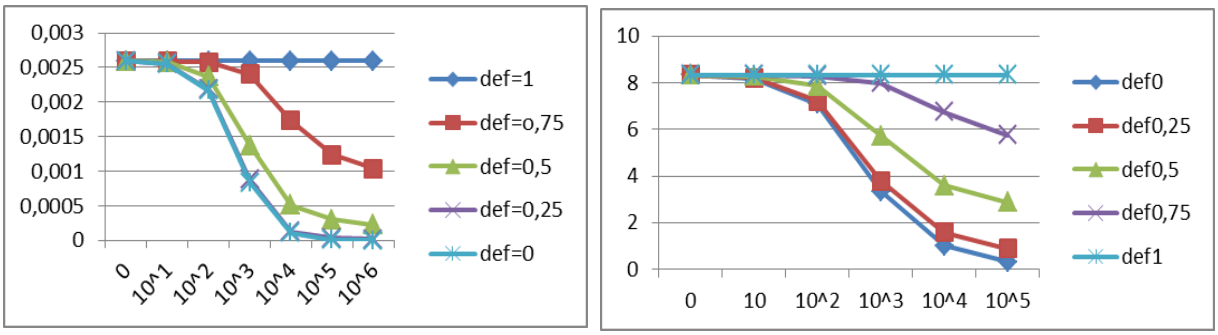
$$w_1(\xi_1) = w''_{01}R_2(\alpha\xi_1) + w'''_{10}R_1(\alpha\xi_1) + \frac{\bar{q}}{4\alpha^4}(1 - R_4(\alpha\xi_1)), \quad 0 \le \xi_1 \le \nu$$

$$w''_1(\xi_1) = w''_{01}R_4(\alpha\xi_1) + w'''_{10}R_3(\alpha\xi_1) + \bar{q}R_2(\alpha\xi_1), \tag{2.13}$$

$$w_2(\xi_2) = w''_{10}a_{13}(\nu,\xi_2) + w'''_{10}a_{14}(\nu,\xi_2) + \bar{q}b_1(\nu,\xi_2), \quad 0 \le \xi_2 \le 1-\nu$$

$$w''_2(\xi_2) = w''_{10}a_{33}(\nu,\xi_2) + w'''_{10}a_{34}(\nu,\xi_2) + \bar{q}b_3(\nu,\xi_2).$$

Figure 2 shows the relationship (2.13), respectively, the largest deflection w_{max} and bending moments w''_{max} with the generalized parameter of rigidity of the system "beam-foundation" $\bar{\lambda} = 4\alpha^4 = \frac{KL^4}{EI}$ for a number of values of the parameter $\nu = 0; 0{,}25; 0{,}5; 0{,}75; 1$, characterizing the degree of damage to the foundation: $\nu = 1$ – fully justified, $\nu = 0$ – absence of a foundation. The calculations correspond to a single dimensionless load



a) *b)*

Figure 2: The dependence:
a) the largest deflections; *b)* the largest bending moment in the right clamp – from length damage area.

Figure 3 shows the reduction (as a percentage of the free beam) the largest bending moment in the beam at the reinforcement of its foundation of varying length and relative stiffness.

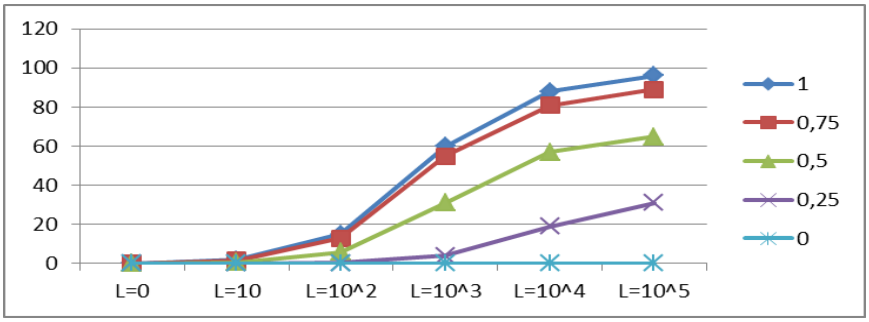


Figure 3: Effect of the length and rigidity to the foundation on value of the largest bending moment in the right clamp of beam.

3 FREE VIBRATION BEAM SUPPORTED ON AN ELASTIC FOUNDATION

To date, there are a number of works devoted to the study of dynamic processes caused by the sudden formation of defects in beams and plates. In particular, in papers [2-4] considers the transition dynamic process caused by the sudden formation of transverse cracks in a loaded beam. Beam modeled conjugation of two segments connected by a torsion spring whose stiffness is determined by the depth of cracks. One of the initial conditions is the static deflection of the intact beam. In [5-8] studied the dynamic process in the loaded component beams arising during sudden longitudinal stratification, caused break shift links in the seam. In [9-11] considered vibrations plates with a sudden change of support conditions, caused by partial separation of support links. In [12-14] solved the problem of the vibrations of the beam when it is sudden partial destruction. In [4, 6, 11, 16] studied transients dynamical process caused by sudden transformation of the internal structure of rod systems: coupling and bearing conditions their elements. In [17] is modeled by a sudden breaking of the reinforcing bar and the longitudinal vibrations caused by this defect. Note ,that in all these studies considered forced movement of the beam (plates) under the load ,produced by expansion into an infinite series of the initial state and the external load on the damaged natural vibration modes of the beam (the plate), and using the Duhamel integral.

It is practically important to develop methods of analysis of transient dynamic processes in the beams on an elastic foundation, initiated by the sudden operational damage of foundation: in the simplest case of total or partial destruction of it. Manifestations of structural nonlinearity, i.e. changes in the calculation scheme loaded beam on an elastic foundation, and the consequences of them – are not described in the prior literature.

In this part, an algorithm for determining the forms and frequencies of free vibrations of bending beams, in whole or in part simply supported on an elastic Winkler foundation. In its construction were used the approaches, the effectiveness of which is shown in the above-cited work: method of initial parameters, the vectors of state and the initial parameters, the matrix of influence of initial parameters and other. Eigenfunctions and eigenfrequencies of free vibrations are important dynamic characteristics of the "beam – foundation" system and used to solve inhomogeneous differential equations, describing forced vibrations.

3.1 Free vibration beam partially supported on the elastic foundation

Consider free transverse vibrations of a continuous beam (Figure 1 *c*) Deflections of the beams in the cross – sections denoted x_1 and x_2, respectively, v_1 and v_2. Without reducing the generality of the constructions it is supposed to be specific rigid clamping beam ends. Differential equations of natural vibrations of the beam segments are integrated separately, and in-

tegration constants are determined from the boundary conditions and the conditions of conjugation of segments.

3.1.1. Free transverse vibrations of the 1st segment

Natural vibrations of the beam in the area $0 \le \xi_1 \le \nu$ described by differential equations of the form [10]

$$\frac{\partial^4 w_1}{\partial \xi_1^4} + 4\alpha^4 w_1 + \frac{\partial^2 w_1}{\partial \tau^2} = 0, \tag{3.1}$$

where we have introduced the dimensionless variables and parameters

$$\xi_i = \frac{x_1}{L}; w_1 = \frac{v_1}{L}; \tau = \frac{t}{L^2}\sqrt{\frac{EI}{\rho A}}; A = bh; \alpha = \sqrt[4]{\frac{kL^4}{4EI}}; \nu = \frac{v_1}{L}.$$

Putting free harmonic vibrations, we divide the variables in the equation (3.1) the representation

$$w_1(\xi_1, \tau) = W_1(\xi_1)\sin\bar{\omega}\tau, \tag{3.2}$$

where $\bar{\omega} = \omega L^2\sqrt{\frac{\rho A}{EI}}$ – the dimensionless natural frequency of transverse vibration (natural frequency parameter); $\omega = \frac{\bar{\omega}}{L^2}\sqrt{\frac{EI}{\rho A}}$ – dimensional frequency.

Substituting (3.2) into (3.1) gives the equation forms its free vibrations of segment

$$W_1^{IV} + 4\alpha^4\left(1 - \left(\frac{\omega}{\omega_0}\right)^2\right)W_1 = 0, \tag{3.3}$$

where $\omega_0 = \sqrt{\frac{k}{\rho A}}$ – parameter having a dimension of frequency [1/*c*], and called "conventional", which compares the vibration frequency ω investigated beams.

We are looking for the solution of equation (3.3) Euler substitution

$$W_1 = Ce^{n\xi_1}, \tag{3.4}$$

where *C* and *n* – constants to be determined.

Substituting (3.4) into (3.3), we obtain the characteristic equation for the differential equation (3.3)

$$n^4 + 4\alpha^4\left(1 - \left(\frac{\omega}{\omega_0}\right)^2\right) = 0. \tag{3.5}$$

Multiplier in brackets depending on the value $\frac{\omega}{\omega_0}$ can be positive ($\frac{\omega}{\omega_0} < 1$), negative ($\frac{\omega}{\omega_0} > 1$) and zero ($\frac{\omega}{\omega_0} = 1$).

Let $\frac{\omega}{\omega_0} < 1$. Then the roots of the equation (3.5) can be represented in the form

$$n_j = (\pm i \pm 1)\beta_1, \quad (j=1,2,3,4),$$

where $\beta_1 = \alpha^4 \sqrt{1-\left(\frac{\omega}{\omega_0}\right)^2}$.

In this case, the natural vibration shape function defined by [10]

$$W_1(\xi_1) = w_{10}S_4(\xi_1) + w'_{10}S_3(\xi_1) + w''S_2(\xi_1) + w'''S_1(\xi_1), \tag{3.6}$$

where $w_{10} = w_1(0), w'_{10} = w'_1(0), w''_{10} = w''_1(0), w'''_{10} = w'''_1(0)$ – the initial parameters of the 1st segment.

$$S_1(\xi_1) = \frac{ch\beta_1\xi_1 \sin\beta_1\xi_1 - sh\beta_1\xi_1 \cos\beta_1\xi_1}{4\beta_1^3}; S_2(\xi_1) = \frac{sh\beta_1\xi_1 \sin\beta_1\xi_1}{2\beta_1^2};$$

$$S_3(\xi_1) = \frac{ch\beta_1\xi_1 \sin\beta_1\xi_1 + sh\beta_1\xi_1 \cos\beta_1\xi_1}{2\beta_1}; S_4(\xi_1) = ch\beta_1\xi_1 \cos\beta_1\xi_1 - \text{Krylov function.}$$

Note, that the $S'_1 = S_2, S'_2 = S_3, S'_3 = S_4, S'_4 = -4\beta_1^4 S_1$ и

$$S_1(0) = S_2(0) = S_3(0) = 0, S_4(0) = 1.$$

Let ω $\frac{\omega}{\omega_0} > 1$. Then the equation (3.5) in the form

$$W_1^{IV} - 4\alpha^4\left(\left(\frac{\omega}{\omega_0}\right)^2 - 1\right)W_1 = 0. \tag{3.7}$$

In this case, the roots of the characteristic equation

$$n^4 - 4\alpha^4\left(\left(\frac{\omega}{\omega_0}\right)^2 - 1\right) = 0, \tag{3.8}$$

take the form

$$n_{1,2} = \pm\lambda_1;\ n_{3,4} = \pm i\lambda_1;\ \lambda_1 = \lambda_1 = \sqrt{2}\alpha\sqrt{\left(\frac{\omega}{\omega_0}\right)^2 - 1} \tag{3.9}$$

and forms of natural vibrations determined by the function

$$W_1\xi_1 = w_{10}K_4(\lambda_1\xi_1) + w'_{10}K_3(\lambda_1\xi_1) + w''_{10}K_2(\lambda_1\xi_1) + w'''_{10}K_1(\lambda_1\xi_1), \tag{3.10}$$

where

$$K_1(\lambda_1\xi_1) = \frac{sh\lambda_1\xi_1 - \sin\lambda_1\xi_1}{2\lambda_1^3}; \qquad K_2(\lambda_1\xi_1) = \frac{ch\lambda_1\xi_1 - \cos\lambda_1\xi_1}{2\lambda_1^2}; \qquad K_3(\lambda_1\xi_1) = \frac{sh\lambda_1\xi_1 + \sin\lambda_1\xi_1}{2\lambda_1};$$

$K_4(\lambda_1\xi_1) = \frac{ch\lambda_1\xi_1 + cos\lambda_1\xi_1}{2}$ – another type of Krylov's functions.

Their properties

$$K_1' = K_2,\ K_2' = K_3,\ K_3' = K_4,\ K_4' = \lambda_1^4 K_1 \ \ and \ \ K_1(0) = K_2(0) = K_3(0) = 0,\ K_4(0) = 1.$$

Finally let $\frac{\omega}{\omega_0} = 1$. Then the equation (3.3) takes the form

$$W_1^{1V} = 0 \tag{3.11}$$

and deflection function $W_1(\xi_1)$ obtain the successive integration of the equation (3.11) using the initial parameters

$$W_1(\xi_1) = w_{10} + w_{10}'\xi_1 + w_{10}''\frac{\xi_1^2}{2} + w_{10}'''\frac{\xi_1^3}{6} \tag{3.12}$$

Further action on the first section we consider the case $\frac{\omega}{\omega_0} > 1$.

We introduce:

– the vector of state of the first segment: $\bar{W}_1(\xi_1)$:

$$\overline{W_1}(\xi_1) = \left\{ W_1(\xi_1)\ \ W_1'(\xi_1)\ \ W_1''(\xi_1)\ \ W_1'''(\xi_1) \right\},$$

where $W_1(\xi_1)$ – dimensionless deflection of the beam; W_1', W_1'', W_1''' – dimensionless cross-sectional angle of rotation, bending moment and shear force, respectively;

– the vector of initial parameters: $\overline{W}_{10}$

$$\overline{W}_{10} = \left\{ w_{10}\ \ w_{10}'\ \ w_{10}''\ \ w_{10}''' \right\}$$

– Influence function matrix: $V(\xi_1)$

$$V_{1\,(4\times4)}(\xi_1) = \begin{pmatrix} K_4(\lambda_1\xi_1) & K_3(\lambda_1\xi_1) & K_2(\lambda_1\xi_1) & K_1(\lambda_1\xi_1) \\ \lambda_1^4 K_1(\lambda_1\xi_1) & K_4(\lambda_1\xi_1) & K_3(\lambda_1\xi_1) & K_2(\lambda_1\xi_1) \\ \lambda_1^4 K_2(\lambda_1\xi_1) & \lambda_1^4 K_1(\lambda_1\xi_1) & K_4(\lambda_1\xi_1) & K_3(\lambda_1\xi_1) \\ \lambda_1^4 K_3(\lambda_1\xi_1) & K_2(\lambda_1\xi_1) & \lambda_1^4 K_1(\lambda_1\xi_1) & K_4(\lambda_1\xi_1) \end{pmatrix}.$$

Then the state of the first segment describes how the matrix equation

$$\bar{W}_1(\xi_1) = V(\xi_1)\bar{W}_{10}. \tag{3.13}$$

The vector of state $\bar{W}_1(\xi_1)$ at the end of the first segment

$$\bar{W}_1(\nu) = V(\nu)\bar{W}_{10}. \tag{3.14}$$

3.1.2 Free transverse vibrations of the 2nd segment.

Free transverse vibrations of the segment described by the equation [10]

$$\frac{\partial^4 w_2}{\partial \xi_2^4} + \frac{\partial^2 w_2}{\partial \tau^2} = 0. \tag{3.15}$$

Separating the variables, we obtain

$$w_2(\xi_2, \tau) = W_2(\xi_2)\sin\omega\tau, \tag{3.16}$$

$$W_2^{IV}(\xi_2) - \bar{\omega}^2 W_2(\xi_2) = 0, \quad W_2 = Ae^{r_2\xi_2}, \tag{3.17}$$

where $r_2^4 = \bar{\omega}^2$; $r_{21} = \lambda_2$; $r_{22} = -\lambda_2$; $r_{23} = i\lambda_2$; $r_{24} = -\lambda_2$; $\lambda_2 = \sqrt{\bar{\omega}}$.
The general solution of equation (2.17) has the form

$$W_2(\xi_2) = w_{20}K_4(\lambda_2\xi_2) + w'_{20}K_3(\lambda_2\xi_2) + w''_{20}K_2(\lambda_2\xi_2) + w'''_{20}K_1(\lambda_2\xi_2),$$

where $w_{20}, w'_{20}, w''_{20}, w'''_{20}$ – the initial parameters of the second segment.

We introduce:

– the vector of state of the second section: $\bar{W}_2(\xi_2)$

$$\bar{W}_2(\xi_2) = \{W_2(\xi_2)\ \ W_2'(\xi_2)\ \ W_2''(\xi_2)\ \ W_2'''(\xi_2)\};$$

– the vector of initial parameters: $\bar{W}_{20}$

$$\bar{W}_{20} = \{w_{20}\ \ w'_{20}\ \ w''_{20}\ \ w'''_{20}\};$$

– influence function matrix: $V_2(\xi_2)$

$$V_{2\,4\times4}(\xi_2) = \begin{pmatrix} K_4(\lambda_2\xi_2) & K_3(\lambda_2\xi_2) & K_2(\lambda_2\xi_2) & K_1(\lambda_2\xi_2) \\ \lambda_2^4K_1(\lambda_2\xi_2) & K_4(\lambda_2\xi_2) & K_3(\lambda_2\xi_2) & K_2(\lambda_2\xi_2) \\ \lambda_2^4K_2(\lambda_2\xi_2) & \lambda_2^4K_1(\lambda_2\xi_2) & K_4(\lambda_2\xi_2) & K_3(\lambda_2\xi_2) \\ \lambda_2^4K_3(\lambda_2\xi_2) & K_2(\lambda_2\xi_2) & \lambda_2^4K_1(\lambda_2\xi_2) & K_4(\lambda_2\xi_2) \end{pmatrix}.$$

Then the state of the second segment describes the matrix equation

$$\bar{W}_2(\xi_2) = V_2(\xi_2)\bar{W}_{20}. \tag{3.18}$$

From conditions of conjugation of segments areas has

$$\bar{W}_1(\nu) = \bar{W}_2(0) \ \text{ or } \ V_1(\nu)\bar{W}_{10} = V_2(0)\bar{W}_{20}.$$

Given that $V_2(0)$ – the identity matrix, we obtain $\bar{W}_{20} = V_1(\nu)\bar{W}_{10}$ and, consequently, from (3.18) we have $\bar{W}_2(\xi_2) = V_2(\xi_2)V_1(\nu)\bar{W}_{10}$.

Those: state at both segments is determined by the parameters of the first segments.

State at the end of the second segment when $\xi_2 = 1-\nu$ determined by the vector $\bar{W}_2(1-\nu)$

$$\bar{W}_2(1-\nu) = V_2(1-\nu)V_1(\nu)\bar{W}_{10} = V_{21}(1-\nu,\nu)\bar{W}_{10}. \tag{3.19}$$

Here the matrix of influence $V_{21}(1-\nu,\nu) = V_2(1-\nu)V_1(\nu)$.

Two initial parameter known $w_{10} = w'_{10} = 0$.

There are also known two components of the vector of state at the end of the second segment

$$W(1-\nu) = W_2'(1-\nu) = 0.$$

Substituting these values in the matrix equation (3.19), written in block form, we obtain

$$\begin{pmatrix} \begin{pmatrix} 0 \\ 0 \end{pmatrix} \\ \begin{pmatrix} W_2''(1-\nu) \\ W_2'''(1-\nu) \end{pmatrix} \end{pmatrix} = \begin{pmatrix} \begin{pmatrix} c_{11} & c_{12} \\ c_{21} & c_{22} \end{pmatrix} & \begin{pmatrix} c_{13} & c_{14} \\ c_{23} & c_{24} \end{pmatrix} \\ \begin{pmatrix} c_{31} & c_{32} \\ c_{41} & c_{42} \end{pmatrix} & \begin{pmatrix} c_{33} & c_{34} \\ c_{42} & c_{44} \end{pmatrix} \end{pmatrix} \begin{pmatrix} \begin{pmatrix} 0 \\ 0 \end{pmatrix} \\ \begin{pmatrix} w_{10}'' \\ w_{10}''' \end{pmatrix} \end{pmatrix}.$$

Whence

$$\begin{pmatrix} c_{13} & c_{14} \\ c_{23} & c_{24} \end{pmatrix} \begin{pmatrix} w_{10}'' \\ w_{10}''' \end{pmatrix} = 0. \tag{3.20}$$

The frequency equation is obtained by equating to zero the determinant

$$\begin{vmatrix} c_{13} & c_{14} \\ c_{23} & c_{24} \end{vmatrix} = 0, \tag{3.21}$$

where

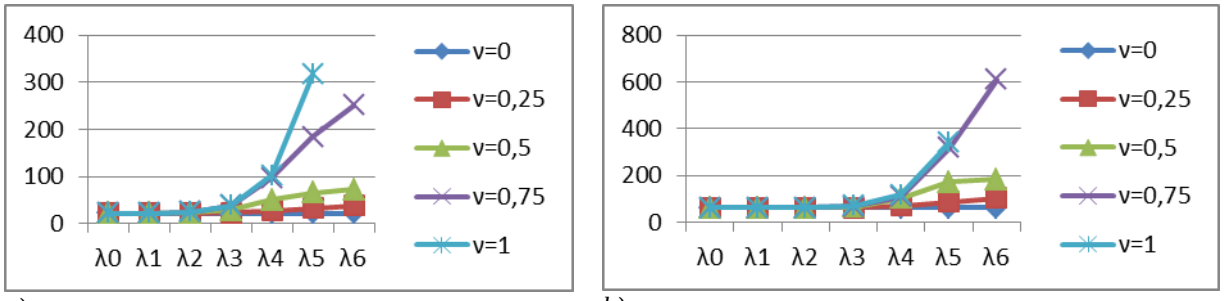
$$C_{13} = K_4(\lambda_2(1-\nu))K_2(\lambda_1\nu) + K_3(\lambda_2(1-\nu))K_3(\lambda_1\nu) + K_2(\lambda_2(1-\nu))K_4(\lambda_1\nu) + \lambda_1^4 K_1(\lambda_2(1-\nu))K_1(\lambda_1\nu).$$

$$C_{14} = K_4(\lambda_2(1-\nu))K_1(\lambda_1\nu) + K_3(\lambda_2(1-\nu))K_2(\lambda_1\nu) + K_2(\lambda_2(1-\nu))K_3(\lambda_1\nu) + K_1(\lambda_2(1-\nu))K_4(\lambda_1\nu).$$

$$C_{23} = \lambda_2^4 K_1(\lambda_2(1-\nu))K_2(\lambda_1\nu) + K_4(\lambda_2(1-\nu))K_3(\lambda_1\nu) + K_3(\lambda_2(1-\nu))K_4(\lambda_1\nu) + \lambda_1^4 K_2(\lambda_2(1-\nu))K_1(\lambda_1\nu).$$

$$C_{24} = \lambda_2^4 K_1(\lambda_2(1-\nu))K_1(\lambda_1\nu) + K_4(\lambda_2(1-\nu))K_2(\lambda_1\nu) + K_3(\lambda_2(1-\nu))K_3(\lambda_1\nu) + K_2(\lambda_2(1-\nu))K_4(\lambda_1\nu).$$

Figure 4 shows the dependence of the two frequencies of the free vibrations of the beam from relative stiffness of grounds for different sizes of the damaged area of the foundation



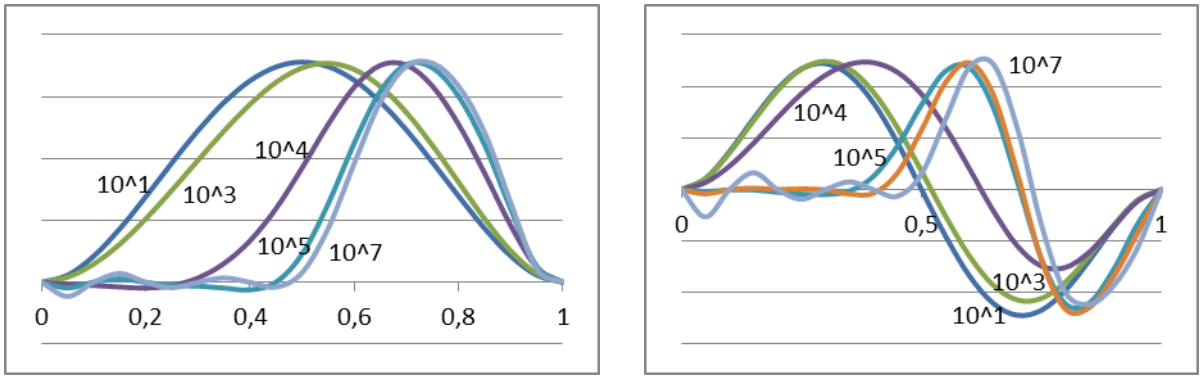
a) *b)*

Figure 4: The natural frequencies of flexural vibrations damaged beam: *a)* – first, *b)* – second.

4 FORCED VIBRATIONS BEAM PARTIALLY SUPPORTED ON THE ELASTIC FOUNDATION

Forced vibrations of the beam consisting of two segments, formed after the partial destruction of the foundation, described by corresponding non-homogeneous equation

$$\frac{\partial^4 w_1}{\partial \xi_1^4} + 4\alpha^4 w_1 + \frac{\partial^2 w_1}{\partial \tau^2} = q' \quad \text{and} \quad \frac{\partial^4 w_2}{\partial \xi_2^4} + \frac{\partial^2 w_2}{\partial \tau^2} = \bar{q} \tag{4.1}$$



a) *b)*

Figure 5: Forms of free vibration of the beam: *a*) – first , *b*) – second.

Expending movement $w_i(\xi_i,\tau)$ (i = 1, 2) in the forms of natural vibrations (3.13) and (3.18), respectively, with coefficients in the form of well-known functions of time using orthogonal forms of natural vibrations, satisfying the initial conditions

$$w_i(\xi_i,0) = w_{cm}(\xi_i), \quad \left.\frac{\partial w_i}{\partial \tau}\right|_{\xi_i,0} = 0 \tag{4.2}$$

obtain function of deflection on segments [11]

$$w_i(\xi_i,\tau) = \sum_{n=1}^{\infty}\left[\frac{\int_0^{\nu_i} w_{cm}(\xi)W_{in}(\xi)d\xi}{\int_0^{\nu_i} W_{in}^2(\xi)d\xi}\cos\bar{\omega}_n\tau + \frac{2\bar{q}\int_0^{\nu_i}(\xi)W_{in}(\xi)d\xi}{\bar{\omega}_n^2\int_0^{\nu_i} W_{in}^2(\xi)d\xi}\sin^2\frac{\bar{\omega}_n\tau}{2}\right]W_{in}(\xi), \tag{4.3}$$

where $\nu_1 = \nu, \quad \nu_2 = 1-\nu.$

5 A NUMERICAL EXAMPLE

Reinforced concrete beam length L = 6,7 *m*, rectangular cross-section with sides of width b = 0,25 *m*, height h = 0,18 *m*, moment of inertia of the cross-section of the $I = 1{,}215\cdot10^{-4}\,m^4$, Young's modulus of the beam material $E = 3{,}05\cdot10^{10}\frac{N}{m^2}$. Material of foundation – a ballast layer of crushed stone with module $K_1 = 75\frac{MPa}{m}$. Coefficient of stiffness of foundation $K = K_i b = 18{,}75\cdot10^6\,Pa$. Parameter $\bar{\lambda} = \frac{KL^4}{EI} \approx 10^4$. Setting ends beams are clamped. The beam is loaded with a uniformly distributed load of intensity $q = 13{,}5\frac{kN}{m}$ (brick wall height of 3 *m*, a length of 6.7 *m*, a thickness of 0.25 *m*, the proportion of the material $18\frac{kN}{m^3}$).

In the initial (unstrained) state the maximum bending moment $\bar{M}_{\max 0} = 0{,}099\bar{q}$, $\bar{M} = \frac{ML}{EI}$, $\bar{q} = \frac{qL^3}{EI}$. Normal stress $\sigma = 39\frac{kg}{cm^2}$.

Table 1 contains the ratios $K_{quasi} = \frac{M_{quasi}}{M_{st.}}$ and $K_{dinam} = \frac{M_{dinam}}{M_{st.}}$ increasing the maximum bending moment in the beam at different degrees, respectively, quasi-static and sudden damage to the base

The degree of damage, $1-\nu$	1	0,75	0,5	0,25	0
Quasi-static, K_{quasi}	1	1,41	3,53	6,56	8,33
Sudden, K_{dinam}	1	1,57	4,52	11,29	14,53

Table 1: Splash of max bending moment at the foundation damage.

6 CONCLUSIONS

A mathematical model of free transverse vibrations of simply supported beam partially on an elastic Winkler foundation. The beam appears conjugation of two segments, one of which is fully supported by the foundation, the other is free. The spectrum of the natural frequencies of the beam on the foundation of partial damage frequency is determined by the equation obtained procedure similar to that used in the finite element method (FEM) in the construction of finite element stiffness matrix. We introduce four component vectors of the state – the dimensionless deflection, turn the cross-section, the bending moment and shear force. In matrix form obtained according to the state vectors in an arbitrary section of the vector of initial parameters. Vectors of state presented a set of blocks, including kinematic and power parameters. This matrix is the influence of the initial section of the cell becomes final, always 4×4. The frequency equation is obtained by equating the determinant of this matrix is zero. The use vectors of state, and the initial parameters of the procedure reduces the influence of the matrix to the fourth, with any number of mating parts of the beam, which significantly reduces the complexity of the calculations.

As a result, we obtained the relationship between the natural frequencies, the mechanical characteristics of the beam and the foundation and damage parameters: the length of the damaged portion of the foundation and its localization in the overall length of the beam.

Keywords: Viscous damper, Reliability, Sensitivity, Subset Simulation.

Abstract. *Viscous dampers are energy dissipation devices widely employed for the seismic control of structures. The performance of systems equipped with viscous dampers has been extensively analyzed by employing deterministic approaches. However, these approaches neglect the response dispersion due to the uncertainties in the input as well as in the structural system properties. Some recent works highlighted the important role of these uncertainties in the seismic performance of systems with linear or nonlinear viscous dampers. The present study focuses on the uncertainty in the damper properties and it aims at evaluating its influence on the probabilistic response of the damped system. In particular, the variability of the damper properties is assumed to be constrained by the tolerances allowed in qualification and production control tests. A preliminary study on the damper response is carried out to relate the constitutive damper characteristics to the parameters controlled in the experimental tests and to evaluate the consequences of damper parameter variations on the dissipation properties of the device. In the subsequent part of the study, the response hazard curves, providing the relation between the values of the response parameters of interest and the relevant yearly exceedance probability, are evaluated. In the analyses, a simplified structural system is considered, and the Subset Simulation (SS) algorithm is employed together with the Markov Chain Monte Carlo method to achieve a good estimate of small probabilities of exceedance. A sensitivity analysis, considering the expected variations in the damper properties, is finally carried out by employing the Augmented SS method to study the influence of the device acceptance ranges on the hazard curves.*

1 INTRODUCTION

Supplemental energy dissipation systems are widely employed for the seismic control of new and existing structures. In particular, viscous dampers provide an efficient tool to dissipate the seismic input energy into heat, by reducing both the displacement and force demand in the structures [1, 2]. To date, the performance of systems equipped with viscous dampers has been extensively analyzed by employing deterministic approaches neglecting the response dispersion due to the uncertainties in the input as well as in the structural system properties.

However, these deterministic approaches provide only an approximate assessment of the seismic performance [3]. Some recent works have highlighted the important role of the uncertainties in the seismic performance of structures equipped with viscous dampers [4, 5, 6, 7] and the different propagation of ground motion uncertainties in systems equipped with linear or nonlinear viscous dampers [8, 9, 10]. The present study focuses on the influence of the uncertainties in the damper properties. In the approach suggested by codes and followed in practical design [11, 12, 13, 14], this uncertainty is bounded by the tolerances allowed in the qualification and production control tests. Consequently, design procedures usually involve a safety check based on the responses obtained by upper and lower bounds of the damper properties, chosen coherently with the test tolerances. However, the actual level of safety provided by the suggested design procedures is a problem requiring further investigation, as pointed out in [10], and the relevance of this topic is mainly due to the low robustness inherent to the structure-dampers system, where the unexpected dissipative device failure can lead to a progressive collapse of the potentially non-ductile structure.

The present paper aims at evaluating the influence of these allowed tolerances in the probabilistic performance of the system, by providing useful information on the exceedance probability of the response parameters of most interest for the performance assessment (as described by response hazard curves) and by using an approach to the problem that is more efficient and reliable with respect to those used in previous studies on the same topic.

A preliminary analysis of the damper response is developed to relate the damper constitutive characteristics to the parameters controlled in the experimental tests and to analyze the variation in the dissipation properties of the device.

In the subsequent part of the study, response hazard curves are developed by employing a simplified model of the structural system. These curves provide the relation between the values of the response parameters of interest and the relevant yearly probability of exceedance. A sensitivity analysis, considering the expected variations in the damper properties, is then carried out to assess the influence of the device acceptance ranges on the hazard curves. The response measures considered include the maximum values of the deformation, related to the damage of the structural system and the damper failure [15], and the maximum values of the relative velocity, related to the damper force. The model uncertainties considered in the applications concern the earthquake scenario parameters and the ground motion characteristics, while other uncertainties concerning the structure response are neglected [16, 17]. The numerical applications, involving both linear and nonlinear viscous dampers show that tolerances allowed in the tests provide notable differences among the observed values of the response parameters of interest.

It is noteworthy that the probabilistic response of the system was analyzed in the previous studies by employing approaches consistent with the PEER framework [18]. This latter is a widely employed framework that permits a separation of the tasks related to the seismic hazard, structural vulnerability and expected losses assessment. The application of the framework is usually based on a description of the seismic input in terms of a small set of real records.

This approach does not permit to achieve an accurate estimate of small failure probabilities. For this reasons, in this study the Subset Simulation algorithm with Markov Chain Monte Carlo method are employed to obtain a good estimate of small probabilities of exceedance [19]. Coherently with this approach, the Augmented SS method is used for the sensitivity analysis [20]. This simulation techniques require a seismological stochastic model and the one proposed in [21, 22] has been used for the analyses.

2 DAMPER RESPONSE SENSITIVITY

The response of viscous damper is usually described by an exponential constitutive law in the form [23, 24]

$$F_d = c|v|^{\alpha}\,\mathrm{sgn}(v) \tag{1}$$

where F_d is the measured force and c and α are two constitutive parameters: the former is a multiplicative factor while the latter describes the nonlinear behaviour ($\alpha = 1$ for the linear case).

In a sensitivity study aiming at evaluating the consequences of variations of the damper parameters on the system performance, these two parameters could be assumed to vary freely.

However, the experimental procedure for the production controls suggest a different approach to the sensitivity analysis, involving characteristic parameters directly linked to the experimental test results, as explained hereafter. In general, the design is based on a target value of the maximum velocity v_0 attained at a circular frequency $\omega_{0,test}$ relevant to the seismic response, and the production control tests are oriented to check the damper behavior at this design condition. More precisely, sinusoidal cycles simulating the design conditions, i.e., the displacement histories $u(t) = v_0 / \omega_{0,test} \sin(\omega_{0,test} t)$, are imposed to the damper and the corresponding maximum damper force $F_{d,test}$ is measured. Some tolerance is allowed in the force value and acceptance criteria usually requires that the difference between the measured value of the maximum force $F_{d,test}$ and the expected (design) value $F_{d0,test}$ is lower than +/- $pF_{d0,test}$ [11, 12, 13]. The safety check is coherently carried out by considering the worst conditions compatible with the acceptance criteria [11, 12, 13], by adopting a lower/upper bound approach.

In this context, rather than investigating the system response by considering a free variation of the constitutive parameters it is more useful to link the variability of the response to the outcomes of the acceptance tests. Thus, in this study the response is investigated by assuming p, describing the acceptance tolerance $pF_{d0,test}$, as a system parameter and by introducing a second parameter λ to identify the different pairs (c,α) providing the same force variation $pF_{d0,test}$. The pairs (c,α) satisfying the equality constraint lie on a curve, whose parametric expression is made explicit. Let c_0 and α_0 denote the reference values assumed in the structural design. A variation $(\hat{c},\hat{\alpha})$ of the constitutive parameters provides the following variation $\hat{F}_{d0,test}$ of the maximum force $F_{d0,test}$ expected in the sinusoidal test

$$\hat{F}_{d0,test} = F_{d,test} - F_{d0,test} = F_{d0,test}\left[\left(1+\frac{\hat{c}}{c_0}\right)\cdot(v_0)^{\hat{\alpha}} - 1\right] \tag{2}$$

The equation clearly shows that both $\hat{c}$ and $\hat{\alpha}$ contribute to this variation and the previous expression can be rewritten by introducing the tolerance parameter p as

$$p = \left(1 + \frac{\hat{c}}{c_0}\right) \cdot (v_0)^{\hat{\alpha}} - 1 \tag{3}$$

It is evident (Figure 1) that the same variation p can be obtained by different pairs $(\hat{c}, \hat{\alpha})$ and the constraint between these parameters can be described by introducing the parameter λ

$$\hat{c}(p, \lambda) = c_0 \frac{1+p}{(v_0)^{\lambda}} - 1 \tag{4}$$

$$\hat{\alpha}(p, \lambda) = \lambda \tag{5}$$

so that the pair (p, λ) provides a representation of the response variability that is alternative to the representation provided by $(\hat{c}, \hat{\alpha})$. The condition λ=0 coincides with a force variation due only to a variation of the response scale factor $\hat{c}$ =p, whereas the other values describe a force variation p involving a combination of $\hat{c}$ and $\hat{\alpha}$.

To complete the preliminary analysis of the damper variability effects, a linearized form of the previous relationship between the constitutive parameters is derived. This form can be of interest in the sensitivity analysis of problems where eqn(1) is the only source of nonlinear behaviour and the local response variation can be conveniently approximated by analytical linear operators [25, 26, 27]. The relationships corresponding to eqns(3-5) are

$$p = \frac{\hat{c}}{c_0} + \ln(v_0)\hat{\alpha} \tag{6}$$

$$\hat{c} = c_0[p - \lambda \ln(v_0)] \tag{7}$$

$$\hat{\alpha} = \lambda \tag{8}$$

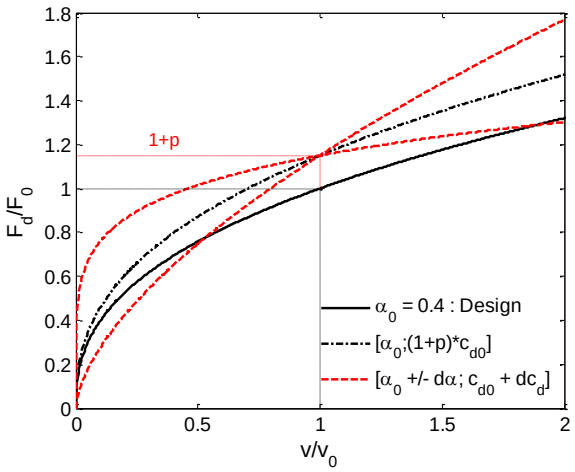

Figure 1: Variations allowed for the damper response.

Figure 2 shows the parametric curves containing the pairs $(\hat{c}, \hat{\alpha})$, evaluated for 3 values of the force variation factor p. The 3 cases reported correspond to p = - 0.3, p = 0.0, p = + 0.3.

These curves are obtained by intersecting the surfaces provided by eqn.(3) (nonlinear expression) and by eqn.(6) (linear approximation) with horizontal planes identifying the force variations. The results concerning the case of linear viscous damper (α =*1*) and nonlinear viscous damper with α =*0.2* are reported respectively in Figure 2a and Figure 2b. It can be ob-

served that the differences between the results obtained by using the nonlinear (exact) and the linear approximation become negligible in the case of the nonlinear damper. In this latter case, a notable percentage variation of α is linked to very small variation of c.

The energy dissipation properties are analyzed and reported in Figure 3. The energy dissipated in a cycle at the design conditions is denoted by W_{d0}. The corresponding energy dissipated in the same test by a damper with different properties depend on p and λ and it is denoted by W_d. Figure 3 shows the values of the ratio W_d / W_{d0} obtained by varying the parameters. The solid lines correspond to the results measured for fixed values of the force factor p. The cases $p = -0.30, -0.15, 0, 0.15, 0.30$ are reported and the points of these curves describe the variations relevant to different pairs $(\hat{c}, \hat{\alpha})$. Dashed lines connect the points with the same variation of c. Results of Figure 3a refer to a linear viscous damper and Figure 3b refers to a nonlinear viscous damper with $\alpha = 0.2$. Given a value of the force factor p, the energy dissipated changes significantly by varying the pair $(\hat{c}, \hat{\alpha})$. Higher values of $\lambda = \alpha$ result in a reduction of the dissipative properties and this trend is more evident in the linear case. The discussed trend of the dissipation properties are valid in the neighborhood of the design conditions and different trends are observed for cycles with larger (or smaller) amplitudes which can be representative of the response for seismic inputs with intensity levels higher (or lower) than the design one.

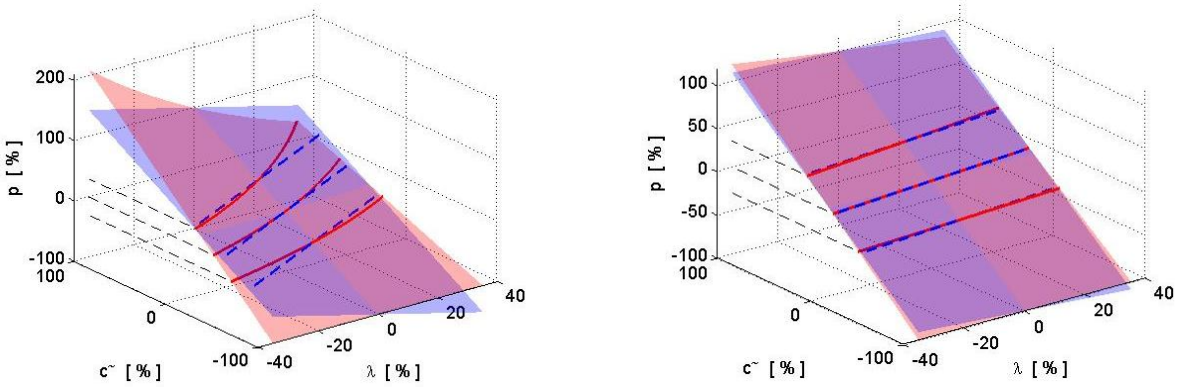

Figure 2: Linear/nonlinear p-α–c_d relationships for different p values (-30; 0; +30 %): a) α_0 = 1.0; b) α_0 = 0.2.

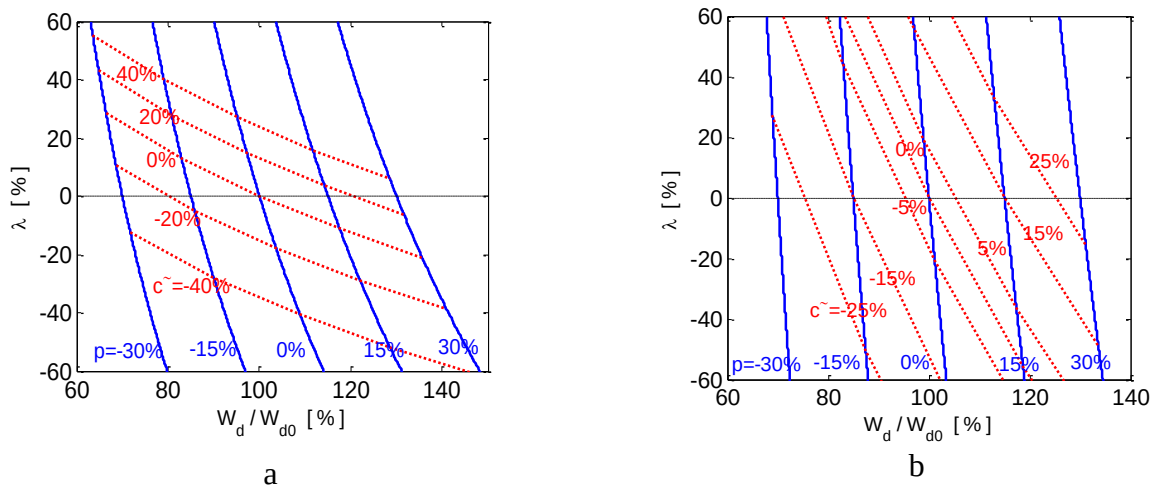

Figure 3. Dissipated energy variation in cyclic paths (amplitude 0.0454m, circular frequency 2π)

3 SEISMIC RESPONSE SENSITIVITY

3.1 Seismic performance

The seismic assessment and design of structures is usually carried out by evaluating via structural analysis the statistics of one (or more) response parameter of interest D and by ensuring that the $P[D > d^*]$ of exceedance of a fixed threshold d^* is lower than an acceptable value P^*. The random variable D can be expressed in terms of the ratio between a performance demand and the relevant capacity, so that a unitary threshold implies failure at ultimate condition. This way, D accounts for the uncertainties in the loading actions, in the model and the capacity. Typical response parameters employed in the context of the performance assessment of buildings with viscous dampers are: inter-storey drifts, absolute accelerations at storey, total base shear, forces on dampers, strokes on dampers.

Code design and assessment procedures aim at satisfying the reliability constraint in an indirect way, as they evaluate a conventional demand measure $d_0 < d^*$ which is obtained from loadings of intensity whose exceedance probability P_0 is lower than the acceptable probability P^* [3]. Amplification factors are usually considered to pass from d_0 *to* d^*.

In the specific case of the seismic analysis of buildings equipped with dampers, the design is carried out by evaluating the response for seismic events with a mean annual frequency of occurrence varying from $1 \cdot 10^{-2}$ (service limit state) to $2 \cdot 10^{-3}$ (ultimate limit state) [11, 28, 29] while the safety target requires that the probability of failure is lower than 10^{-5} -10^{-6} [11, 29].

In order to relate the design condition, described by the pairs (d_0, P_0), to the effective system reliability, described by the couple (d^*, P^*), it is useful to evaluate the response hazard function

$$G_d(d) = P[D > d] \tag{9}$$

associating a generic value of the response parameter threshold d to the corresponding probability of exceedance. The conventional design value d_0 can be linked to the response value associated to a given probability of exceedance by introducing the inverse function $G_D^{-1}(P)$ and defining the ratio

$$\gamma(P) = \frac{G_d^{-1}(P)}{d_0} \tag{10}$$

This ratio can be interpreted as the amplification factor for the design value d_0 providing the response parameter value corresponding to the desired probability of exceedance.

Design procedures generally do not involve a probabilistic analysis but aim at providing the value of d_0 by means of a deterministic analysis. For example, the seismic design is usually based on the description of the seismic input in terms of a pseudo-acceleration response spectrum and a reduced set of (artificial or natural) ground motions accounting for the record-to-record variability effects. The conventional design value of the response d_0 is obtained as the mean of the maximum response values. This design approach introduces further sources of approximation in the evaluation of the system reliability which are not addressed in this work.

3.2 Response hazard curve evaluation

Let X be the vector of the random variables of the system lying in the domain Ω, including both the variables describing the ground motion, for which a stochastic model is required,

and the structural system uncertainties. The system parameters are described by the vector $\vartheta \in \Gamma$, collecting the damper parameters p and λ, as discussed in the previous section.

The failure corresponds to the region of response events such that $G_d(d \mid \vartheta) = \{x : g_d(x \mid \vartheta) > d\}$, having denoted with $g_d(x \mid \vartheta)$ the response function providing the value of the parameter d, once the sample x and the parameters ϑ are assigned. The response hazard function can be obtained as

$$G_d(d \mid \vartheta) = \int_{\Omega} I_d(x \mid \vartheta) p_X(x) dx \tag{11}$$

where $p_X(x)$ if the probability density function (PDF) of the system variables and $I_d(x \mid \vartheta)$ is the indicator function, such that $I_d = 1$ if $x \in G_d(d|\vartheta)$ (equivalently $g_d(x|\vartheta) > d$), otherwise $I_d = 0$. In the following, it is assumed that the $p_X(x)$ is not influenced by the parameters ϑ, although the formulation can be extended to the general case $p_X(x|\vartheta)$ [20].

The sensitivity problem is approached by considering the augmented reliability problem proposed in [20], i.e., by considering ϑ as a fictitious random variable with arbitrary PDF $p_\Theta(\vartheta)$. By this approach, the response sensitivity can be estimated with the same simulations employed for estimating the reliability, thus significantly reducing the computational effort with respect to other approaches.

The response hazard function can be obtained through the Bayes' Theorem in the form

$$G_d(d \mid \vartheta) = \frac{p_\Theta(\vartheta \mid d)}{\Theta(\vartheta)} G_d(d) \tag{12}$$

where

$$G_d(d) = \int_{\Omega x \Gamma} I_d(x \mid \vartheta) p_X(x) p_\Theta(\vartheta) dx d\vartheta \tag{13}$$

and

$$p_\Theta(\vartheta \mid d) = \frac{\int_{\Omega x \Gamma} I_d(x \mid \vartheta) p_\Theta(\vartheta) d\vartheta}{G_d(d)} \tag{14}$$

In this formulation, both X and ϑ are random variables and the probability of exceeding the threshold d is a rare event that can be efficiently evaluated by the Subset Simulation-Markov chain method [19].

3.3 Uncertainties description

The seismic event is described by defining a seismic source characterized in terms of moment magnitude M and source-to-site (hypocentral) distance R. The description of the uncertainty associated with the seismic input is completed by the specification of a stochastic ground motion model, considering the properties of the construction site. The intensity of the seismic event is described by the moment magnitude M and its uncertainty is modeled by the Gutenberg-Richter law defined on the interval $[m_{\min}, m_{MAX}]$ and corresponding to the following PDF of M given an earthquake event [30]:

$$p_M(m) = \frac{\beta e^{-\beta m}}{\beta e^{-\beta m_{\min}} - \beta e^{-\beta m_{MAX}}} \quad m \in [m_{\min}, m_{MAX}] \tag{15}$$

where $\beta = \ln(10)b$ is a parameter related to the number of the expected earthquakes per annum with magnitude exceeding m. More precisely, it is assumed that the occurrence of an event with $M > m$ is a Poisson process with exceedance frequency $\lambda(m) = 10^{a-bm}$ and no event is expected for $M > m_{MAX}$. It is also assumed that no significant response is observed for $M < m_{\min}$, so the response hazard function, referred to a time interval one year long, can be obtained as $G_d(d) = \left(1 - e^{-\lambda(m_{\min})}\right) P[D > d \mid M > m_{\min}]$ by starting from the outcomes of the subset procedure $P[D > d \mid M > m_{\min}]$.

The ground motion is generated by starting from a white noise $w(t)$, described by the N-dimensional vector $\mathbf{w}$ of values w_i assumed at the instant $t_i = i\Delta t$, where Δt is the finite time interval assumed for the numerical integration.

Following the Atkinson-Silva model [21, 22], the ground motion is obtained by modulating in time the white noise by means of the function $e(t)$, which yields the time-function $z(t) = e(t)w(t)$. The amplitude and the frequency content are obtained by multiplying its Fourier transform $\bar{z}(f)$ (normalized to have a mean square amplitude of unity) by the radiation spectra $\varepsilon_{\text{mod}} A(f)$, where $A(f)$ is a deterministic function of the frequency f while ε_{mod} is a random scaling factor describing the amplitude variability [31]. The final ground motion acceleration $a(t)$ is obtained by the inverse Fourier transform of $\bar{z}(f) \& A(f)$. The time modulating function and the radiation spectra A depend on the moment magnitude, the distance and the local characteristic of soil. The scaling factor ε_{mod} is a random variable with lognormal distribution and unit median value. Further details on the ground motion model are reported in Appendix 1.

The set of random variables $x = [m, r, \varepsilon, \mathbf{w}]$ consists of the three scalar quantities m, r, ε and the vector-valued quantity $\mathbf{w}$ whose dimension N depends on the discretization of the time interval.

The uncertainties on the structural system are not considered in this work, given their generally low influence on the probabilistic response when also the seismic randomness is taken into account [16, 17].

4 STRUCTURAL RESPONSE

The structural system considered in the study consists of a linear S-DoF system with period $T = 1.0s$ and damping rate $\xi = 0.05$. Two added dissipative systems are analyzed, the former is a linear system with $\alpha_0 = 1.0$ and the latter is a nonlinear system with $\alpha_0 = 0.2$.

For what concerns the seismic scenario, the following values have been assumed for the seismic hazard parameters $a = 4.5$, $b = 1.0$, $m_{\min} = 5$, $m_{MAX} = 8$. An hypocentral distance $R = 20km$ is assumed and the soil conditions are described by Vs=310 m/s. For the time discretization, a time-interval $\Delta t = 0.02s$ is considered, corresponding to *N=3750.*

The linear system viscous constant c has been designed to add a damping ratio $\xi_d = 0.3$ whereas the nonlinear system viscous constant has been calibrated to provide similar performances at the design conditions. More precisely, the equivalence has been established by considering the value assumed by the maximum displacement mean hazard curve $G_U(u_0)$ at P_0 as performance indicator. The two systems are characterized by very close values of u_0 for the probability of exceedance $P_0 = G_U(u_0)$=0.0021 (10% within 50 years); this probability value is usually assumed for the seismic design at ultimate limit conditions [11, 28, 29].

Table 1 reports the viscous damper properties (α_0 and the c_0) and the performances for the linear and nonlinear damped system at the design conditions. The response parameters considered for the performance comparison are: the maximum relative displacement U (controlling the construction damage and the damper failure), the maximum relative velocity V and the maximum force on the damper F_d (controlling the damper failure), and the maximum absolute acceleration A (controlling the damage of acceleration sensitive facilities).

Viscous Properties	α_0		1.00	0.20
	c_0/m	[g-s$^\alpha$/m$^\alpha$]	3.77	0.94
Performances	u_0	[m]	0.037	0.037
	v_0	[m/s]	0.276	0.285
	F_{d0}	[N]	208	146
	a_0	[m/s^2]	1.799	1.896

Table 1: Properties of the damping systems and relevant response at the design conditions.

Subset simulation analyses are performed to estimate the reliability of the damped systems for both the linear and nonlinear viscous dampers case. The first part of the next section compares the reliabilities of the reference systems (corresponding to the nominal damper properties), whereas the second part shows the effects of the variability of the damper viscous properties on the reliability. The probabilistic description of the system response is given in terms of hazard curves (complementary cumulative distribution function CCDF), providing the annual probability of exceedance for each relevant response parameters.

4.1 Probabilistic response at the reference conditions

In evaluating the seismic reliability of the systems at the reference conditions ($p = 0, \lambda = 0$), the set of uncertain parameters consists of those characterizing the earthquake excitation, i.e., magnitude, white-noise components and the model parameter ε_{mod}. As stated before (in Section 3.0), structural system parameters are assumed to be deterministic.

In order to estimate exceedance probabilities up to 10^{-6}, subset simulations are carried out using 6 conditional levels (with threshold levels identified by a percentile equal to 10%) with 600 samples/level and a total number of samples equal to 540x5 + 600 = 3300. The averaged result of 10 independent simulations are presented.

Because of the adopted design criteria, the linearly and nonlinearly-damped systems show the same displacement u_0 at the probability of exceedance P_0 while the other response parameters exhibit different values. The ratios between the demand parameters and the reference values corresponding to the design conditions are reported in the Figure 4, so the unit values are located at the probability of exceedance P_0 and the values reported in the horizontal axis coincide with the ratio introduced in eqn.10. The maximum response parameters corresponding to the probability of exceedance 10^{-6} are highlighted in the figure by the coloured dashed lines, and relevant numerical values are collected in Table 2.

The linear and nonlinear damped systems exhibit different probabilistic responses within a range of exceedance probabilities up to 10^{-6}. In fact, the exceedance probabilities of the maximum displacements and velocities are higher for the linear system than for the linear system, for values below the design value, and lower for values higher than the design value. An opposite trend is observed for the damper force, with the linear system requiring an higher strength capacity than the nonlinear one for rare seismic events. The accelerations show also a

different trend and the performance required by the nonlinear system are generally higher than those required by the linear system both for frequent and rare events. Qualitative trends observed are in agreement with results presented in previous studies obtained by conditional based approaches (PEER framework) [8, 10].

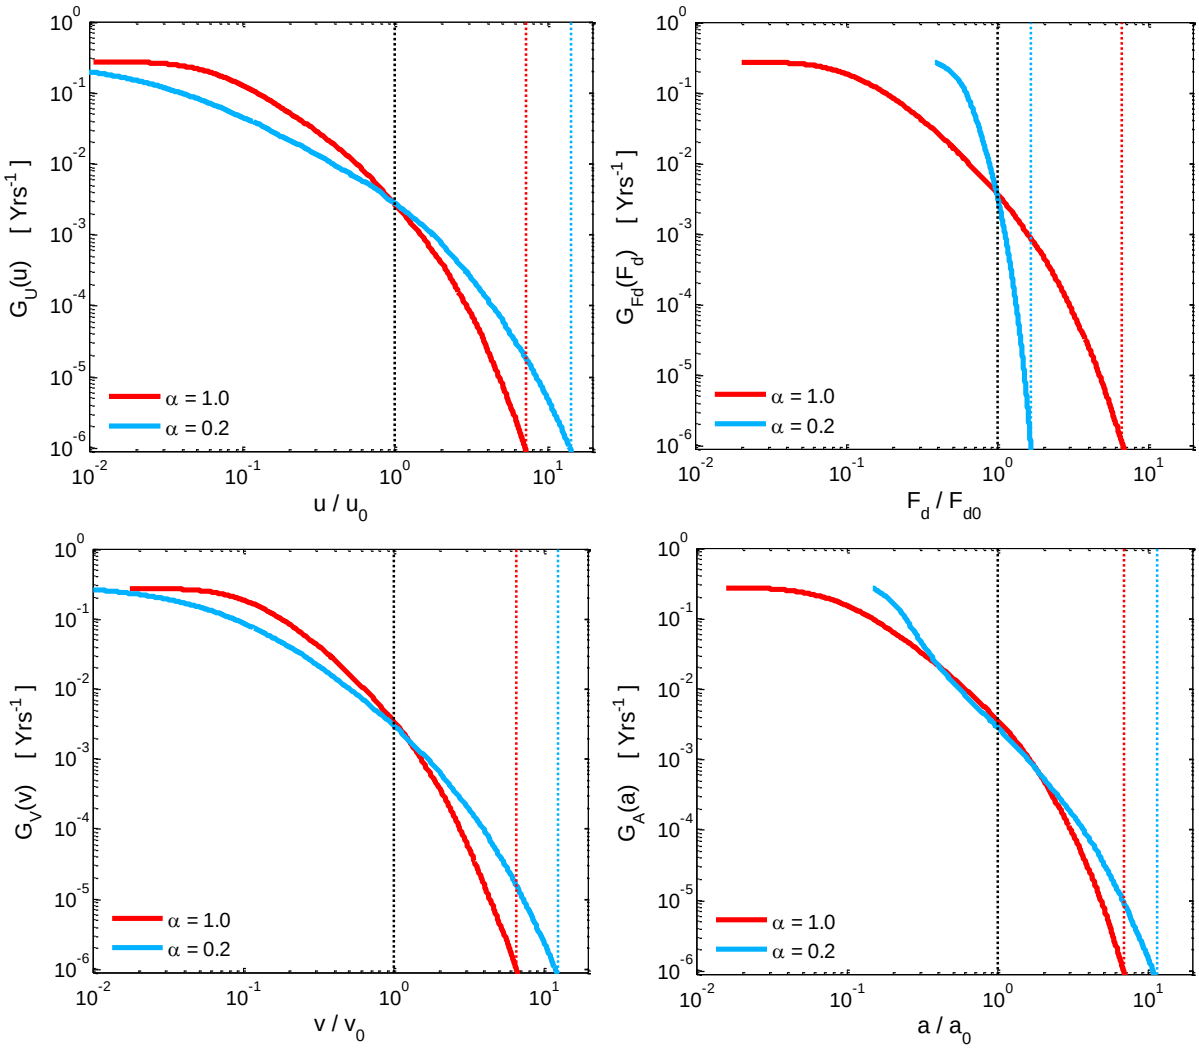

Figure 4. Normalized response hazard curves for linear (α=1.0) and nonlinear (α= 0.2) dampers.

α_0	1.00	0.20
$\gamma_U(P = 10^{-6})$	7.20	14.32

4.2 Effect of viscous damper properties variability

In this section, the influence of the variability of the viscous properties on the hazard curves is analyzed. The reference response evaluated in the previous section is compared with

the response obtained with the upper and lower bound of variations allowed in control production tests, as discussed in Section 2. The two limit values $p = \pm 0.15$ are assumed for the force $\hat{F}_{d0,test}$ measured in the test at the design conditions, according to the limits suggested in [13]. Once p is assigned, only the parameter λ varies and gives the possible pairs of constitutive parameter variations $\hat{\alpha}$ and $\hat{c}$ (see eqns. 4-5).

The system response sensitivity is carried out by considering an "augmented reliability problem" [20] in which the λ-variability is added to the seismic uncertainties previously introduced. In order to investigate a realistic field of variation in the damper response, a uniform distribution function on [-0.20,+0.20] is assumed for the system parameter, λ, in this case coinciding with the nonlinear exponent variation $\hat{\alpha}$. With the aim of increase the accuracy in the estimation of the exceedance probabilities a number of conditional samples greater than the number used in the previous section and equal to 1500 is used for each simulation level, for a total amount of samples equal to 1350x5 + 1500 = 8250. The range of the parameter variation has been discretized in 4 bins J_i (i=1,..,4), and the hazard curves of the two extreme bins, centered at $\lambda = \hat{\alpha} = \pm 0.15$ are reported in the following. An average of 50 independent simulations is used.

In Figures 5 the hazard curves of displacements, damper forces and absolute accelerations are plotted with a semi-logarithmic representation. Both the linear (left charts) and nonlinear (right charts) damped systems are considered, and the response parameters values are normalized by dividing them by the design value obtained in the reference design condition, as in the previous section. Each chart shows the reference curve (black solid line), a pair of blue dashed curves related to the upper bound $p = +0.15$ and describing the response variation for the two extreme bins of the parameter variation $\lambda = \pm 0.15$, a pair of red dashed curve related to the lower bound $p = -0.15$ and describing the response variation for the two extreme bins of the parameter variation $\lambda = \pm 0.15$

In the linear case, the perturbed condition with *p=-0.15* produces (moving towards the small probability range) an amplification on both the displacement and acceleration responses, while the opposite trend is observed for the damper force. The highest displacement variations occur when *p=-0.15* and λ is in the bin centred at the value λ*=-0.15*. This is a consequence of both the reduction of the damper force due to the negative value of *p* and the nonlinearity introduced by the negative variation of λ (α<1) in the system behaviour, which results in larger displacements for less probable events (see Figure 4 for *u* parameters). A different trend is observed for the forces, where the worst condition is represented by *p=+0.15*.

At the minimum probability of exceedance considered, the increment of the maximum displacement threshold is about 35% and the force threshold is about 20% while lower increments are observed for the absolute acceleration threshold.

Similar trends are shown in the nonlinear case where both the displacement and the acceleration demands grow for *p=-0.15*, while the damper forces increase when *p=+0.15*. However, in this case results are less sensitive to the parameter λ, expressing the percentile variation of the nonlinear exponent α.

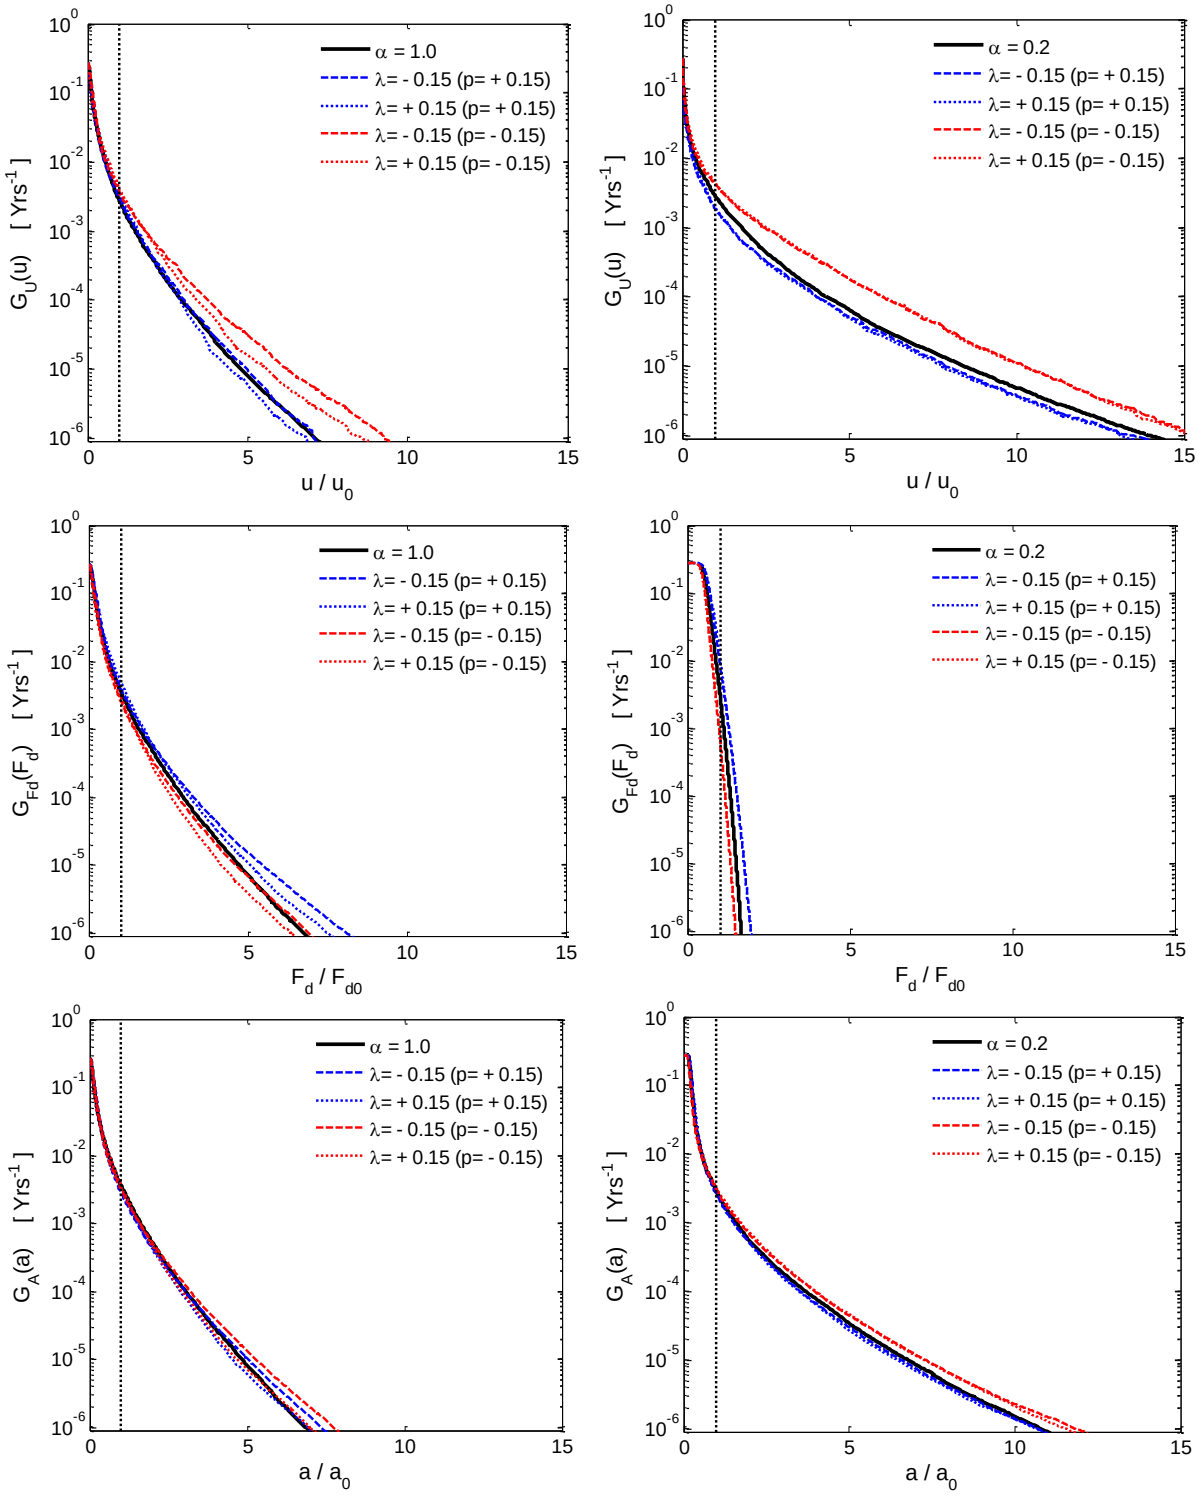

Figure 5. Effects on the response hazard curves due to the perturbation on the damper parameters.

5 CONCLUSIONS

The paper analyzes the influence of both the seismic uncertainties and the variability of the viscous damper behaviour on the probabilistic response of passively protected systems. The probabilistic response is evaluated by means of advanced statistical simulation methods (Subset simulation with Markov chains), able to furnish an accurate estimation of the demand hazard for low values of the exceedance probability.

The effects of the variability of the viscous damper properties coherent with the tolerance range allowed by the codes for device control tests is studied via reliability-sensitivity analysis. This analysis is performed by carrying Subset simulations on an "augmented reliability problem".

A comparison between the performances of two systems consisting of the same structure and of added linear (α=1) and nonlinear (α=0.2) viscous dampers is presented. The dampers are designed to achieve the same seismic performances (displacement response) at the usual design conditions suggested by codes of practice and corresponding to an annual probability of exceedance of 0.0021.

It is observed that the variability expected according to control production tests influences differently the response hazard curves for rare events. Considering probability of exceedance in the range 10^{-5}-10^{-6}, it is observed that some response parameters are more sensitive to the damper parameter variations than others. Liner and nonlinear cases exhibit similar trends of variation but the amount of the response variations are very different in the two cases.

Current design procedures are based on the estimation of the probabilistic response and relevant structural safety by means of amplification factors increasing conventional design values of the structural response. The results observed in this study provide a contribution towards a more reliable definition of these amplification factors.

8 APPENDIX 1 - DETAILS OF ATKINSON-SILVA MODEL

The Atkinson-Silva ground motion model [21] used in this work is characterized by the radiation spectrum *A(f)* and the time modulating function *e(t).* The radiation spectrum gives a spectral representation of the ground motion at the construction site, accounting for several physical contributions influencing the wave propagation. Its analytical expression is

$$A(f) = \varepsilon_{\text{mod}} A_0(f) \cdot A_n(f) \cdot P_f(f) \cdot V(f) \tag{16}$$

The (two corner frequencies) point-source spectrum is represented by $A_0(f)$

$$A_0(f) = C \cdot M_0 \cdot (2\pi f)^2 \cdot \left((1-\varepsilon) \cdot \frac{1}{1+(f/f_a)^2} + \varepsilon \cdot \frac{1}{1+(f/f_b)^2} \right) \tag{17}$$

where, M_0 is the seismic moment (expressed in *dyne·cm*), related to the moment magnitude M by

$$M_0 = 10^{\frac{3}{2}(M+10.70)} \tag{18}$$

and C is a constant given by

$$C = 10^{-20} \cdot \frac{\hat{R} \cdot V \cdot F_s}{4\pi\rho\beta^3} \tag{19}$$

where $\hat{R}$, V, F_s are respectively the radiation pattern ($\hat{R} = 0.55$), a factor partitioning the total shear-wave energy into 2 horizontal components ($V = 0.71$) and the free-surface amplification factor ($F_s = 2.0$); ρ and β represent the soil density ($\rho = 2.8 t/m^3$) and wave velocity ($\beta = 3.5 km/s$) near the source; the multiplicative factor 10^{-20} is in order to obtain *cm* as unit dimension for the ground motion (*cm/s*^{2} for accelerations). The two corner frequencies f_a and f_b and the ε parameter are related to the magnitude by

$$\log(f_a) = 2.181 - 0.496 \cdot M \tag{20}$$

$$\log(f_b) = 1.380 - 0.227 \cdot M \tag{21}$$

$$\log(\varepsilon) = 3.223 - 0.670 \cdot M \tag{22}$$

The $A_n(f)$ function, characterizing the path effects of seismic waves, is given by

$$A_n(f) = \frac{1}{R} e^{\frac{-\pi f R}{Q(f)\beta}} \tag{23}$$

where the 1/R term represents the geometrical spreading effect. The effect of the waves-transmission is accounted by the *quality factor* $Q(f)$,, defined as

$$Q(f) = Q_0 f^n \tag{24}$$

whit $Q_0 = 180$ and $n = 0.45$ regional parameters. The $P_f(f)$ function accounts for the path-independent loss of high-frequency in the ground motion and it is defined by

$$P_f(f) = e^{(-\pi k f)} \left[1 + \left(\frac{f}{f_{\max}} \right)^8 \right]^{-0.5} \tag{25}$$

Whit k = 0.03 and f_{max} = 100 Hz. The soil amplification factor V(f) is taken according to [32] for generic soil ($V_{S,30}$ = 310 m/s). The model-error parameter ε_{mod} is the adding log-normal random variable ($\mu_{ln\varepsilon}$ = 0, $\sigma_{ln\varepsilon}$ = 0.5) , according to Jalayer and Beck [31], used for increasing the record-to-record variability. For which concerns the envelope function $e(t)$, it is given by

$$e(t) = a \cdot \left(\frac{t}{T_n} \right)^b \exp\left(-c \cdot \left(\frac{t}{T_n} \right) \right) \tag{26}$$

with parameters $b = -\varepsilon \cdot \frac{\ln(\eta)}{\left[1+\varepsilon\left(\ln(\varepsilon)-1\right)\right]}$, $c = \frac{b}{\varepsilon}$, $a = \left(\frac{\exp(1)}{\varepsilon}\right)^b$ and η=0.05, ε=0.2, as suggested in [22].

The ground-motion total duration is equal to $T_n = 2T_w$ with T_w defined as

$$T_w = 0.05 \cdot R + \frac{1}{2 f_a(M)} \tag{27}$$

The distance R from the earthquake source to the site can be defined as follow, in function of the epicentral distance r and the moment dependent nominal pseudo-depth h ($\log(h) = 0.15M - 0.05$)

$$R = \sqrt{r^2 + h^2} \tag{28}$$

Keywords: Soil structure interaction, Natural period of low rise buildings, Seismic codes in the world, Subgrade reaction modulus of soil

Abstract. *Soil structure interaction (SSI) is an important topic when seismic performance of structures is investigated but rarely taken into account in seismic performance evaluation of low rise buildings. Seismic performance of structures is generally evaluated with three different approaches as equivalent linear earthquake method, modal superposition method and time history analysis method. Equivalent linear earthquake method is the most widespread analysis method for seismic performance evaluation of low rise buildings. Seismic codes in the world generally propose approximate natural period formulas to be used in equivalent linear earthquake analysis procedure. Despite that soil properties have a considerable effect on natural period of buildings; there is no soil related term in approximate natural period relations proposed in the seismic codes. This study aims to introduce the importance of subgrade reaction modulus of soil on natural period of buildings and produce a relation between these two phenomena. In accordance with this purpose, a number of relations being used over the world are examined. Consequently a number of novel approximations are introduced for use of design engineers.*

1 INTRODUCTION

During earthquakes buildings are exposed to base excitations and gives different responses to those excitations. Buildings responds to those excitations with three components: structure, foundation and soil underlying the foundation. As these components are combined with each other, structure, foundation and soil interacts with each other, this phenomenon is known as Soil Foundation Structure Interaction (SFSI) or simply Soil Structure Interaction (SSI) [1].

Soil Structure Interaction is rarely taken into account during dynamical analysis of low rise buildings. The simplifications and approximations made during dynamical analysis of low rise buildings, such as natural period approximations, neglects effect of SSI. ASCE 7 [2] and Eurocode 8 [3] are some of the important seismic codes in the world. The natural period approximations recommended in these seismic codes do not take SSI into account for low rise buildings.

There is not an exact definition for the terms high rise or low rise buildings, but it may be defined as buildings that have few number of storeys or height of the building is under a certain value. In ASCE 7 [2] the approximate natural period formula is recommended for buildings that have 12 or less number of storeys. In some seismically risky zones in Turkey, buildings are not allowed to have more than 3 or 4 storeys. Accordingly, in this study we examined a building with 3 storeys.

The examined building in this study is a typical low rise building with 3 storeys and is symmetric in both lateral directions. Also typical cross sections are defined for all beams, all columns and all slabs. Since we consider low rise buildings, building is modeled as a reinforced concrete structure. Floor plan of the examined generic building is shown in Figure 1.

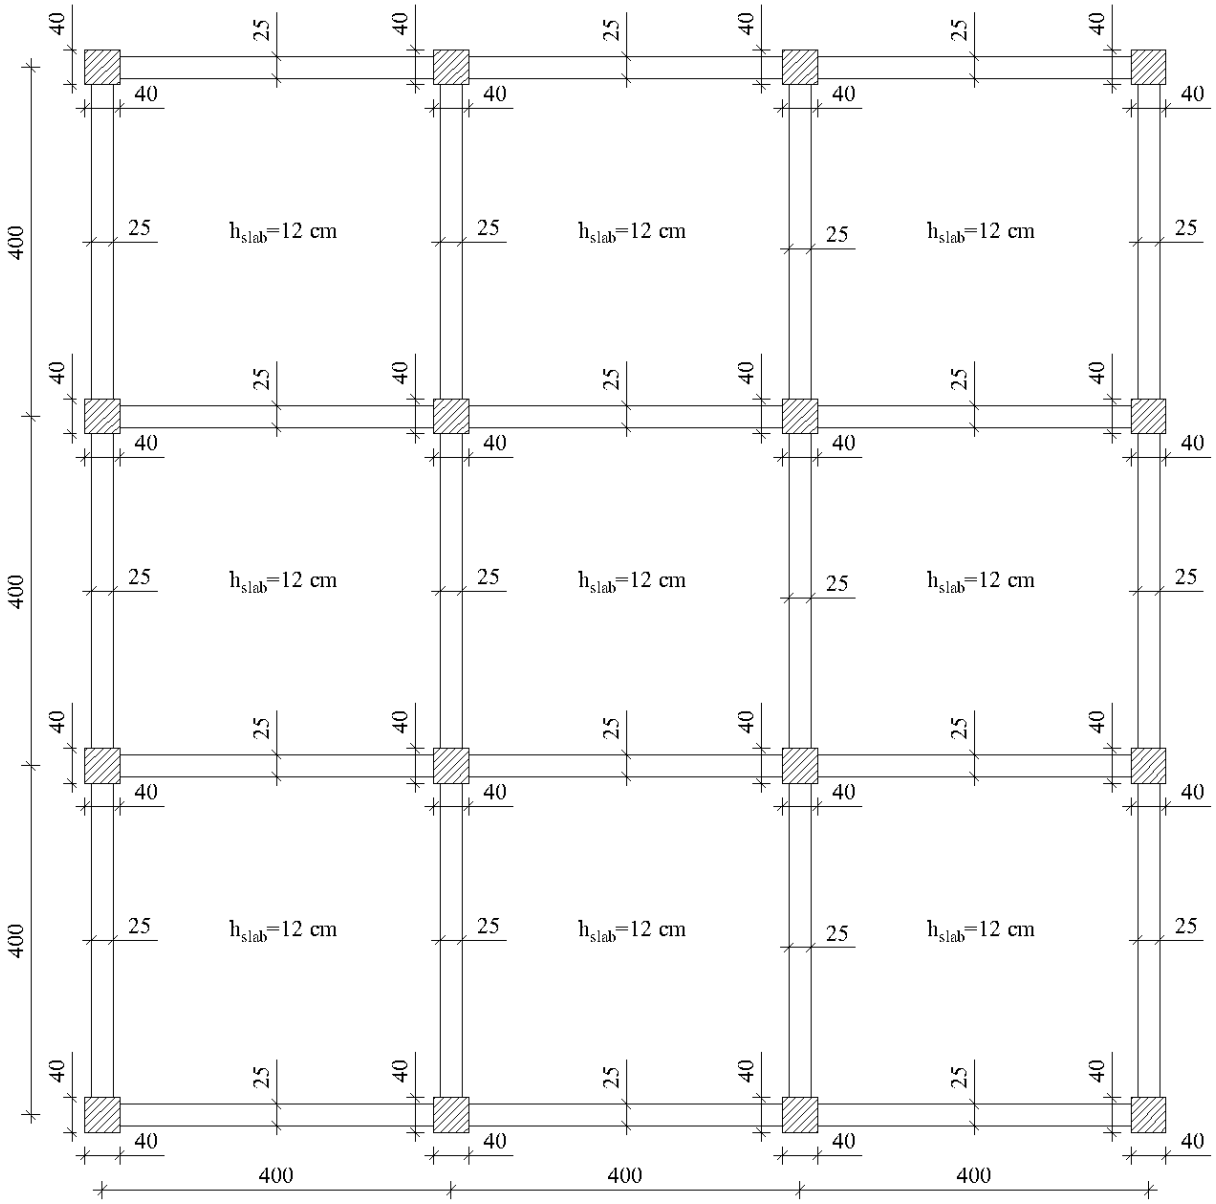

Figure 1 – Floor plan of the investigated building

The most widespread approach to consider SSI is the well-known Winkler Springs Method. In this approach, underlying soil layer is modeled as linear elastic springs in both lateral and vertical directions. Stiffness of those springs represents the subgrade reaction modulus of underlying soil layer.

In this study we aim to introduce novel approximations for natural period of low rise buildings which takes SSI into account. Accordingly a number of modal analysis are performed for a generic low rise building and we introduced a number of new approximations for first natural period of low rise buildings.

2 INVESTIGATION OF SUBGRADE MODULUS EFFECT

2.1 Properties of Investigated Building

As stated before, all columns and all beams are modeled with the same cross section. All beams are modeled as rectangular frame elements with dimensions of 50 cm depth and 25 cm width. All column elements are modeled as rectangular frame elements with $40\ \text{cm} \times 40\ \text{cm}$

dimensions. All slab elements are modelled as shell elements having a bending thickness of 12 cm. Also the foundation of the building is modeled as a shell element with a thickness of 100 cm.

All structural members are modelled with the same linear elastic material which represents reinforced concrete material. Young's modulus for this material is defined as $E = 3\times10^7$ kN/m^2 and Poisson's ratio is defined as $\upsilon = 0.2$. For this material mass per unit volume is defined as $\rho = 2.5$ kNs^2/m/m^3.

As shown in floor plan given in Figure 1, the investigated structure has 3 bays in X direction and Y direction. In both directions bay widths are equal to each other and 4 meters. This symmetric floor plan is adopted to simplify the problem and focus only on first natural period of the building which is equal to second natural period. As stated before the investigated building has 3 storeys and each storeys has the same height as 3 meters.

With those properties mentioned above, the investigated typical low rise building is defined and some modal analysis are performed.

2.2 SSI Procedure and Analysis

In this study Winkler springs method is employed to take SSI into account. In Winkler springs method, the underlying soil layer modeled as linear elastic springs and stiffness of these springs-spring constants- represents the subgrade reaction modulus of the soil layer. Lateral and vertical springs are modeled at column ends. Since the soil layer is continuous along the foundation or floor area, each spring set at each column end represents an area. Columns at inner points represents the area of a bay which can be calculated as $Area = 4\times4 = 16$ m^2 while columns at internal points on edges represents half of that area as $Area = 8$ m^2 and columns at corners represents quarter of that area as $Area = 4$ m^2. Spring constants calculated by using those areas and soil subgrade modulus.

$$K_s = k_s \times Area \tag{1}$$

To perform modal analysis OpenSees [4] software is utilized. Firstly, the investigated structure is modeled with a fixed base which means neglecting the SSI. Then, the modal analysis are performed considering SSI by using Winkler springs. At this step, subgrade reaction modulus of the soil layer is increased gradually and modal analysis performed repeatedly. To represent the subgrade reaction modulus values encountered generally, subgrade modulus values are increased gradually from 500 kN/m^3 to 10000 kN/m^3.

The calculated first natural periods are divided by the period value that neglects SSI to determine a simple ratio. As subgrade reaction modulus values increases, that ratio decreases exponentially. By using this relation two nonlinear regression coefficients are determined which relates period of SSI model to period of non-SSI model as a function of subgrade reaction modulus.

First natural period of the building with fixed base is determined as $T_{fix} = 0.2544$ sec. For subgrade reaction modulus values from 500 kN/m^3 to 10000 kN/m^3, first natural period of the building is determined as given in Table 1.

k_s (kN/m^3)	T (sec)	k_s (kN/m^3)	T (sec)
500	0,9751	5500	0,3535
1000	0,7014	6000	0,3447
1500	0,5829	6500	0,3372
2000	0,5140	7000	0,3308
2500	0,4683	7500	0,3253
3000	0,4356	8000	0,3204
3500	0,4110	8500	0,3161
4000	0,3918	9000	0,3123
4500	0,3764	9500	0,3089
5000	0,3639	10000	0,3059

Table 1 – First natural period and subgrade reaction modulus

Beside the first natural period values the ratio determined by dividing first natural period values of SSI models by first natural period of non-SSI model, can be plotted as shown in Figure 4.

$$\Gamma(k_s) = \frac{T_{SSI}}{T_{FIX}} \tag{2}$$

$$T_{SSI} = \Gamma(k_s).T_{FIX} \tag{3}$$

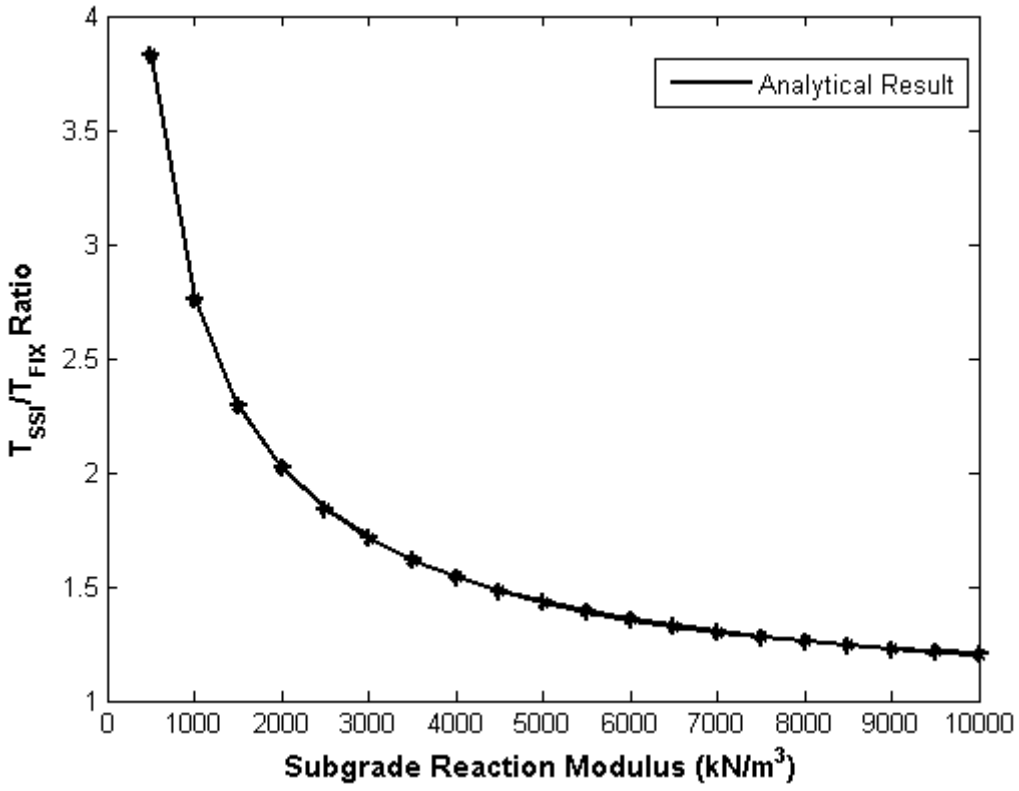

Figure 4 – First natural period ratio with respect to subgrade reaction modulus

In Figure 4 the graph shows the first natural period ratio determined by dividing period of SSI model by period of non-SSI model. As this plot is obtained by using analytical results, this curve is not an approximation. This curve represents the real relation between subgrade reaction modulus and $\Gamma(k_s)$.

The curve shown in Figure 4 can be represented by an inverse exponential function or inverse parabolic function. While using non-linear regression to determine an appropriate function to that curve, an inverse parabolic expression is recommended, regarding physical meaning of the problem.

The recommended relation is in the form shown below;

$$\Gamma\left(k_s\right)=1+\frac{\beta_1}{k_s}+\frac{\beta_2}{k_s^2} \tag{4}$$

Suitability of the recommended relation can be evaluated by considering that infinite subgrade reaction modulus yields 1, which corresponds to the fixed base condition. At the recommended expression, the third term is added to smoothen the expression.

The determined regression coefficients are as given below;

$$\begin{aligned}\beta_1 &= 2,2.10^3\\ \beta_2 &= -4.10^5\end{aligned} \tag{5}$$

Thus the recommended relation between the periods of SSI model and non-SSI model is determined as;

$$\Gamma\left(k_s\right)=1+\frac{2200}{k_s}-\frac{400000}{k_s^2} \tag{6}$$

In Figure 5 the graph shows the first natural period ratio determined by the recommended mathematical expression.

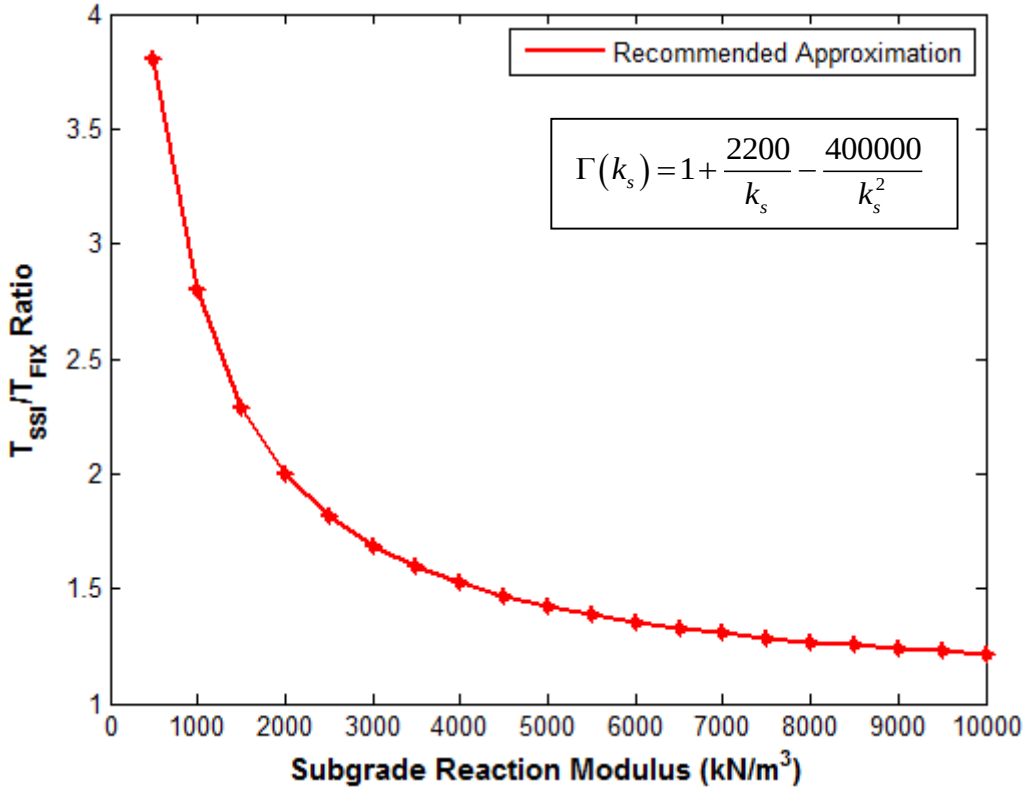

Figure 5 – Approximation for first natural period ratio with respect to subgrade reaction modulus

Thus the first natural period of structure while considering SSI, can be approximated by the relation given below.

$$T_{SSI} = \left(1 + \frac{2200}{k_s} - \frac{400000}{k_s^2}\right).T_{FIX} \tag{7}$$

3 CONCLUSION

In this study effect of subgrade reaction modulus on first natural period of low rise buildings is investigated. By utilizing nonlinear regression a novel approximation is introduced which relates first natural period of buildings determined by neglecting SSI to first natural period determined by not neglecting SSI. Then it can be said that the approximations recommended in prominent seismic codes to determine first natural period of low rise buildings can be modified. The introduced expression may be seen inconsistent since all analysis procedure considers a typical building with typical dimensions. However, the expression can give satisfactory results for low rise buildings, since aim of this study refers to low rise buildings. Nevertheless, further study is going on to introduce novel approximations for buildings with varying dimensions.

A PROBABILISTIC APPROACH TOWARDS AN EVALUATION OF EXISTING CODE PROVISIONS FOR SEISMICALLY ISOLATED STRUCTURES (ECCOMAS CONGRESS 2016)

Anastasios Tsiavos[1], **Bozidar Stojadinovic**[2]

Keywords: Seismic Isolation, Seismic probabilistic risk assessment, Performance-based design, Code provisions, Strength reduction factor

Abstract. *Following modern design codes, seismically isolated superstructures are designed to respond in the elastic response range or to exhibit limited inelastic behavior. However, the behavior of seismically isolated structures when the superstructure enters the inelastic response range has not been extensively investigated in the past. This paper aims at answering the following questions: What is the probability that a (code-compliant) seismically isolated structure will yield? Will it develop a ductility demand μ larger than that implied by its design strength reduction factor?*

The probabilistic investigation of such a behavior is important for two reasons: First, to estimate the conservativism implied by the existing code provisions for seismically isolated structures. Second, to account for the case in which the seismic forces acting on an existing seismically isolated structure could exceed the design forces due to a ground motion stronger than the design ground motion level. The investigation is conducted using a two-degree-of-freedom model of a seismically isolated structure. The hysteretic behavior of the seismic isolation devices and the isolated superstructure is simulated in Matlab and OpenSees using a bilinear elastic-plastic model. The results are obtained by analyzing the responses of the isolated structure to a large number of recorded ground motions.

Fragility curves to estimate the probability that the structure enters the inelastic range ($\mu>1$), if it is designed according to the existing American and European code provisions for seismically isolated structures are determined through probabilistic seismic demand analysis (PSDA). The influence of the isolated structure overstrength and the isolation system hardening is discussed. Additional fragility curves are provided for other values of the engineering demand parameter (EDP) that are not allowed in the existing code provisions (e.g. superstructure displacement ductility $\mu>2$). The effects of seismic isolation and superstructure design parameters on the fragility curves is quantified through parametric analysis.

1 INTRODUCTION

Base isolation is a seismic response modification technology developed in mid 1970's to control the extent of damage to structures subjected to strong ground motion excitation. However, the acceptance of the technology increased significantly after the observed response of seismically isolated structures in 3 earthquakes: The 1994 Northridge earthquake in the USA, the 1995 Hyogoken-Nanbu earthquake in Japan and the 1999 Chi-Chi earthquake in Taiwan. Over this period, the number of seismically isolated structures worldwide increased, and the building codes have been revised to include design requirements for seismically isolated structures [1].

The elastic design approach, which aims to avoid yielding of the isolated superstructure, is embedded in the design codes worldwide. Eurocode [2] allows a maximum behavior factor value of 1.5 for base-isolated buildings. US ASCE 7 [3] allows the strength reduction factor for a base-isolated superstructure to be 0.375 times the one for a corresponding fixed-base structure and no larger than 2. Given that the large majority of ASCE 7 overstrength factors are between 2 and 3, the superstructure is very likely to remain elastic for the design-level seismic hazard. However, it is still possible for these structures to enter the inelastic range due to an extreme seismic demand or unexpectedly low as-built overstrength.

Constantinou and Quarshie [4], Ordonez et al. [5], Kikuchi et al. [6], Thiravechyan et al. [7] and Cardone et al. [8] investigated the response of inelastic seismically isolated structures and agreed that allowing base-isolated superstructures to yield requires careful consideration because of possible occurrence of large ductility demands. Vassiliou et al. [9-11] concluded that designing typical seismically isolated structures to behave elastically, as prescribed by current seismic design codes, is not overly conservative but a necessity that emerges from the fundamental dynamics of such structures.

This study aims at quantifying the probability that an isolated superstructure designed according to the current design codes enters the inelastic behavior range. Additionally, incremental dynamic analysis [12] is performed to determine the behavior of the isolated structure for ground motions caused by events of higher seismic hazard than the design hazard level. Huang et al [13] have presented fragility curves for the estimation of the probability of failure of base-isolated nuclear power plants for a range of spectral acceleration values. Han et al [14] used the damped spectral acceleration at the effective period of the isolators $S_a\ (T_{eff})$ as an intensity measure to determine similar fragility curves for non-ductile reinforce concrete buildings.

Four assumptions are made in the study. First, the displacement and strength capacities of the isolators are assumed to be sufficient to meet any demands. Second, friction-pendulum bearings are assumed, unless explicitly stated otherwise. Third, the overstrength, i.e., the difference between the actual and the yield strength of the isolated superstructure, is not explicitly considered in the model. Fourth, the response of the dynamic model is computed in-plane to an earthquake excitation that has a single horizontal component, disregarding the coupled bi-directional horizontal and vertical response of the isolators as well as the effect of multi-directional excitation on the response of isolated superstructure.

2 DYNAMIC MODELLING

The dynamics of a base-isolated structure, following to the work of Naeim and Kelly [15], is investigated using a two-degree-of-freedom (2-DOF) in-plane model, presented in Fig. 1. The system consisting of the isolation bearings and the isolation base is defined as the isolation system. The structure above the isolation system is defined as the isolated superstructure.

Masses m_s *and* m_b represent the mass of the isolated superstructure and the mass of the base above the isolation system, respectively. The stiffness and damping are denoted as k_s, c_s, when referring to the superstructure and as k_b, c_b when referring to the base. The stiffness k_b is the post-yielding stiffness of the isolators [16], whereas the equivalent stiffness shown in Fig. 1 is the effective stiffness k_{eff} of the isolators.

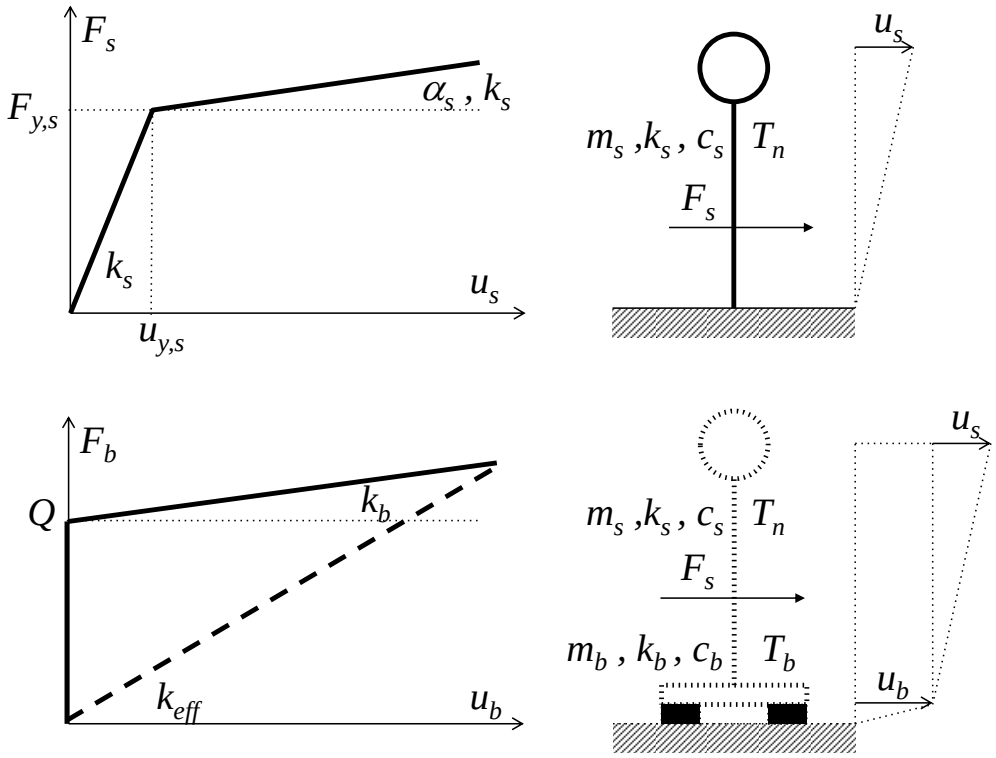

Figure 1: Parameters of the SDOF model of a fixed-base structure and of a 2-DOF model of a base-isolated structure.

Horizontal displacement u_s is the relative displacement of the superstructure with respect to the base and u_b is the horizontal displacement of the isolation bearings with respect to the ground. The ground displacement to which the system is subjected is denoted as u_g. The notation used to describe the inelastic response of fixed-base single-degree-of-freedom (SDOF) structures is adopted as follows. The vibration period of the SDOF system is T_n. The displacement ductility ratio μ is defined as:

$$\mu = \frac{u_m}{u_y} \tag{1}$$

where u_m and u_y denote the maximum inelastic displacement and the yield displacement of the SDOF system, respectively. The strength reduction factor R_y is the ratio of the minimum strength required to maintain the SDOF system response in the elastic range, $F_{el,s}$ to the SDOF system yield strength $F_{y,s}$:

$$R_y = \frac{F_{el,s}}{F_{y,s}} \tag{2}$$

The following quantities are defined for the 2-DOF model of the base-isolated structure:

1. Period and cyclic frequency of the isolated superstructure:

$$T_n = 2\pi\sqrt{\frac{m_s}{k_s}},\ \omega_n = \sqrt{\frac{k_s}{m_s}} \tag{3}$$

2a. Isolation period and cyclic frequency:

$$T_b = 2\pi\sqrt{\frac{m_s + m_b}{k_b}},\ \omega_b = \sqrt{\frac{k_b}{m_s + m_b}} \tag{4}$$

2b. Effective isolation period and cyclic frequency:

$$T_{eff} = 2\pi\sqrt{\frac{m_s + m_b}{k_{eff}}},\ \omega_{eff} = \sqrt{\frac{k_{eff}}{m_s + m_b}} \tag{5}$$

3. Non-hysteretic structural and isolation system damping ratios:

$$\xi_s = \frac{c_s}{2m_s\omega_s}, \qquad \xi_b = \frac{c_b}{2\left(m_s + m_b\right)\omega_b} \tag{6}$$

4. Mass ratio:

$$\gamma_m = \frac{m_s}{m_s + m_b} \tag{7}$$

The strength of the isolation system is defined as Q (force at zero displacement).

Dynamic equilibrium of the isolated superstructure and the base isolation system gives:

$$\left(m_s + m_b\right)\ddot{u}_b + m_s\ddot{u}_s + k_b u_b + Qz_b\left(t\right) + c_b\dot{u}_b\left(t\right) = -\left(m_s + m_b\right)\ddot{u}_g \tag{8}$$

Dynamic equilibrium of the isolated superstructure alone gives:

$$m_s\ddot{u}_s + m_s\ddot{u}_b + a_s k_s u_s(t) + (1-a_s)k_s u_{y,s} z_s(t) + c_s\dot{u}_s(t) = -m_s\ddot{u}_g \tag{9}$$

Consequently, Equations (8) and (9) become equations of motion of the combined structure-isolation system. Equations (10) and (11) are derived by dividing equations (8) and (9) by (m_s+m_b). The inelastic displacement demand for the isolation system and the isolated superstructure can be obtained by solving Equations (10) and (11) using Matlab [17].

$$\ddot{u}_b + \gamma_m\ddot{u}_s + \omega_b{}^2 u_b + \frac{Q}{m_s + m_b} z_b + 2\xi_b\omega_b\dot{u}_b = -\ddot{u}_g \tag{10}$$

$$\ddot{u}_s + \ddot{u}_b + 2\xi_s\omega_n\dot{u}_s(t) + a_s\omega_n^2 u_s(t) + (1-a_s)\omega_n^2 u_{y,s} z_s(t) = -\ddot{u}_g \tag{11}$$

An identical 2-DOF model was developed in OpenSees [18] to compute the inelastic displacement demand of both systems, using bilinear inelastic behavior models as the one shown in Fig. 1 for the superstructure and the isolators. This model gives identical results with the ones obtained using the Bouc-Wen models presented above in Matlab. The calculation process using Bouc-Wen models in Matlab was performed to quantify the fundamental parame-

ters of the problem. However, the results presented on this study are computed with bilinear models (Fig. 1) using OpenSees for reasons of computational efficiency.

3 CODE EVALUATION: DESIGN HAZARD LEVEL

Eurocode 8 [2] allows a maximum strength reduction factor value of 1.5 for base-isolated buildings, thus implying the development of limited inelastic behavior in the isolated superstructure for the design hazard level. A number of recorded ground motions were selected and scaled until its acceleration response spectrum matches the design spectrum, as defined in Eurocode 8 [2]. The 2-DOF structure of Fig. 1 was subjected to the scaled ground motion ensemble. Lognormal probability distributions were fit to the determined displacement ductility demand values of the structure for this ground motion ensemble. The probability that the structure enters the inelastic range, thus exceeding the values implied by the code, is determined through the statistical processing of the recorded ductility values.

3.1 Design of the isolated structure

The structure that has been investigated in this study is the National Opera of Greece, which belongs to the Stavros Niarchos Foundation (SNF) Cultural Center. This structure has been chosen as an example of inelastic design of base-isolated structures, as a strength reduction factor of 1.5 has been used for its seismic design [19]. The design spectrum for the structure (PGA=0.267g) was based on a microzonation study, conducted due to the importance of the project, and is shown in Fig. 2 below. The return period of this spectrum is 475 years, which corresponds to 10% probability of exceedance in any 50 year period.

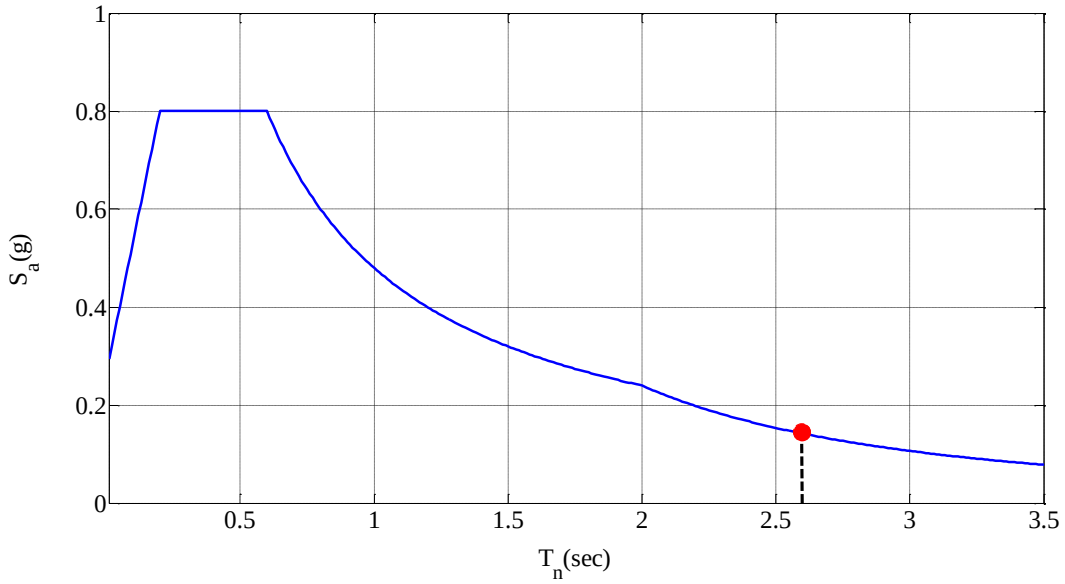

Figure 2: Elastic design acceleration spectrum [19]

The strength of the isolation system is determined using Equation (12) for friction-pendulum bearings with the coefficient of friction μ_f=0.05 (g the acceleration of gravity). The mass ratio is γ_m=0.9.

$$Q = \left(m_s + m_b\right)\mu_f\, g \tag{12}$$

Then, for m_s=120000 tons, Q=58860 kN. The effective period of the isolators is T_{eff}=2.6 sec. The design displacement for the isolators (ξ_{eff}=15%, S_e=0.141g) is D_d=235*1.5=351 mm. Then, the post-yielding stiffness of the isolators k_b=(k_{eff} D_d-Q)/D_d=303922 kN/m, which leads to a period T_b=4 sec. The yield strength of the structure for a behavior factor of q=1.5 is F_y=(m_s+m_b)S_a(T_{eff})/q=165536 kN.

3.2 Ground motion excitation

The ground motion ensemble used to excite the model of the isolated structure presented in Fig. 1 was taken from the strong motion database presented by Vassiliou and Makris [20]. From the 183 ground motions used that study, 20 motions were chosen for this study, using the minimization of the root-mean-squared error (*RMSE*) between the selected motions' acceleration response spectrum and the target design spectrum (Fig. 2), as performed by Carlson et al [21]. *RMSE* is defined as follows:

$$\mathrm{RMSE} = \sqrt{\frac{\sum_{i=1}^{n}\left[\ln\left(\mathrm{Sa}_{\mathrm{tar}}(\mathrm{T_i})\right) - \ln\left(\mathrm{Sa}_{\mathrm{rec}}(\mathrm{T_i})\right)\right]^2}{\mathrm{n}}} \tag{13}$$

where $Sa_{tar}(T_i)$ and $Sa_{rec}(T_i)$ represent the spectral acceleration at the ith period, T_i, for the target spectrum and recorded ground motion acceleration response spectrum, respectively, and n represents the number of spectral points. The median of the selected ground motion ensemble spectra and the target spectrum are shown in Fig. 3.

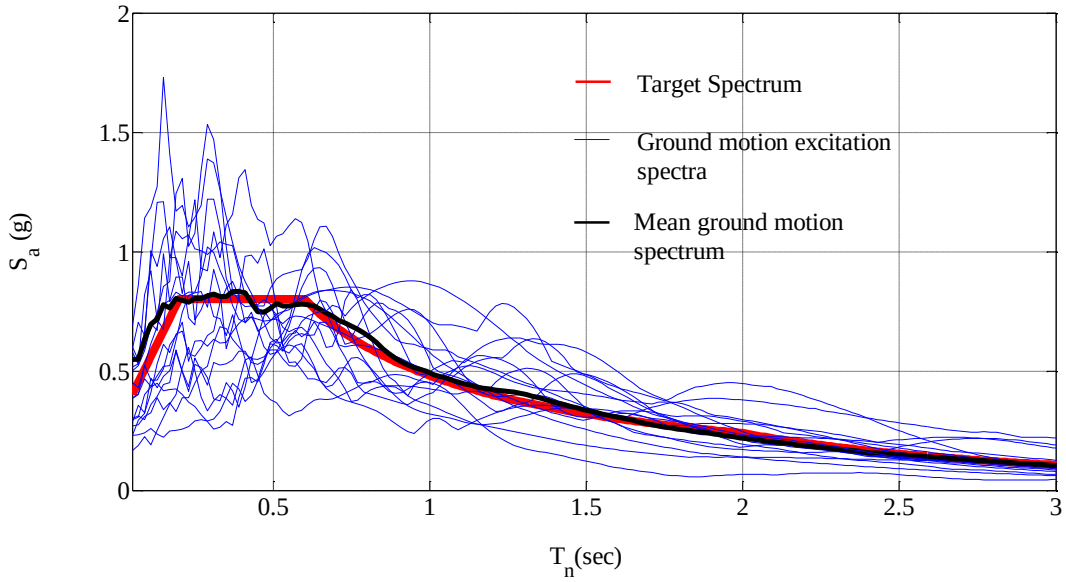

Figure 3: Elastic design acceleration spectrum (Eurocode 8) and median spectrum of the 20 ground motion excitation spectra selected based on their matching with the design spectrum (RMSE factor).

According to EC8, in the range of periods between $0.2T_1$ and $2T_1$, where T_1 is the fundamental period of the structure in the direction where the accelerogram is applied, no value of the mean 5%-damping elastic spectrum, calculated from all time histories, should be less than 90% of the corresponding value of the 5%-damping elastic response spectrum.

3.3 Probabilistic evaluation at the design hazard level

The structure presented at section 3.1 was excited by the ground motion excitation ensemble shown in Fig. 3. The displacement ductility demand developed in the superstructure was calculated for each ground motion excitation and it is shown in Fig. 4. A lognormal probability distribution was fit to the displacement ductility data and is presented in Fig. 4. The probability of exceedance of μ=1 for the given hazard level (Return period: 475 years, Probability of exceedance=10% in 50 years) is given by the PEER probabilistic PBEE evaluation methodology shown in Equation (14) [22, 23]:

$$G(EDP) = \int_0^\infty G(EDP \mid IM) f(IM) dIM \tag{14}$$

where *f(IM)* is the Probability Distribution Function (PDF) of the Intensity Measure *IM* and *G(EDP|IM)* is the Probability Distribution Function (PDF) of the Engineering Demand Parameter *EDP* given the Intensity Measure *IM*. The *EDP* chosen in this study is the displacement ductility μ and the IM is the 5% damped spectral acceleration at the effective period of the isolators S_a (T_{eff}) [14].

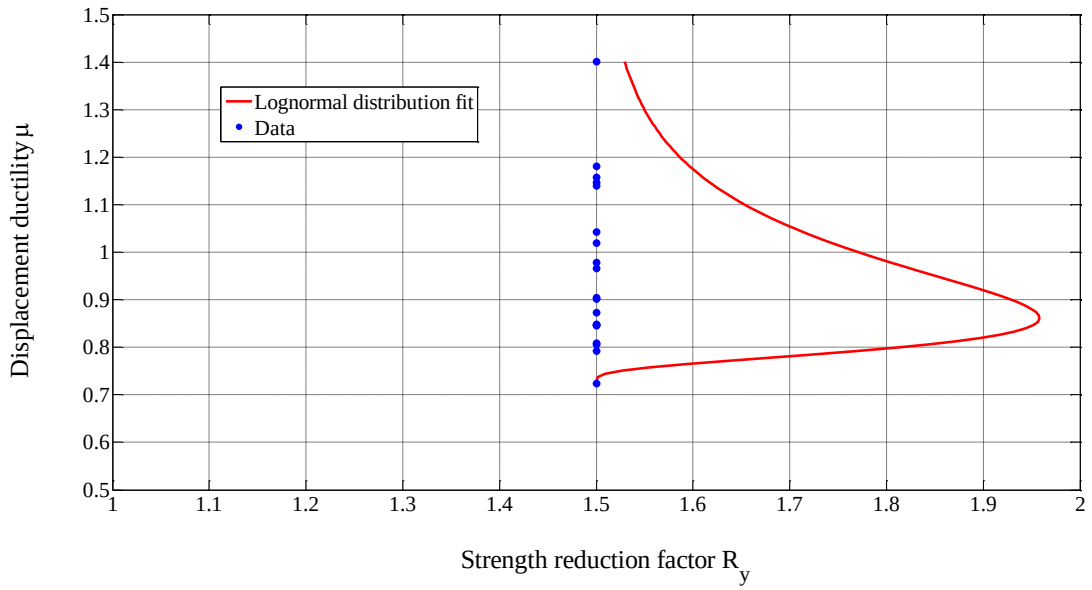

Figure 4: Displacement ductility values μ for Ry=1.5 and lognormal distribution fit

For this lognormal distribution (μ=0, σ=0.17), the probability of exceedance of μ=1 is 50% given the exceedance of the intensity measure S_a (2.59 sec)=0.141 g. The probability of the exceedance of the intensity measure S_a (2.59 sec)=0.141 g is 10% in 50 years, which corresponds to the design hazard return period of 475 years. Then, from Equation (14), the total probability that the displacement ductility μ exceeds 1 is 5%. This probability that is associated with damage in the superstructure is considered relatively high for the importance of this structure. Therefore, the choice of a strength reduction factor R_y=1.5 does not guarantee the quasi-elastic behavior implied by the code for this structure. However, the consideration of overstrength that has not been taken into account in this case study may change this conclusion, as it would reduce the probability of inelastic behavior in the superstructure.

4 CODE EVALUATION: BEYOND DESIGN HAZARD LEVEL

4.1 Incremental Dynamic Analysis

The evaluation of the existing code provisions for isolated structures for seismic hazard levels that are higher than the design hazard level requires the statistical processing of the dynamic response of the structure to a large number of strong ground motion excitations. This process can be effectively performed for the targeted hazard levels using Incremental Dynamic Analysis (IDA) [12]. The incremental analysis was performed for the fixed-base period of the isolated superstructure T_n=0.31 sec. The results of the analysis for a wide range of intensity measures S_a (T_{eff}) are shown in Fig. 5.

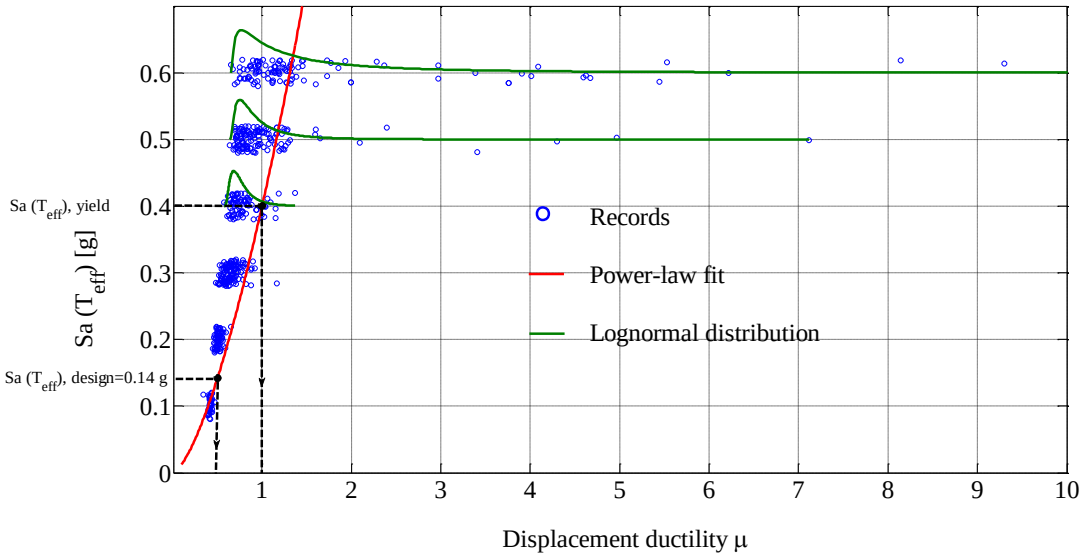

Figure 5: Displacement ductility values μ for different values of spectral acceleration $S_a(T_{eff})$, power-law fit to the presented displacement ductility values and lognormal distribution fit for each spectral acceleration $S_a(T_{eff})$

The $S_a(T_{eff})$ values presented are selected from the set {0.1g, 0.2g, 0.3g, 0.4g, 0.5g, 0.6g} within a 5% tolerance range. A power-law fit was performed to indicate the general trend of the displacement ductility μ results for varying $S_a(T_{eff})$ values. Lognormal probability distributions were fit to displacement ductility μ data for each spectral acceleration value $S_a(T_{eff})$ above the yield limit $S_a(T_{eff}),_{yield}$. According to the results of the power-law fit, the design acceleration of the structure corresponds to a displacement ductility μ=0.5. The yield spectral acceleration value, which corresponds to displacement ductility μ=1 is $S_a(T_{eff}),_{yield}$=0.4 g. This spectral acceleration, which can lead to damage in the superstructure, exceeds the design value by a factor of 3. If higher $S_a(T_{eff})$ values than this value are considered (e.g. $S_a(T_{eff})$=0.5 g or $S_a(T_{eff})$=0.6 g), extensive damage may occur in the superstructure, as the corresponding ductility demand values may exceed μ=7.

This exceedance of the design spectrum even by a factor as high as 3 over a large range of periods has been reported in numerous seismic events (Mexico City 1985, Kobe 1995, Nepal 2015) in the past. A large number of ground motions recorded on "soft" soils have produced response spectra of a sharp rather than flat shape, with well-defined peaks around the site fundamental period, as presented by Gazetas et al [24]. Thus, such high demands on isolated structures cannot be excluded from consideration.

5 CONCLUSIONS

- Two different ground motion selection procedures have been used in this study to evaluate the inelastic behavior of the National Opera of Greece for different seismic hazard levels.
- The results obtained through a spectral matching procedure based on the RMSE factor [21] indicate a 5% probability of inelastic behavior and associated damage in the superstructure for the design seismic hazard level (return period of 475 years).
- However, the results obtained through IDA [12] show that the design spectrum must be exceeded 3 times for a development of inelastic behavior in the superstructure. This scaling process was performed for selected values of spectral acceleration $S_a(T_{eff})$, which restricts the ground motion variability, compared to the spectral matching procedure that was used for the design hazard level evaluation.
- The overstrength of the superstructure was not considered in this study. The consideration of overstrength is expected to reduce the probability of inelastic behavior in the superstructure.

Keywords: pounding, non-linear analysis, three-dimensions, adjacent structures.

Abstract. *In the last decades, a number of reconnaissance reports have revealed that pounding between adjacent buildings, during strong earthquakes, may induce local and in some extreme cases severe structural damage. The problem of earthquake-induced pounding of adjacent buildings has been the subject of great scientific interest, while several recent numerical studies have quantified the effects of seismic pounding of buildings, with the majority of researchers simulating the problem in two dimensions (2D). The results from the various 2D parametric studies have demonstrated the potentially detrimental effects of pounding on the dynamic response of multistory buildings and revealed the importance of this problem regarding the safety and functionality of colliding structures. Furthermore, most of the numerical studies have been limited to the utilization of linear elastic structural models to simulate the adjacent buildings. The current study parametrically investigates the effect of pounding on the inelastic response of base isolated structures, which are simulated as non-linear 3D multi-degree of freedom systems subjected to bidirectional earthquake excitations. Specifically, the influence of certain parameters, such as the angle of the seismic incidence, the width of the seismic gap, characteristics of the isolation system and the configuration of the adjacent structures on the peak response, is parametrically examined, for various near-fault excitations. All numerical simulations are performed using a specially developed software that implements an innovative, simple and efficient approach to model impacts in 3D, taking into account the arbitrary location of contact points and the geometry at the vicinity of impact.*

1 INTRODUCTION

Frequently, neighboring buildings are constructed very close to each other, sometimes without any clearance between them. Hence, structural poundings may inadvertently occur between adjacent buildings, due to deformations of their stories, during strong seismic excitations. Consequences of such pounding incidences, ranging from local light damage to severe structural damage or even collapse, have been observed and reported after severe earthquakes. Poundings may also occur even in cases of seismically isolated buildings when the width of the available seismic gap around them is relatively limited, due to the large horizontal relative displacements that are expected at the isolation level, especially during near-fault, pulse-like ground motions.

Although several research studies have been conducted in order to investigate the problem of earthquake-induced poundings of adjacent structures and its consequences, most of them have been limited to simplified planar (2D) analyses [1–6], apparently due to the involved complexities and the consequently excessive computational cost. However, the effect of crucial factors, such as the consideration of both orthogonal seismic components, friction phenomena that occur during pounding, non eccentric impacts, irregularities, or asymmetries in the plan view of the colliding structures, which may excite the torsional vibration of a building and further increase the possibility of impacts during earthquakes, are essential parameters that can be taken into account only through three-dimensional (3D) simulations.

Recently, some researchers have shown great interest on the exploration of the effects of earthquake induced pounding of seismically isolated structures using 3D nonlinear dynamic analyses [7–12]. More specifically, Matsagar and Jangid, 2010 [7] investigated the seismic response of a single-story asymmetric structure supported on various base isolation systems during impact with adjacent structures. The effects of impact were found to be severe for systems with flexible superstructure, stiffer adjacent structures and increased eccentricities. Pant and Wijeyewickrema, 2014 [11] used a three-dimensional finite element model in order to investigate the seismic performance of a four-story building under bidirectional far-fault non-pulse-like and near-fault pulse-like ground motions scaled to represent two levels of shaking. Seismic pounding of the building with the retaining walls at its base was simulated using a specially developed purpose contact element that accounts for friction. Polycarpou *et al.*, 2015 [13] considered a new methodology for simulating earthquake induced pounding of seismically isolated buildings that are modeled as 3D multi-degree-of-freedom (MDOF) systems. An example of a 3-story seismically isolated building, pounding against the surrounding moat wall, has been presented to demonstrate the advantages of the proposed methodology.

The current study, utilizing the methodology described in [13, 14], aims to thoroughly investigate the circumstances under which spatial poundings may occur and assess the effect of some important parameters on the peak structural response considering pounding incidences. Nonlinear time-history analyses are carried out considering the arbitrary direction of the ground motion with respect to the structural axes of the simulated structures. The influence of the isolator's characteristics, the superstructure stiffness and the separation distance between the building and the retaining walls at its base is also investigated, while considering different geometrical arrangements for the moat walls.

2 MODEL FOR SIMULATION OF SEISMIC POUNDING

The numerical simulation of 3D pounding enables the investigation of certain parameters that are associated with the spatial movement of the seismically isolated building and cannot be explored through planar dynamic analyses. The effects of seismic pounding on the response of base-isolated reinforced concrete buildings under bidirectional excitations are

hereby investigated. A 3D model of a base isolated building is considered, where a recently proposed methodology [13, 14], which takes into account the arbitrary location of impacts and the geometry at the point of impact, is used. In particular, a new approach to the numerical problem of spatial impact modeling that does not require the a priori determination of the contact points was presented, taking also into account the geometries of the colliding structures at the vicinity of an impact.

More specifically, the simulated base isolated buildings are modeled as 3D-MDOF systems with shear-type behavior for their superstructures in the horizontal directions. The slab at each floor level of the superstructure is represented by a rigid diaphragm that is mathematically simulated as a convex polygon, while the masses are considered to be lumped at the floor levels, having three dynamic degrees of freedom (DOFs), i.e. two translational, parallel to the horizontal global axes, and one rotational along the vertical axis. Thus, considering ground excitations only in the horizontal directions, which is the most important case, no displacements occur in the vertical direction, since the translational dynamic DOFs of the structure refer only to horizontal planes. Consequently, it is assumed that the impact forces occur only in horizontal planes.

The time-history analysis involves the numerical integration of the differential equations of motion at each time step and the calculation of the resulting displacements, velocities and absolute accelerations at each DOF of each building. Based on the deformed position of each floor diaphragm in the 3D space, an automatic contact detection check is performed to identify potential contacts between structures, which are subsequently used for the computation of appropriate impact forces to be applied at the corresponding DOFs.

The majority of the force-based impact models that are available in the scientific literature calculate the impact force as a function of the interpenetration depth between the colliding bodies. However, the usage of the interpenetration depth as the key variable constitutes a significant drawback in the case of 3D impact modelling, as it cannot correctly assess the proper values of the impact forces. Therefore, in the proposed methodology, the area of the overlapping region, instead of the interpenetration depth, is used as the key variable in the calculation of the impact forces. Figure 1 describes, schematically, how the proposed impact model works. In particular, when two slabs, which are modelled as polygons, come in contact, they form an overlapping region that is either a triangle or a quadrilateral. The algorithm uses the geometry of the overlapping area at each time step in order to determine the location of the action point of the impact forces, as well as the direction and the magnitude of the impact forces. The Coulomb law of friction restricts the magnitude of the tangential impact force below a certain value.

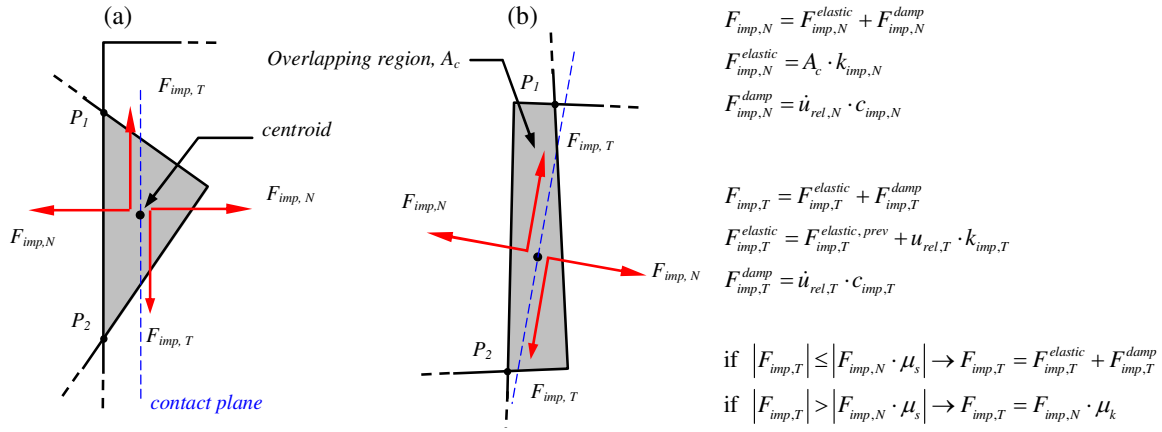

Figure 1: Schematic representation of the contact plane, based on the geometry of the indentation region, which can be either (a) a triangle, or (b) a quadrilateral.

3 DATA ANALYSIS

A three-storey (three-bay by three-bay), base-isolated reinforced concrete moment-frame building is chosen as a typical model structure (Figure 2). The building is symmetric with coinciding centers of mass and stiffness. The retaining walls extend from the ground level up to the base level of the building. All column sections of the simulated building have square dimensions of 45 x 45 cm^2. The bay width of the building in both directions is 5.5 m while each storey height is 3.2 m. The elastic modulus of concrete is assumed to be 30 GPa with a Poisson's ratio of 0.2. A uniformly distributed mass of 250 tons is considered for the roof mass, while a 340 tons floor mass is assumed at each other floor level, including the base of the building. For the determination of the Rayleigh damping matrix, the viscous damping ratios for the first and the fourth eigenfrequencies are taken as 0.05 and 0.02, respectively. Due to symmetry, the first two eigenmodes are translational along the two horizontal axes. The fundamental eigenperiods of the corresponding conventionally fixed-supported building are: $T_{x,fixed} = T_{y,fixed} = 0.311\sec$.

A coupled plasticity model is used for simulating the bidirectional lateral response of the seismic isolators. The aforementioned model is based on the hysteretic behavior proposed by Wen, 1976 [15] and Park *et al.*, 1986 [16] and recommended by Nagarajaiah *et al.*, 1991 [17]. Here, for each bearing element an isolation period based on the post-yield stiffness of 2.0 seconds, a yield displacement equal to 1.0 cm and a normalized characteristic strength $F_{xi}^{x}/W = F_{yi}^{y}/W$ equal to 0.05 or 0.10 are considered.

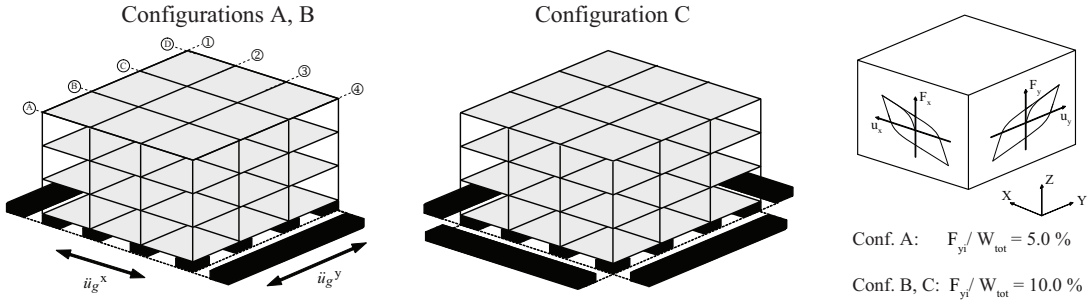

Figure 2: Configurations considered in the present study.

Impacts occur at the isolation level when the clearance from the surrounding moat wall, i.e. the seismic gap, is exceeded, during very strong seismic excitations. Nevertheless, the methodology provides the ability of considering impacts at all floor levels of the seismically isolated building in case of pounding with other adjacent buildings. The moat wall is modeled as a single-mass system, with three dynamic DOF, as in the case of a single-storey structure. The moat wall is taken to be 100 cm thick and 100 cm high, resulting in a substantially stiff barrier, while it's mass is assumed to be 5 tons/m, a number that takes into account the contribution of the backfill soil. The normal impact stiffness is $k_{imp,N}=2.58\times10^7$ kN/m^2, while the corresponding tangential impact stiffness is $k_{imp,T}=5.74\times10^6$ kN/m. The static and kinetic friction coefficients are taken as $\mu_s = 0.8$ and $\mu_k = 0.6$, respectively.

A set of earthquake ground motions has been selected from the Pacific Earthquake Engineering Research Center database. The selected seismic accelerograms (Table 1) are expected to induce large relative displacements to the seismically isolated building, since they are characterized by low-frequency contents, which is one of the most decisive factors for the occurrence of pounding in such structures. The response spectra of the five earthquakes' fault-

normal (FN) and fault-parallel (FP) components that have been used in this study are plotted in Figure 3.

4 INFLUENCING FACTORS IN 3D SIMULATIONS

The effect of the angle of incidence, on the peak structural response of the previously described 3-storey base isolated building, is presented in this section. The simulated structures are subjected, simultaneously, to two orthogonal, horizontal seismic excitations of their supporting ground. By rotating each of the 5 seismic record pairs, as presented in Table 1, from 0° to 180°, with respect to the system's principle axes of construction, with a 5° interval in the clockwise direction, one can consider 37 alternative excitation cases. In order to identify potential differences in the response of a 3-storey building due to the angle of incidence of the ground motion, the half polar plots of peak interstorey drifts are plotted in Figure 3, considering the Loma Prieta and the Northridge earthquakes. Specifically, the peak responses are presented for different characteristics of the seismic isolation system in Figure 4(a) and (b), for both seismic excitations. It is observed that the interstorey drifts tend to decrease with an increase in the normalized characteristic strength of the isolation system, Figure 4(b).

The simulation results indicate that the maximum responses occur at different angles. The critical angle in the longitudinal (*E-W* or *X*) direction is not always at 0 and 90 degrees, but occurs in incidental angles that are quite different for each excitation. In the case of seismically isolated buildings, the maximum relative displacements at the isolation level in the *X*-direction can vary by a factor of 3.9 and 1.4 over the possible angles of interest, for the Loma Prieta and the Northridge earthquakes, respectively. This is considered to be a significant variation. For both excitations, the critical excitation angle for the interstorey deflections is nearly common among all floors. The maximum floor relative displacement in the *X*- direction occurs at the complimentary angle of the maximum interstorey drift in the *Y*- direction. Although, the peak interstorey drifts in each direction depend highly on the incidence angle, the vector sum of the responses (i.e. the vectorial summation of the peak responses in the Cartesian Coordinates X and Y) slightly varies for different angles. As the peak responses of the X and Y components occur at different time intervals, although their vectorial summation does not have a physically meaning nevertheless it provides a conservative upper bound limit that can be used for design purposes.

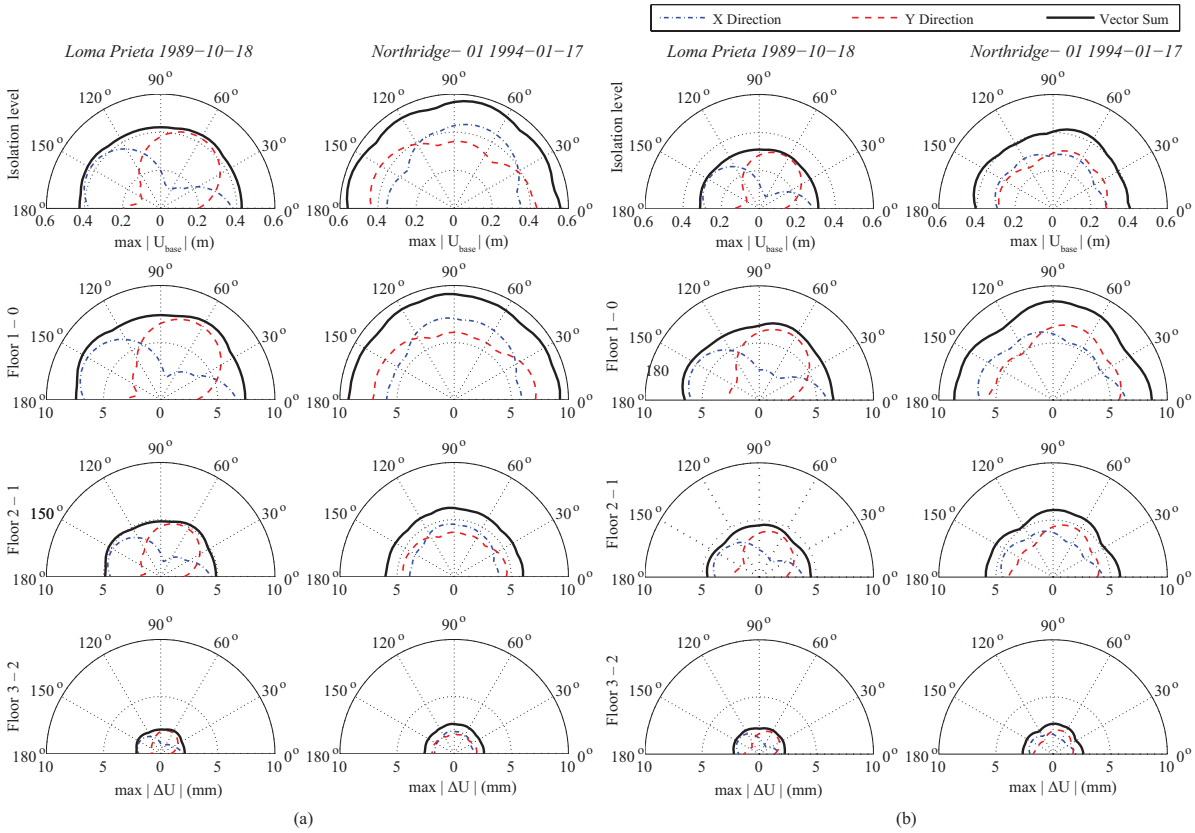

Figure 4: Peak responses of the buildings' corner column A_1 as a function of the angle of incidence considering the no pounding" case, for seismic isolation systems with T_b = 2.0 sec, u_y = 1.0 cm, F_{yi}/W_{tot} equal to (a) 0.05 and (b) 0.10; in both directions.

4.1 Isolator characteristics and configuration

Peak absolute values of the base drifts and the envelope of interstory deflections of the column A_1, are shown in Figures 5 and 6 for various angles of seismic incidence. For the analyses, both FN/FP components of the five selected near-fault ground motions are simultaneously used. The seismic gap is assumed to be 20 cm for the four of the selected exci-

tations and 10 cm for the remaining (Chi-Chi- Taiwan-03) ground motion. Three configurations are considered (Figure 2), as follow:

Conf. A: Base-isolated building with retaining walls in two sides (*E-W* direction)
LRBs: $T_b^x = T_b^y = 2.0$ sec, $u_y^x = u_y^y = 1.0$ cm, $F_{yi}^x / W = F_{yi}^y / W = 5.0\%$

Conf. B: Base-isolated building with retaining walls in two sides (*E-W* direction)
LRBs: $T_b^x = T_b^y = 2.0$ sec, $u_y^x = u_y^y = 1.0$ cm, $F_{yi}^x / W = F_{yi}^y / W = 10.0\%$

Conf. C: Base-isolated building with retaining walls in all four sides
LRBs: $T_b^x = T_b^y = 2.0$ sec, $u_y^x = u_y^y = 1.0$ cm, $F_{yi}^x / W = F_{yi}^y / W = 10.0\%$

In this section, the response of the base-isolated building in each configuration is discussed. The results for the "no pounding" case are presented in Figure 5, and, for comparison purposes, the restricted base drifts of the corner column are also plotted for each excitation in terms of the excitation angle. The variation of the unobstructed base drifts indicate that the value of the incidence angles depends on the characteristics of the earthquakes, in combination with the characteristics of the isolation system. The critical excitation angle of a certain response quantity differs among the various earthquakes.

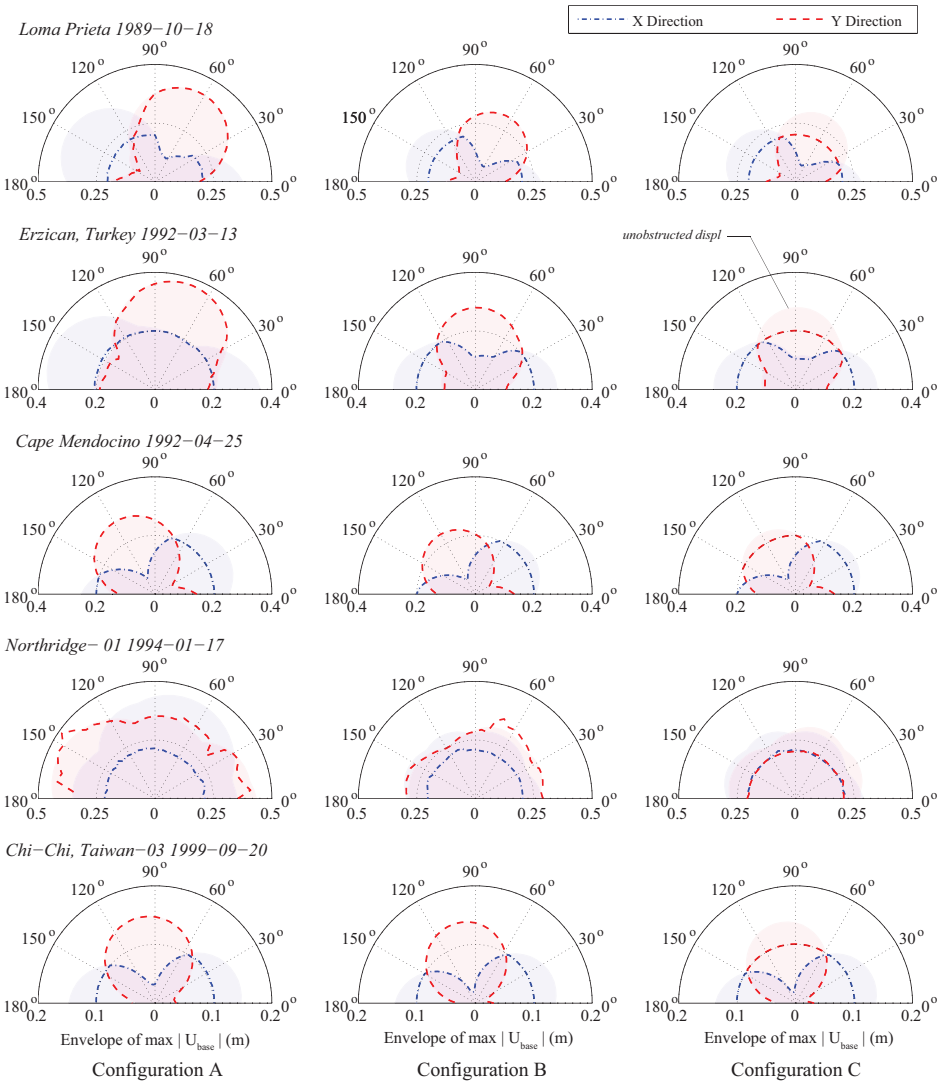

Figure 5: Half-polar plots of maximum unobstructed and restricted relative displacements at the isolation level of the buildings' corner columns in terms of the excitation angle for different configurations.

The peak responses of the superstructure of the base isolated building considering different configurations and the corresponding fixed-supported building without pounding are presented in Figure 6. It becomes evident from the computed results, that the direction of the seismic excitation affects substantially the maximum response of the seismically isolated building, especially during pounding with the surrounding moat walls. The increase in drift demands due to pounding in Configuration B is less compared to Configuration A for all examined ground motions (second and third columns of Figure 6). This is mainly because the available gap size is more restricted in the first case compared to the corresponding maximum unobstructed displacement of the base isolated building, as illustrated in the first two columns of Figure 5.

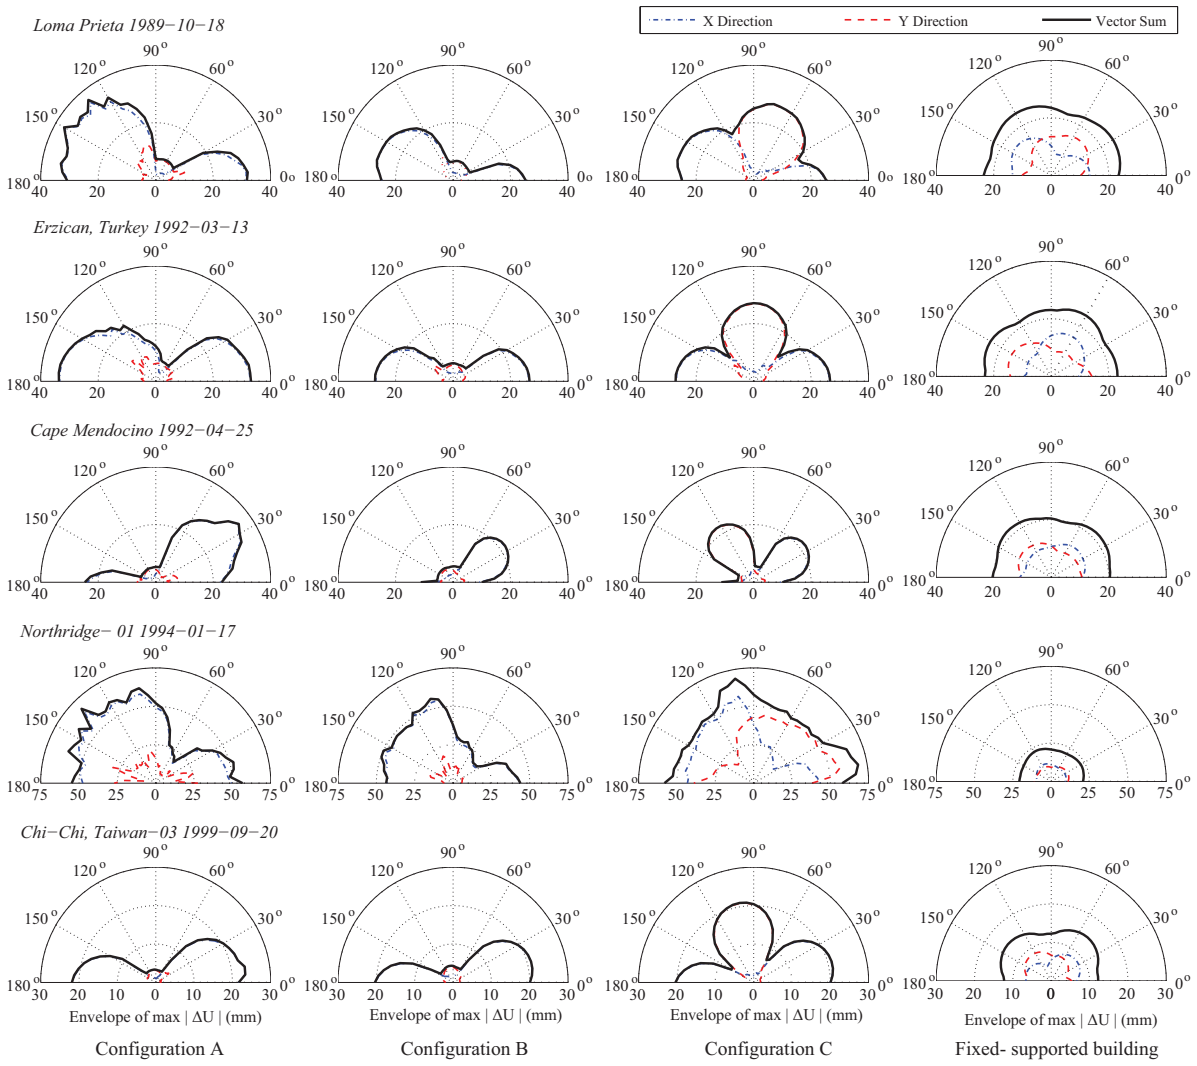

Figure 6: Envelope of peak interstorey drifts of the buildings' corner column A_1 in terms of the excitation angle, considering the pounding case with the moat wall for various configurations; under five near-fault ground motions, and the no pounding case of a conventionally fixed-supported building.

For the configurations A and B, due to poundings with the moat walls at the *X*-direction, if we consider 360°, due to the rotational symmetry of the 180° plots, the plots of the peak responses would resemble 8-shapes, exhibiting a pronounced dependence of the peak response on the incidence angle. Furthermore, the change in the response–angle relationship due to pounding is not so obvious in the *Y*-direction, since impacts occur only in the *X*-direction. For

the Configuration C, the peak response depends on the incidence angle, and the maximum interstorey drifts tend to exhibit two maxima in orthogonal directions. Furthermore, although the retaining walls are placed on each of the four sides of the building, four of the excitations resulted in one-direction impact for a range of excitation angles leading to a petal-like shape response, with two-orthogonal axes of symmetry. For example, for the Loma Prieta excitations, considering an incidence angle, $\theta \approx 30\text{-}100^\circ$, impacts occur only in the *Y*-direction.

The maximum interstorey drift over all examined orientations seems to be polarized in the direction in which the peak base displacement is observed; this polarization is almost perfect for this symmetric-plan building. The value of the maximum inter-storey drift ratio, due to the Northridge earthquake, indicates potential collapse of the first storey. Drift demands due to other earthquakes are significantly lower for all the cases that have been examined. As already discussed, the influence of poundings in the response of the base isolated building can be much less detrimental when isolators with normalized characteristic strength equal to 0.10 are incorporated, however the peak interstorey drifts due to impacts can become higher than those for the corresponding fixed-supported building (as shown in the last column of Figure 6).

4.2 Available gap size

In order to examine the effect of the seismic gap size on the response of the seismically isolated building during pounding with the moat wall, two of the aforementioned configurations are considered. The structural characteristics of the base isolated buildings, as well as the isolation characteristics are kept the same. The width of the seismic gap varies from 15 to 35 cm, with a step of 2.5 cm. Figures 7 (a) and (b) show the relationship among peak interstorey drifts of the 3-storey seismically building, the incidence angle and the width of the available seismic gap of the adjacent walls located in the *E-W* direction under the bidirectional excitation of the Loma Prieta and the Northridge earthquakes, respectively. Similarly organized results are presented in Figure 8, considering impacts with the surroundings walls located around all four sides of the simulated building.

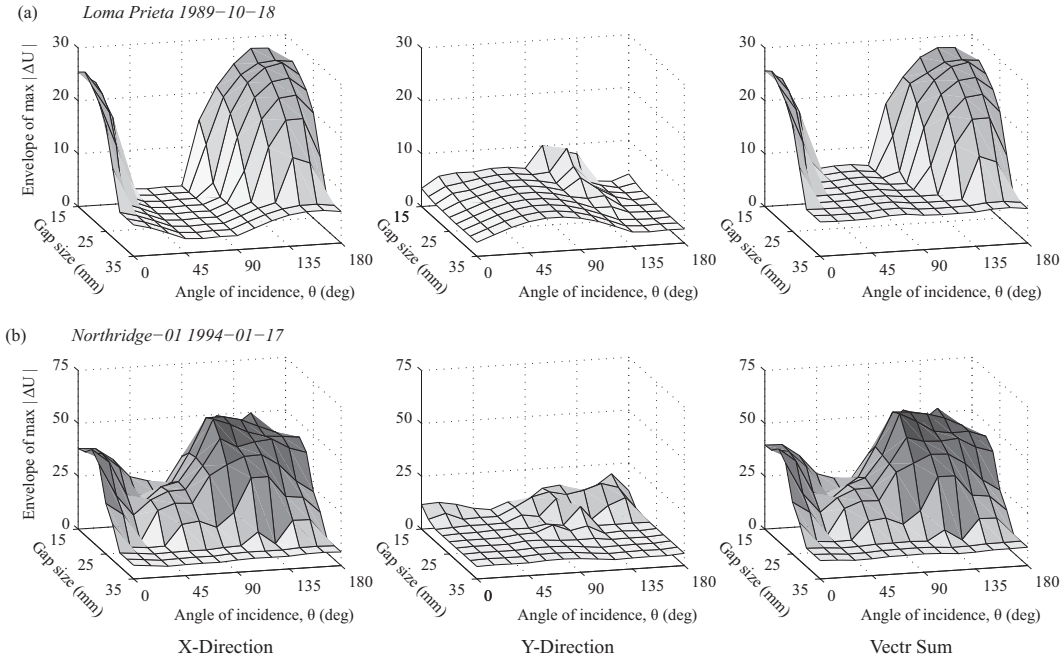

Figure 7: Envelope of the interstory deflections in the X and Y directions, as well as vector sum for different combinations of the excitation angle and the available gap size, considering adjacent walls in the two sides of the building (Conf. B) for (a) the Loma Prieta, and (b) the Northridge excitations.

It becomes evident from the plots, that the angle for which the maximum response is observed is not the same for the two earthquakes that are considered, while the degree by which pounding affects the peak response seems to depend on the ground motion characteristics and the available gap size. The influence of the excitation angle is more pronounced in the case of pounding in one direction, as shown in Figure 7. Furthermore, it is important to mention that although no pounding occurs in the *Y*-direction the deflections of the column A_1 in the Y direction are also considerably affected from pounding in cases with more restricted gap in the *E-W* direction. In general, the vector sum of the superstructure' drifts increases when the separation distance between structures decreases and, then, slightly decreases with further reduction in the separation. It is noteworthy that the interstorey drifts in the X and Y directions, as shown in the first two columns of Figure 8, respectively, present translational symmetry. Furthermore, translational symmetry seems to appear to the vector sum of interstorey drifts due to the bilateral symmetry of the building and the adjacent structures.

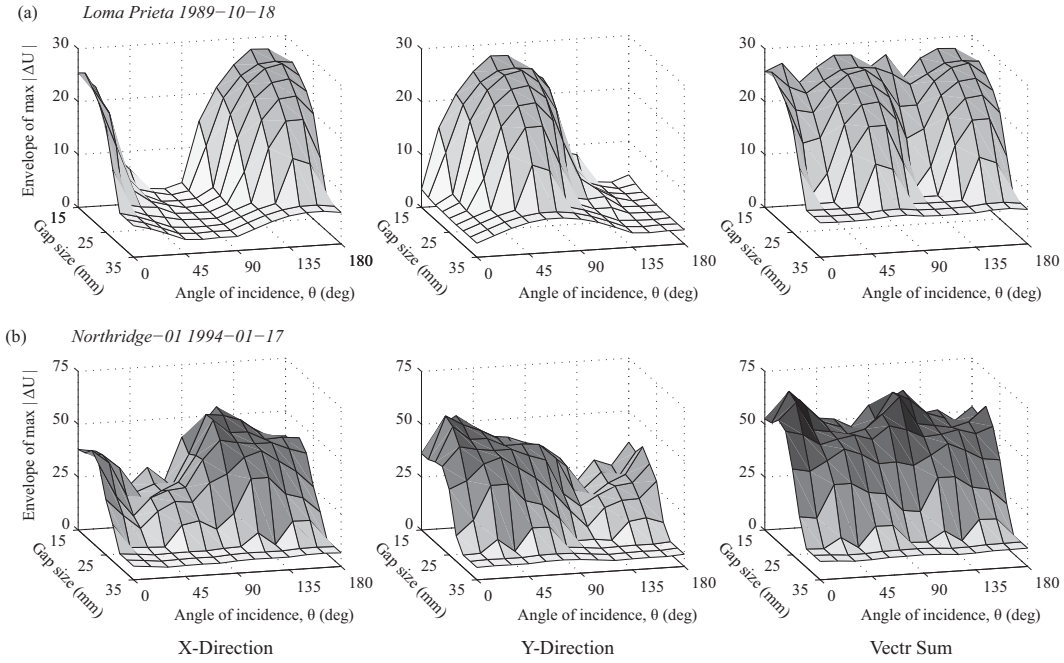

Figure 8: Envelope of the story drifts for various excitation angles and gap sizes for Configuration C under near fault ground motions.

4.3 Stiffness of the superstructure

In order to study the effects of the superstructure's flexibility on the overall dynamic response, the peak interstorey drifts are obtained for different fundamental eigenperiods of the superstructure of the examined three-storey isolated building with impact conditions under the Loma Prieta and Northridge earthquakes, as shown in Figure 9. Different superstructure's stiffnesses are obtained considering different cross sections of the columns. The isolation system considered consists of lead-rubber bearings (LRBs) with normalized characteristic strength $F_{yi}^{x}/W = F_{yi}^{y}/W$ of 0.10 in both directions, with isolation gap distances of 20 cm around all four sides of the structure. It should be noted that the results presented in Figure 9(b) refer to the peak response of the previous section described in Configuration C.

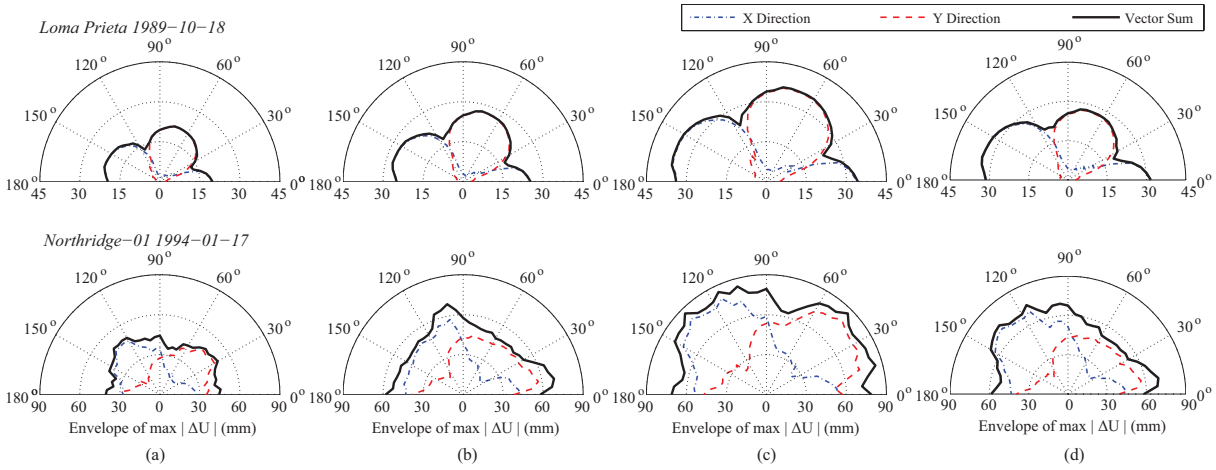

Figure 9: Envelope of peak interstorey deflections of the buildings corner columns in terms of the excitation angle considering superstructure stiffness: $T_{x,\,fixed} = T_{y,\,fixed}$ equal to (a) 0.25 sec, (b) 0.311 sec, (c) 0.394 sec, and (d) $T_{x,\,fixed} = 0.372$ sec, $T_{y,\,fixed} = 0.312$ sec.

These figures show that the superstructure's deflections undergo an increase when the fundamental eigenperiod of the corresponding superstructure increases. This implies that the behavior of the base isolated building during impact becomes adverse while increasing the flexibility of the superstructure. Furthermore, the stiffness of the superstructure does not seem to influence the excitation angle that dominates the response. It is possible to identify a clear pattern in the response of the structure. For structures with equal horizontal stiffness along the two axes of symmetry X and Y, where $T_{x,\,fixed} = T_{y,\,fixed}$, the response shows two separate peaks for the Loma Prieta excitation, one associated with $\theta = 75°$ and the second around $\theta = 165°$, leading to a petal-like shape with double symmetry. For the structures with unequal eigenperiod, instead, the peak tends to be in a single direction, and the plots assume a shape with unequal "petal" length. Furthermore, there is a similar response of the interstorey deflections in *Y*-direction in Figure 9(b) and (d), for both excitations, which relates to the almost identical superstructure stiffness in Y-direction.

5 CONCLUSIONS

The present study demonstrates the importance of implementing an efficient methodology with simple structural and impact modelling in three dimensions, in order to investigate the seismic pounding on the response of MDOF systems. Seismic response of a 3-storey base isolated building during impact with an adjacent moat wall is investigated. The comparative performance of different isolation systems during various impact conditions is studied under five near-fault ground motions. Parametric studies for simulating earthquake induced pounding of seismically isolated buildings are conducted in three-dimensions to observe the influence of the incidence angle, the width of the seismic gap and the flexibility of the superstructure on the peak response of the base isolated building. From the trend of the results presented hereby, the following conclusions are drawn:

- The deflection of the superstructure of a base-isolated building increases significantly when impact with a moat wall takes place during an earthquake. The bearing displacement is consequently reduced.
- The detrimental effects of pounding may become more severe for certain values of the excitation angle. The incidence angle, in which the amplification of the superstructure response due to pounding with the adjacent building obtains its maximum value, generally coincides with the angle in which the peak base displacement occurs.

- In general, the degree by which the incidence angle affects the interstory deflections seems to be significantly affected by the surrounding wall arrangement.
- The normalized characteristic strength of the isolators has significant influence on the peak response of a base-isolated structure during impact. This can be justified considering that with an increase of the F_{yi}/W_{tot} ratio, the relative displacements at the isolation level decrease substantially, in combination to the influence of the width of the available seismic gap compared to the corresponding maximum unobstructed displacements under those excitations.
- As the seismic gap between the base-isolated building and the adjacent wall decreases, there is an increase in the deflections of the superstructure up to a certain value of the gap distance and, then, onwards the deflections of superstructure decrease.
- Increased flexibility of the superstructure increases significantly the drifts of the superstructure during impact with the adjacent structure.

NUMERICAL NON-LINEAR SIMULATION OF THE IN-PLANE BEHAVIOUR OF R/C FRAMES WITH MASONRY INFILLS UNDER SEISMIC-TYPE LOADING

Keywords: Numerical simulation, Masonry-infilled R/C frames, Shear failure of columns.

Abstract. *A non-linear 2-D numerical simulation is presented that can capture the in-plane hysteretic behaviour of reinforced concrete (R/C) frames with masonry infills when they are subjected to combined vertical and cyclic seismic type horizontal loads. The effectiveness of this simulation was validated extensively in the past by comparing numerical predictions with results from a series of pseudo-dynamic tests whereby a number of 1:3 scale, one-bay, one-storey R/C frame specimens, including relatively weak masonry infills, were subjected to combined vertical and cyclic horizontal seismic-type loads under controlled laboratory conditions. The numerical modelling of the surrounding R/C frame included its flexural non-linear behaviour by simulating the development of plastic hinges either at the two ends of the R/C beam and/or at the top and toe of the R/C columns. All geometric and mechanical characteristics of the concrete and the longitudinal reinforcement of the R/C cross-sections were considered in detail. Sufficient shear reinforcement was assumed for both R/C beam and columns capable of prohibiting shear mode of failure. However, observations of failure modes for R/C infilled frames with columns under-designed in shear have shown that, when subjected to earthquake loads, the development of shear failure for the columns is an additional realistic scenario. The first part of the work presented here is investigating such an interaction of masonry infill with the R/C frame simulating both flexural and shear modes of failure for the R/C columns. This numerical simulation retains the non-linear behaviour of the masonry infill itself as well as the non-linear behaviour at the contact area where the masonry-infill and the surrounding frame. The second part of the present work examines the influence of the foundation deformability for such multi-storey infilled frames having an increased in-plane stiffness due to the presence of the masonry infills.*

1 INTRODUCTION

An extensive experimental and numerical study ([3], [4], [5] ,[6], [7]) was carried out at the laboratory of Strength of Materials and Structures, Aristotle University, in order to examine the in-plane seismic behaviour of infilled R/C frames. This study as well as previous studies ([1], [2]) demonstrated that the stiffness and strength of the masonry infilled, single-storey, R/C frames can be affected by various non-linear mechanisms such as:

a) The non-linear behaviour of the R/C frame including flexural limit state (plastic hinges) and shear limit state.

b) The non-linear mechanisms that develop at the interface between the R/C frame and the masonry infill.

c) The level of non-linear deformations that develop within the masonry infill itself.

In all these cases it was reported that the frames developed plastic hinges at their R/C beam and columns. All these have been simulated successfully, as is shown in section 2. In addition, it is also demonstrated that through a certain modification to this numerical approach proposed by Soulis [1] the shear limit state of the R/C columns at predefined locations can also be simulated. In order to validate this proposed modification the experimental study conducted by Sariyiannis is utilized [8]. He subjected a number of one-storey one-bay 1/3 scaled infilled frames to axial forces at the columns as well as horizontal seismic type cyclic forces at the level of the beam. Nine repaired infilled frames and two repaired bare frames were examined in this study. These specimens were produced by repairing damaged 1/3 scaled R/C infilled frames tested previously by Stylianides [3]. These original virgin frames had a non-reinforced brick-masonry infill panel which was simply connected to the surrounding R/C frame by a continuous mortar joint. After this initial test sequence was completed the damaged frames were repaired in order to be tested again [8]. As expected, the type of failure of the columns depended on the type of failure of the masonry infills. In a number of specimens tested by Sariyiannis [8] shear sliding of the infill along a horizontal mid-height mortar joint or corner crushing of the masonry infill was accompanied by the shear failure of the R/C columns. Two of these masonry infilled frame specimens, namely F1NR and F8NR [8], failed as a result of corner crushing of the infill and shear failure of the column. The masonry infilled frame F8NR is employed in the current paper in an effort to validate the proposed modified numerical simulation of masonry infilled R/C frame that can also realistically simulate this shear type of failure.

Stavridis [9], also carried out an experimental program of quasi-static tests with single-bay, single-storey, masonry-infilled, non-ductile RC frames, which were scaled sub-assemblages of a prototype structure. These tested specimens were 2/3-scaled models of such frames in a prototype building with design details representative of those used in the construction practice in California during the 1920's [9]. Two of these specimens (referred to as CU1 and CU2) were single-storey, single bay masonry infilled frames that were tested with quasi-static cyclic loads [9]. A third specimen represented a three storey frame with two bays; this was tested on a shake table at UCSD [9]. After reaching the peak load, the specimen CU1 developed diagonal shear cracks in the concrete columns as an extension of the dominant cracks in the masonry infill. The same failure pattern was reported for the CU2 specimen with a window opening. Again, one of the columns in the CU2 specimen had a major shear crack which developed close to mid-height of the column. Koutromanos et al. [10], demonstrated the ability of a proposed nonlinear finite element model to capture the response of masonry-infilled reinforced concrete frames under cyclic loads. Diffused cracking and crushing in concrete and masonry are simulated by a smeared-crack continuum model, while dominant cracks as well as masonry mortar joints are modeled with a cohesive crack interface model.

The interface model adopts an elasto-plastic formulation to describe the mixed-mode fracture of concrete and masonry. This model accounts for cyclic crack opening and closing, reversible shear dilatation, and joint compaction due to damage. The constitutive models have been validated successfully with experimental data and applied to the dynamic analysis of a three-storey, two-bay, masonry-infilled, non-ductile, reinforced concrete frame, which was tested on a shake table [9]. The plane-stress smeared-crack model was used for the simulation of the continuum elements representing masonry units and concrete elements. The numerical simulation presented by Koutromanos et al. [12] can accurately reproduce the load–displacement response, crack patterns, and failure mechanisms of the infilled frames including the shear cracking of infill and the surrounding frame.

Valid numerical models of multi-storey infilled frames were investigated in the past by many researchers (see relevant review in [3] and [4]). The numerical simulation proposed by Soulis [1] was used to simulate the behaviour of three-storey structural formations including masonry infills; in particular a multi-storey planar R/C frame structure, which was constructed and tested at the University of California, Berkeley by Klingner and Bertero [11] was examined. Reasonably good agreement was observed between the numerical results and the experimental measurements regarding the hysteretic behaviour of the “bare”, and infilled three-storey specimens. In the second part of this paper the numerical simulation of the behaviour of a 6-storey masonry infilled R/C frame structure located at the Volvi-Greece European Test Site for Earthquake Engineering [12] is examined employing an elastic dynamic analysis and a non-linear “push over” analysis. Six basic structural configurations are studied including a "Bare" structure (only the R/C frames without any masonry infills) and various formations that resulted with the addition of masonry infills for this specimen of a simple R/C multi-storey building. These structural formations that were studied numerically correspond exactly to this 6-storey 1/3 scaled model building during a period of 10 years, from 1994 onwards. A large number of low-amplitude dynamic tests have been conducted in-situ over an extended period, mainly from 1995 till 2006. By combining this large volume of dynamic response measurement data from the various in-situ low-vibration sequences, the most important mode shapes and eigen-frequencies were identified. This six-storey masonry infilled structure is numerically simulated in section 3. Initially, its dynamic behaviour is predicted utilizing the same simulation technique adopted in section 2 assuming, however, linear material properties and different foundation conditions. Next, a non-linear “push over” numerical analysis is performed in order to identify numerically its bearing capacity and the sequential appearance of various failure modes as predicted by this numerical simulation. In this “push over” analysis the soil-foundation conditions of the six-storey masonry infilled R/C frame structure is examined assuming either rigid or relatively flexible contact interface.

Frame Code name	Vertical load on Columns (KN)	Technical description of masonry infill	Masonry Infill thickness (mm)	Technical description of the interface between frame and infill	Longitudinal reinforcement ratio (ρ)
F8NR **Repaired** [8]	80	Infill with mortar **O** reinforced with reinforced plaster, without transverse reinforcement	83	mortar **O** thickness **10mm** The reinforced plaster is in contact with the surrounding frame	1.01%
CU1[9]	156	Infill with mortar **N**	95	mortar **N** thickness **10mm**	1.00%
CU2[9]	156	Infill with mortar **N**	95	mortar **N** thickness **10mm**	1.00%

2 THE NUMERICAL SIMULATION OF THE BEHAVIOUR OF SINGLE-STOREY SINGLE-BAY MASONRY-INFILLED R/C FRAMES

The present work studies the interaction of masonry infill with the R/C frame including in this numerical simulation the development of flexural (plastic hinge) and/or shear limit state for the surrounding R/C frame. Three scaled R/C infilled frame specimens, one of them, namely specimen F8NR, tested by Saryiannis [8] and two of them, namely CU1, CU2, tested by Stavridis[9], are utilized for the verification of the proposed numerical simulations. In all these cases the numerical response predictions are compared with the corresponding experimental results. Brief information on the selected masonry infilled R/C specimens is listed in table 1 and figures 1 and 2. The influence exerted by the interface mortar joint between the masonry infill and the surrounding frame was also examined here [3], [4], as was also done in both studies by Thauampteh [2] and by Soulis[1]. Tables 2, 3 and 4 list the mechanical properties of the materials used in the construction of the specimens.

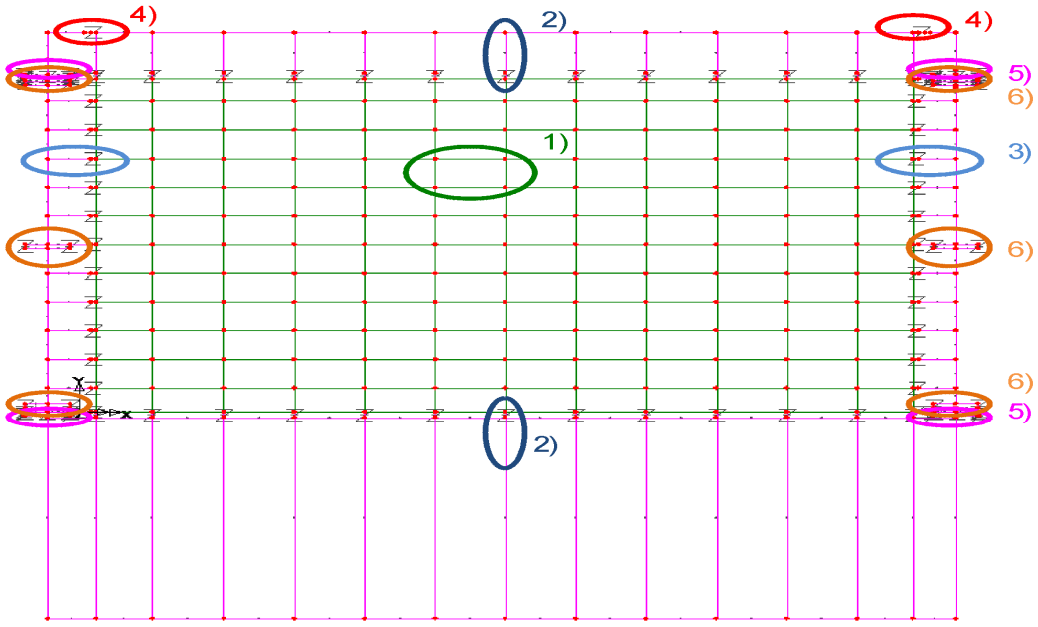

Figure 3. Features of the non-linear numerical simulation of a single-bay single-storey masonry infilled R/C frame

2.1 Simulation of the single storey masonry infilled R/C frame

An extensive study of various numerical simulations of the behaviour observed for masonry infilled R/C one-bay one-storey frame specimens tested by Thauampteh [2], by Stylianides [5], by Valiasis [6], and by Yasin [7] was included in the work by Soulis[1] together with an extensive validation process, utilizing the results of all these experimental studies ([2], [5], [6], [7]). Here a modified numerical model similar to the one presented before is examined that incorporates the simulation of the formation of shear limit state in predefined locations along the height of the two columns of such R/C specimens. The features of the numerical simulation are presented in figure 3 and in more detail in figures 4 and 5. These features are the same as the ones proposed by Manos, Soulis & Thauampteh before ([3], [4]) with the

addition of the possibility of shear limit state at predetermined locations along the height of the R/C columns of the single storey R/C frame. In figure 3 these non-linear mechanisms are denoted as: (1) corresponding to the non-linear behaviour of the masonry infill itself, (2) the infill-beam interaction at the contact region, (3) the infill-column interaction at the contact region (4) the formation of a plastic hinge at the end of a beam, (5) the formation of a plastic hinge at the top or bottom of a column and finally (6) the formation of a shear limit state along the height of a column. These non-linear mechanisms are also depicted in some detail in figure 4 (non-linear mechanisms (1), (2), (3) and (4) and in figure 5 (non-linear mechanisms (5) and (6)).

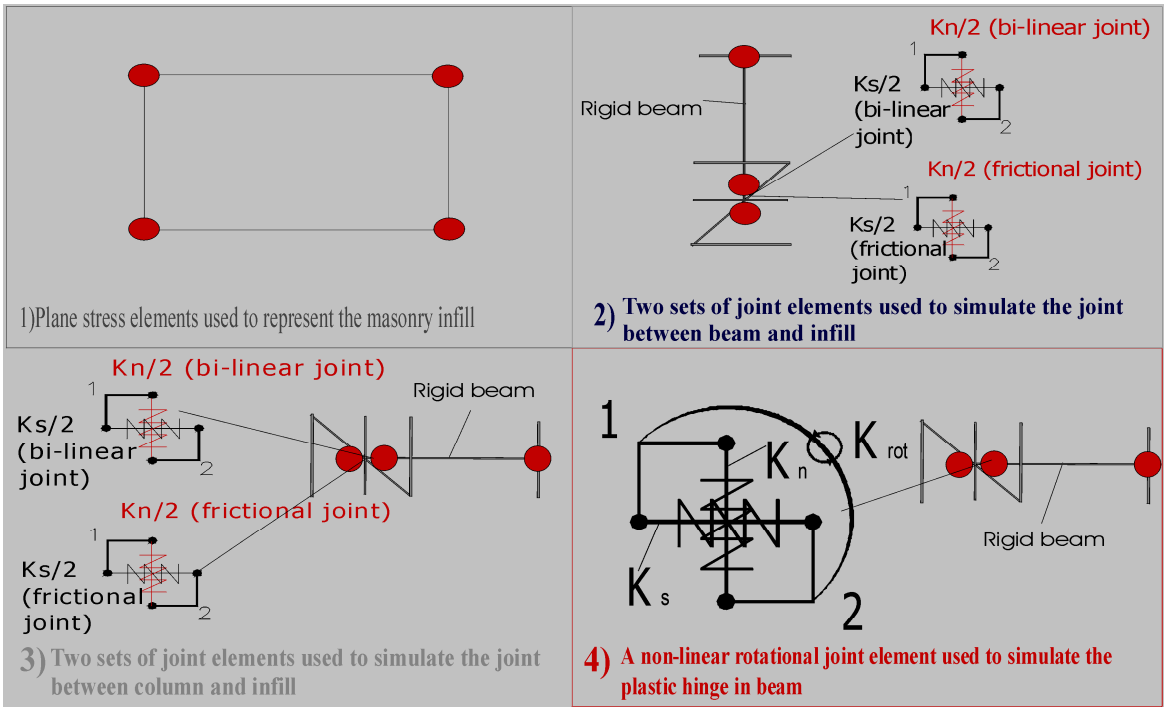

Figure 4. Details of the non-linear numerical simulation for the infill, the interface between infill and R/C frame and for the plastic hinge in the R/C beam.

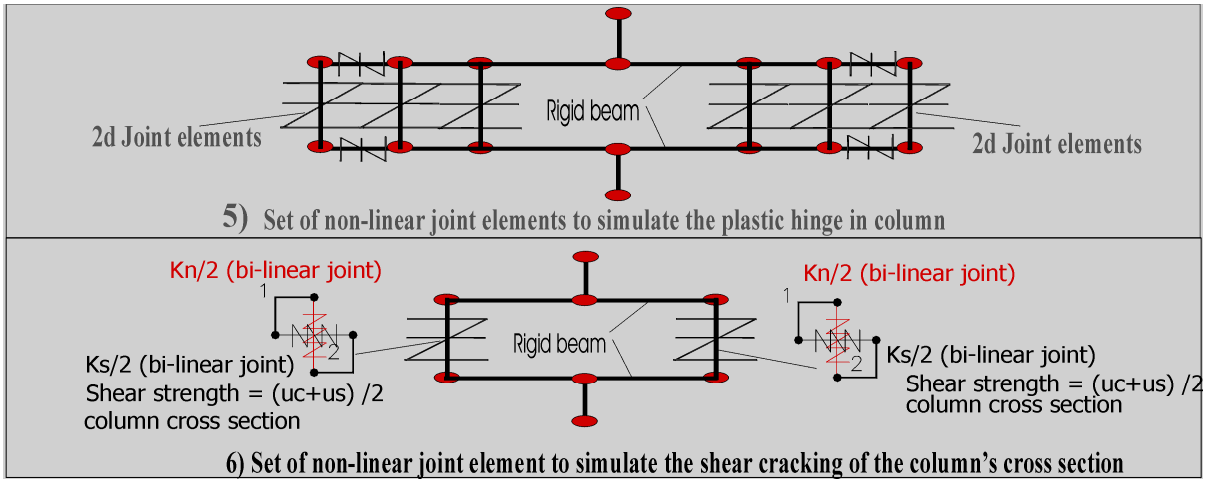

Figure 5. Details of the non-linear numerical simulation for the plastic hinge in the R/C column and for the shear limit state also at the column.

All these non-linear mechanisms are numerically simulated with a combination of rigid zones and non-linear joint elements (figures 4 and 5) with properties based on the geometric data, the material properties of the constituent materials (masonry, mortar, concrete, longitudinal steel) and the relevant structural detailing. Each one of the numerical simulations of the specific non-linear mechanisms (1) to (5) has been validated separately by Soulis [1] and Manos ([3], [4]) utilising relevant laboratory measurements obtained by Thauampteh [2]. Subsequently, this validation was also complemented by including all these non-linear mechanisms in the numerical simulation of a number of one-bay one-storey laboratory specimens by comparing the predicted cyclic behaviour for these specimens with observed performance ([1], [2], [3], [4], [5], [6], [7]). The additional shear limit state non-linear mechanism, represented by detail (6) in figure 5, is numerically approximated again by a combination of rigid zones and non-linear joint elements with properties based again on the geometric data of the column cross section, the material properties of the constituent materials (concrete, transverse steel), and the relevant structural detailing. The shear limit state was obtained by calculating the shear capacity for a column cross-section as specified by equations 1, 2 and 3. The location of these non-linear shear limit state zones is based on observed behaviour and accumulated experience for each given case. For the studied specimens three predefined locations along the height of each column were selected capable of developing this shear limit state. Two of these locations are at the ends (top and bottom) of each column in serial sequence with the non-linear mechanism simulating the flexural plastic hinges in these locations. An additional shear limit state mechanism was also placed at mid-height of each R/C column. Two elasto-plastic non-linear 2-D joint elements are used to simulate the shear post-elastic behaviour of a given R/C column cross section by considering also the corresponding column transverse reinforcement (figure 2 and detail No 6 in figures 3, 4 and 5). As per ACI 318:2008 [12] the total shear V_u resisted *(107KN)* by the column's cross section is carried by two parts; the shear resisted by the concrete and the shear resisted by the reinforcement. As already mentioned, the properties of these non-linear 2-D joint elements are specified utilizing the given structural details and equations 1 to 3. Independent numerical tests were carried out employing simple structural problems in order to verify that this way of simulating numerically the shear limit state mechanism responds in the expected way. Next, this numerical approach was applied to the infilled frame specimens included in table 2.

$$V_u = V_c + V_s \tag{1}$$

• Shear resisted by the concrete part of the cross section V_c

• Shear resisted by the transverse steel reinforcement V_s

For normal weight concrete,

$$V_c = \delta \times \left(0{,}17 \times \sqrt{f'_c}\right) \times b \times d \quad \left(where, \delta = 1 + \frac{P_u}{14A_g}\right) \tag{2}$$

$$V_s = \frac{A_{SV} \times f_{yh} \times d}{s_v} \qquad for\ transverese\ reinforcement \tag{3}$$

f_c =cylindrical compressive strength of concrete

b = width of member

P_u = axial force normal to cross section

A_g =gross cross sectional area of concrete

A_{sv} = area of transverse steel reinforcement expected to be effective in resisting the expected shear mode of failure

d = Effective depth of member

s_v = spacing of stirrups

f_{yh}= yield stress of stirrups

2.2 Validation of the proposed numerical simulation

Figures 6a, 6b and 6c depict a comparison between the predicted behaviour, in terms of envelope curves resulting from a monotonic type of loading on the adopted numerical simulation and the corresponding envelope curves resulting from the relevant experiments with the masonry infilled frame specimens F8NR and CU1, CU2.

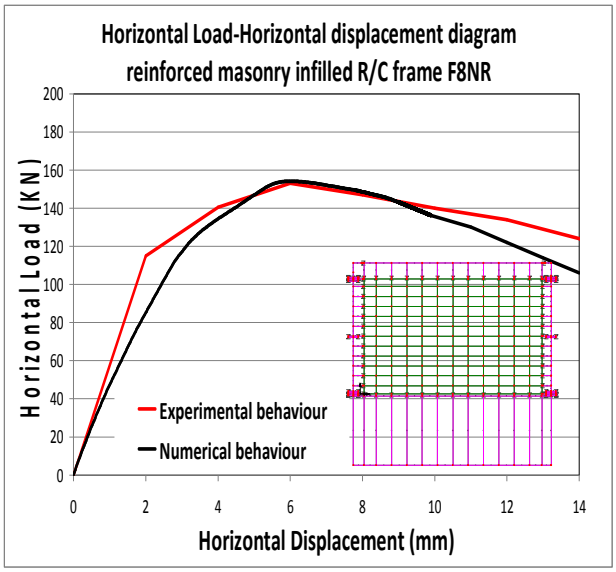

Figure 6a: Comparison of envelope curves for masonry infilled model frame F8NR

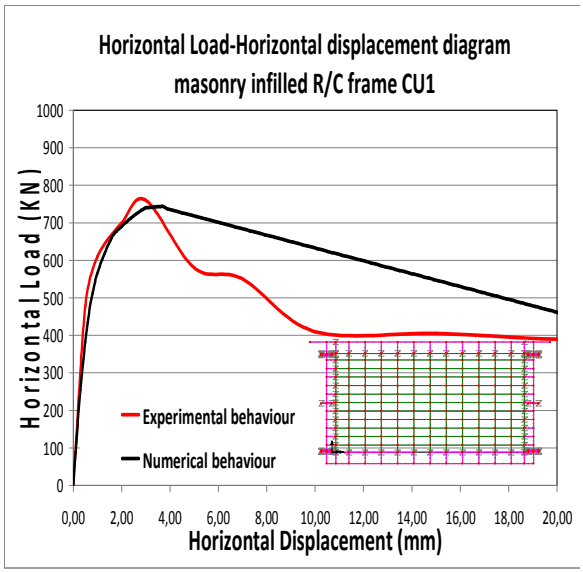

Figure 6b: Comparison of envelope curves for masonry infilled model frame CU1

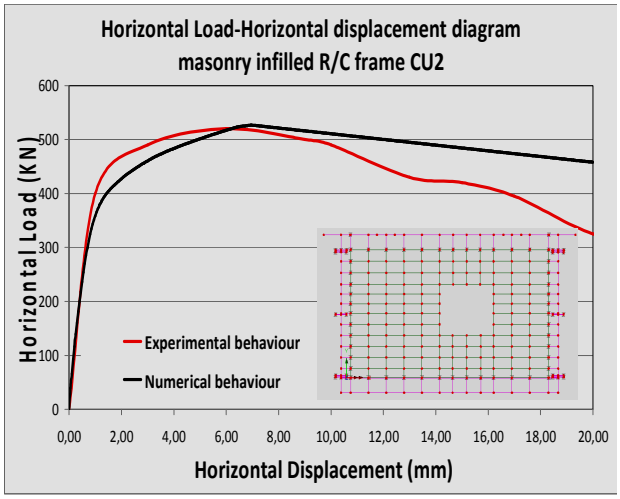

Figure 6c: Comparison of envelope curves for masonry infilled model frame CU2

The deformations to masonry infill observed during the tests and the numerically-predicted non-linear limit state is presented for frames F8NR (figures 7a and 7b), CU1 (figures 7c and 7d), CU2 (figures 7e and 7c). The observed damage patterns of the masonry infill were well approximated by the proposed numerical simulation. The damage pattern of F8NR masonry infilled R/C frame reported experimentally, consisted of corner crushing of the reinforced masonry infill corners in the R/C column and beam joint and a shear cracking in top right column(figure 7a).

Reasonably good agreement can be seen in the damage pattern predicted numerically except that shear limit state is observed both in the top left and the bottom right column (figure 7b). The damage pattern that was observed for masonry infilled frame CU1 includes diagonal/sliding cracks in the infill panels and shear cracks on the top left column and shear cracks in the bottom right column for the experimentally tested specimen (figure 7c). The same limit state pattern was predicted numerically as shown in figure 7d. For the masonry infilled panel with one opening in specimen CU2 the sequence of limit states included successively (figure 7e) a) Infill to frame separation b) diagonal cracks of the infill at the window corners c) shear crack in top left column , and d) diagonal crack in the right bottom

masonry pier and shear crack mid-height of the right column. The same limit state pattern was predicted numerically (figure 7f).

3. VOLVI 6-STOREY MODEL STRUCTURE

The numerical investigation briefly reported in section 2 demonstrates that the proposed numerical model can successfully simulate a number of non-linear mechanisms that can be developed in a single storey masonry infilled frame. In this section it is shown that all these non-linear mechanisms (see introduction a, b and c) can be used to simulate the behaviour of a 6-storey masonry infilled R/C frame structure. This 6-storey masonry infilled R/C frame model structure was constructed and tested at the European Test Site at Volvi, by Manos et al [13], [14], [15]. This structure was utilized for the verification of the proposed numerical simulation.The investigation included two types of analyses; an initial linear dynamic analysis to predict numerically the recorded dynamic response of this structure followed by a non-linear "push over" step-by-step type of numerical analysis of the same infilled frame structure. It must be pointed out that both types of numerical simulations make use of only in-plane stiffness and strength behaviour of the masonry infills units whereas the out-of-plane behaviour and its possible effects, although important, are not addressed here.

3.1. Description of the model structure

This model building was constructed and instrumented at the European Test Site of Volvi in order to monitor its dynamic response under prototype earthquake conditions. An extensive sequence of low-amplitude dynamic tests has been performed. The model included one-bay in each direction, 6-storey, of 1/3-scale with overall external dimensions 1810mm (length) x 5000mm (height) in the weak direction and 1910mm(length) x 5000mm (height) in the strong direction. Its floor level had a height of 1000mm. The cross-section of the columns was 110mmx110mm and that of the beam 100mmx155mmm. In figures 8 a, b and c the masonry infilled, R/C , 6-storey structure is depicted. The basic properties for the concrete and the reinforcement have been monitored through samples taken during construction. Different structural configurations of the 6-storey structure have been tested at the European Test Site of Volvi, in the period of its existence (Manos at al [13], [14], [15]). The structural configuration that is utilized here includes apart from the existing added weight of 50KN, an extra weight of approximately 30KN on the top of a sixth floor specially constructed for this purpose (Masonry scheme 2b, September 1997 – January 2004).

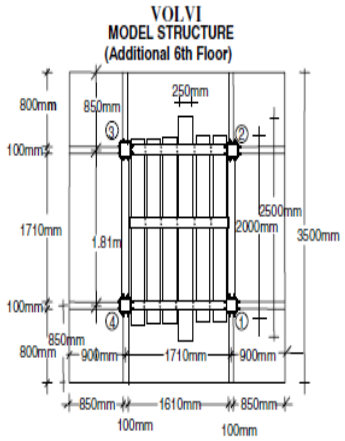

Figure 8 a)Plan view of 6-storey masonry infilled frame structure in European test site at Volvi

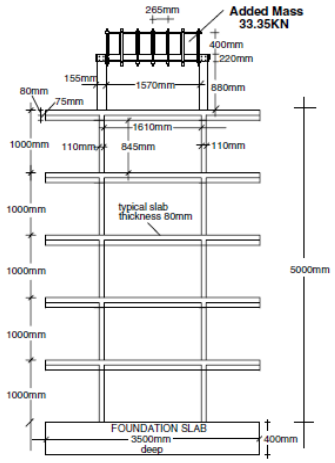

b)Side view of 6-storey "bare" frame structure in European test site at Volvi

c) Side view of 6-storey masonry infilled frame structure in European test site at Volvi

Brief information on the masonry infill used in this model building is listed in table 5. Relevant masonry properties and additional information are given by Thauampteh [2].

Description of the 6-storey structure masonry infill	Masonry Infill thickness (mm)	Technical description of the interface between frame and infill	Longitudinal reinforcement ratio (ρ)
Initial unreinforced Masonry with mortar type **V1**	58.5	mortar **V1** thickness **10mm** (without plaster)	1.01%

Table 5: Outline of all specimens for the 1st and 2nd groups of specimens

As already mentioned, the influence exerted by the interface between the masonry infill and the surrounding frame was also examined in both studies by Thauampteh [2] and by Soulis[1]. Tables 6, 7 and 8 list the mechanical properties of the materials used in the construction of the specimens. The masonry infill panel was connected to the surrounding frame with weak mortar (type V1) similar to the one used in the construction of F2N specimen Thauampteh [2]. In this numerical analysis the influence of this interface is examined together with three different cases of foundation-soil stiffness conditions.

Masonry infill	Masonry Infill thickness (mm)	Compres. strength of masonry (N/mm^2)	Shear strength of masonry diagonal compression (N/mm^2)	Compres. strength of masonry units (N/mm^2)	Compres. strength of concrete columns (N/mm^2)	Compres. strength of concrete slabs (N/mm^2)	Compres. strength of mortar cylinders (N/mm^2)

3.2. Three dimensional elastic numerical simulation of the dynamic response of the 6-storey model structure

Initially, the results from in-situ tests are presented here dealing with the dynamic response of a 6-storey reinforced concrete (R/C) frame structure with masonry infills, which was built for this purpose at the Volvi European Test site. Summary results from the measured main eigen-frequency values resulting from simple pull-out tests on the 6-storey specimen, with masonry infills in all stories, with steel diagonals and extra mass are included in Table 9. A numerical simulation of the 6-storey (R/C) frame structure with masonry infills utilizing the all the provisions considered in section 2 was built and a dynamic analysis was performed. The numerical simulation included a 3-D simulation of the foundation slab, of all the concrete

members (slabs, beams, columns), of the masonry infills, the interface between the masonry infill and the surrounding frame and finally the 6th storey extension. The simulation of the foundation flexibility was approximated by introducing linear springs at the foundation-soil interface. Three different numerical analyses were performed assuming three different levels of soil-foundation stiffness: a) Infinite stiffness (base fixity), b) Medium stiffness (flexible base with foundation-soil interface of E=200Mpa), c) Low stiffness (flexible base with foundation-soil interface of E=10Mpa). Table 9, includes the corresponding summary eigen-frequency results of the numerical simulation studies that were performed assuming these three different soil-foundation stiffness types.

Description of the Structural Configurations for the Volvi Model Structure	1st x-x (Hz) Translational Eigen-frequency	1st y-y (Hz) Translational Eigen-frequency	1st φ (Hz) Torsional	Measuring Procedure
Masonry scheme 2b, June 1998. 6th storey extension Infills in all 5 lower stories (with diagonals) . Measured values [14]	5.005*	4.761*		Permanent & Portable Instruments
Fixed base Values of eigen-frequencies numerically predicted	5.40**	5.31**	5.48**	 3-d Numerical simulation
Flexible base E=200Mpa Values of eigen-frequencies numerically predicted	4.75**	4.67**	5.12**	
Flexible base E=10Mpa Values of eigen-frequencies numerically predicted	2.58**	2.45**	2.69**	

* Experimental value., ** Numerical simulation results

Table 9: In-situ measured and numerically predicted vibration frequencies

3.3. Push over non-linear analysis of the masonry infilled 6-storey model structure

For this non-linear "pushover" analysis of the 6-storey structure, the maximum target displacement at the top was set equal to 61mm, with the displacement profile along the height of the structure assumed to be triangular. The in-plane displacements resulting in this way were imposed at each floor level in a gradual increasing step-by-step fashion. The numerical simulation discussed in section 2 for the R/C masonry infilled frames is applied this time for all the 16 masonry infilled bays that compose this 6-storey masonry infilled frame structure (figure 8c). The horizontal load-horizontal displacement "push-over" response curve resulting from this simulation, which as mentioned includes all non-linear mechanisms for the masonry infill, the surrounding R/C frame, the interface between the masonry infill and frame, is depicted in figure 9. The simulation of the masonry infill, was done utilizing non-linear thick shell finite elements. The isotropic nonlinear material law of Modified Von Mises was utilized for this purpose. The adopted mechanical properties of the initial and the strengthened masonry infill panel are listed in Table 10.

Young Modulus (N/mm^2)	1000
Poisson Ratio	0,20
Tensile strength (N/mm^2)	0,30
Compressive strength (N/mm^2)	1,2
Softening Modulus under compression (N/mm^2)	-10
Softening Modulus under tension(N/mm^2)	-10

Table 10: Mechanical properties used for the description of Von Mises failure criterion of the masonry infills

The numerical simulation of the interface between the prototype R/C frame and the masonry infill is done in the same way as described in section 2.1, utilizing non-linear joint elements in the axial and transverse direction. This interface is assumed to have been built with mortar type V1 (see Thauampteh 2] and Table 8). The simulation of the surrounding R/C frame was also performed utilizing the same simulation technique as described in section 2.1.

3.4 "Pushover" curves and Predicted damage for the numerical simulation of the 6-storey frame of Volvi

Figure 9 depicts the base shear – top horizontal displacement curve obtained for the fully non-linear "pushover" analysis for the 6-storey masonry infilled frame structure assuming base fixity. In the same figure the base shear – top horizontal displacement curve is also obtained assuming a flexible foundation with a foundation-soil interface of E=10Mpa. The target top displacement corresponds to approximately 1% angular deformation of the 6-storey masonry infilled frame structure. Figures 10a,b, and 11a,b depict in more detail the predicted damage pattern (shown with **x** signs) of the masonry infills of the 6-storey masonry infilled structural formation resulting from this "push over" type of analysis for two levels of angular deformation a) 0,41%, b)0,84%.

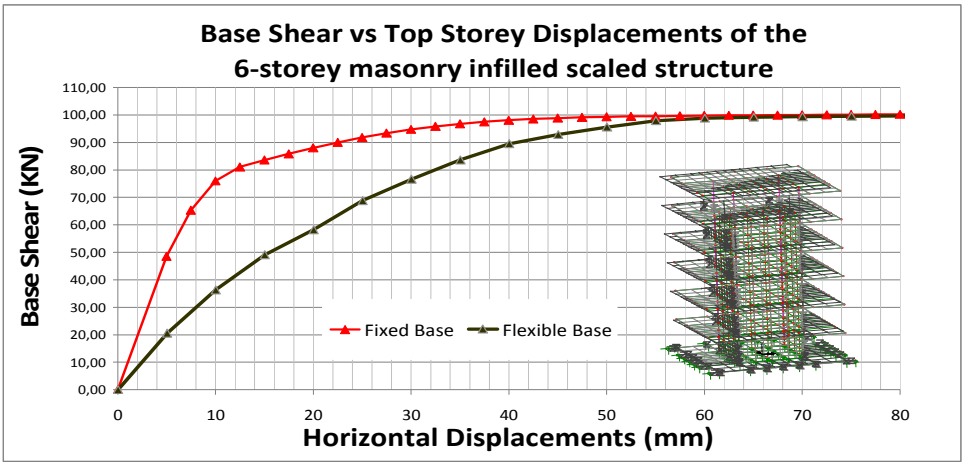

Figure 9: Comparison between push over curves obtained for different foundation conditions

γ=0,0042 ‰(dx=25mm)	γ=0,0084 ‰(dx=50mm)	γ=0,0042 ‰(dx=25mm)	γ=0,0084 ‰(dx=50mm)
			a) Fixed Foundation	b) Fixed Foundation	a) flexible foundation	b) flexible foundation

Figure 10: Masonry infill damage patterns, as predicted for top storey target displacement equal to a) 4,1‰, b)8,4‰ of the building height with fixed foundation

Figure 11: Detail of masonry infill damage patterns, as predicted for top storey target displacement equal to a)4,1‰, b)8,4‰ of the building height with flexible foundation

As can be seen in figure 9, the level of the soil-foundation stiffness influences significantly the non-linear "push-over" response of this 6-storey masonry infilled frame structure. The flexibility of the foundation decreases the shear deformation of the masonry infills and the predicted damage levels (figures 11a and 11b) more than for the case of rigid foundation (figures 10a and 10b). Instead, the predicted damage patterns of the masonry infills in this structure, assuming base fixity, develops as expected at a much lower amplitude of top horizontal displacement. The limit state pattern of the masonry infill predicted in this case is along its diagonal (figure 10b). In this sense the flexibility of the foundation acts as a protective mechanism, provided it is designed to be able to sustain such deformations without any side-effects. Moreover, as concluded by an additional experimental sequence conducted with another model structure at the Volvi European Test Site [15] soil-foundation-structure interaction could lead non-embedded foundations to non-linear behaviour resulting in uplift and/or soil plastification. Therefore, such non-linear foundation responses if controlled by design could be a beneficial source of energy absorption. Otherwise, they may lead to excessive displacements of the superstructure and to foundation failure.

4 CONCLUDING OBSERVATIONS

1. The strength and the monotonic load-displacement behaviour observed during the experiments of single-storey one-bay masonry-infilled R/C frames examined in this study is successfully predicted by the proposed numerical simulation.
2. The proposed numerical simulation represents in a reasonable way the most important influences that the interface between masonry infill and the surrounding frame could exert on the monotonic behaviour of such structural assemblies in terms of stiffness, strength, modes of failure, as demonstrated from the observed behaviour.
3. The development of a shear limit state at the predetermined positions of columns of the surrounding R/C frame observed during the experiments as well as the damage patterns for the masonry infill, in terms of crack propagation are also successfully predicted.
4. This numerical simulation was next validated by a 3-D numerical model for a multi-storey masonry infilled frame model structure located at the Volvi European Test Site. Good agreement could be seen between measured eigen-frequency values and predictions from linear dynamic analysis performed assuming different foundation conditions.
5. Finally, this numerical simulation was successfully applied to the same multi-storey masonry infilled frame model structure located at the Volvi European Test Site this time employing a non-linear "push over" type of analyses that included all the non-linear mechanism employed before. From the obtained results it can be demonstrated that the flexibility of the foundation decreases the shear deformation of the masonry infills and the predicted damage levels more than for the case of rigid foundation. In this sense the flexibility of the foundation acts as a protective mechanism, provided it is designed to be able to sustain such deformations without any side-effects.

Abstract. This paper presents the results of a numerical study aimed at developing a rational approach to assess the degradation of mechanical properties of lead-core bearing devices used for passive seismic isolation. The lead-core rubber bearing is modeled as a multiple-component system. Appropriate constitutive laws and failure criteria are defined for each component of the system. Two alternative constitutive relations are defined for the lead core: bilinear material model by assuming isotropic hardening after yielding, and a model formulated in the framework of continuum damage mechanics. The numerical procedure used to simulate the mechanical response of the device allows the monitoring of accumulated mechanical damage throughout the loading history. Preliminary simulation results obtained by finite element analysis are reported. Specifically, these are shear force-displacement hysteresis loops under various loading conditions in a typical characterization test.

1 INTRODUCTION

The lead-core bearing device is modeled as a multiple-component system. It consists of the following components: lead core, rubber layers, steel shims and thick steel plates. For each material, lead, rubber and steel, an appropriate constitutive law is chosen. The constitutive laws are defined on the meso-scale. At this point, an analogy between the representative volume element in continuum damage mechanics and finite element is postulated. The stress and strain fields in the lead-core bearing device are obtained by finite element analysis on the basis of the postulated constitutive laws. Important macro-characteristics of the bearing can be evaluated throughout the loading history. Such macro-characteristics, if observable, can be employed to calibrate the model or to validate the results obtained by finite element analysis.

2 BEARING DEVICE: SPECIFICATIONS

The geometry of the bearing being modelled and analysed in this study is shown in Figure 1.

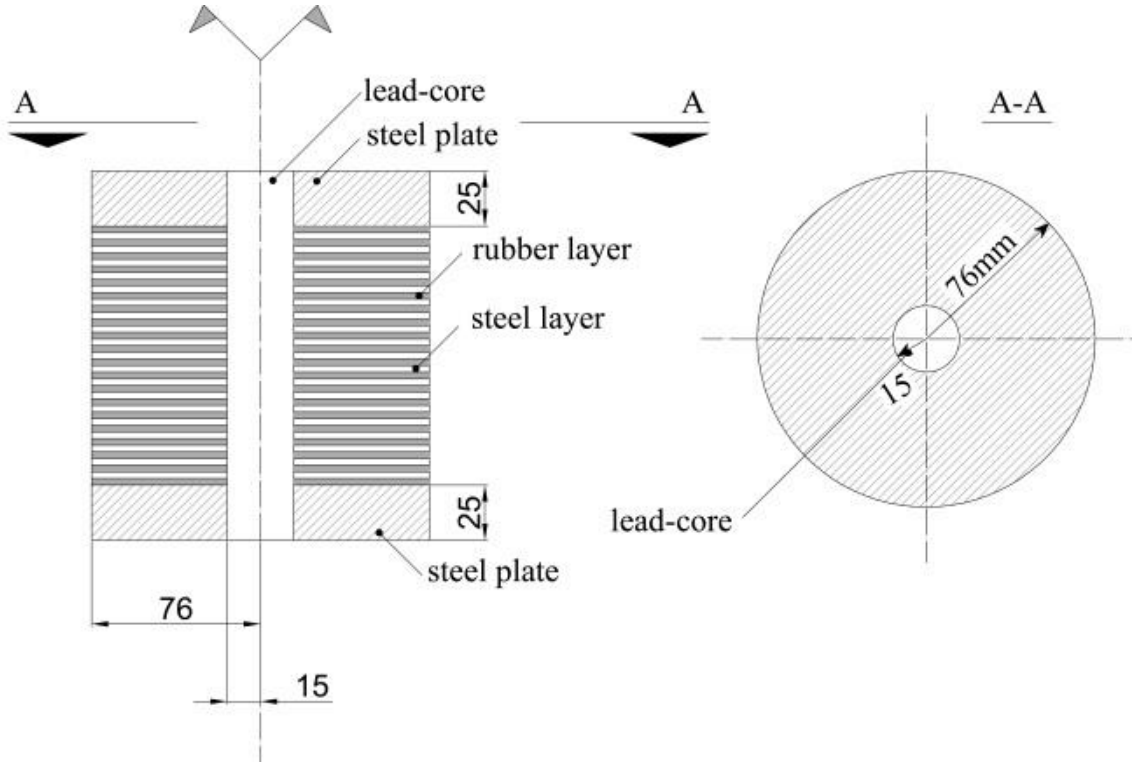

Figure 1: Geometry of the modelled bearing device

As it can be seen, the lead-core bearing device consists of two thick steel plates at the top and at the bottom, rubber layers separated by steel shims, and a lead-core. The thick steel plates are 182mm (2x76) in diameter and 25mm thick with a central cylindrical opening of 30mm diameter. Twenty rubber layers separated by 19 steel shims are stacked between the top and bottom steel plates. The rubber layers and the steel shims are both 182mm in diameter and 3mm thick. They also have a central opening of 30mm diameter along which a lead core of 30mm diameter is fitted.

3 CONSTITUTIVE LAWS

3.1 Steel

Steel is modelled as an isotropic and elastic material. This is justified because, in common usage conditions of the bearing devices, the steel layers and the top/bottom plates remain elastic while yielding occurs in the lead-core and rubber layers. Constitutive law for the steel layers and the top/bottom plates is thus completely defined by initial elastic modulus (Young's Modulus) and Poisson's ratio.

3.2 Lead-core

For the lead-core, a bi-linear stress-strain relationship [1][2][3] is assumed. It is assumed that the material obeys the von Mises yield criterion. An isotropic hardening rule is used to model the post-yielding behavior. As an alternative, a constitutive law based on continuum damage mechanics is formulated, specifically by coupling elasto-palsticity and damage [4]. In this formulation, material response is described by state variables. These variables can be derived form a dissipation potential P that can be written as:

$$P = f + P_X + P_D \tag{1}$$

where f is a function prescribing the yield criterion, P_X describes hardening and P_D represents damage potential [5]. The yield criterion has the following property.

$$\begin{aligned} f < 0 &\rightarrow elasticity \\ f = 0 &\rightarrow plasticity \end{aligned} \tag{2}$$

If both isotropic and kinematic hardening are considered the yield criterion is given by:

$$f = \left(\sigma_{ij} - X\right)_{eq} - R - \sigma_y \tag{3}$$

where

$$\left(\sigma_{ij} - X\right)_{eq} = \sqrt{\frac{3}{2}\left(\sigma_{ij}^D - X_{ij}^D\right)\left(\sigma_{ij}^D - X_{ij}^D\right)} = \left(\sigma_{ij}^D - X_{ij}^D\right)\sqrt{\frac{3}{2}} \tag{4}$$

In equation (4), T_{ij}^D denotes the deviatoric part of a symmetric second order tensor T_{ij}, σ_{ij} is the stress tensor and X is referred to as a back stress (Figure 2).

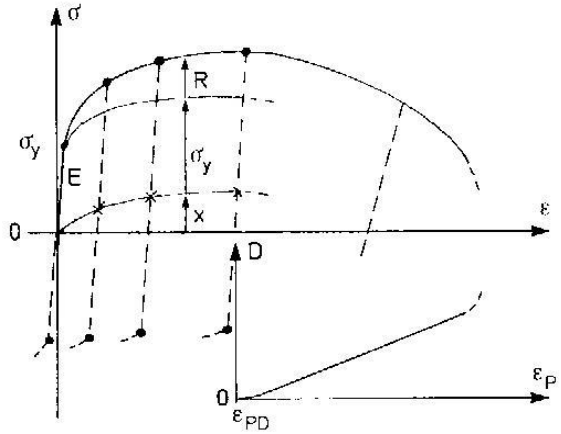

Figure 2: Kinematic back stress X and isotropic hardening stress R [6]

The kinematic back stress X is the locus of the elastic domain center in the stresses space and the isotropic hardening stress R measures the elastic domain increase:

$$R = \sigma - \sigma_y - X \tag{5}$$

The accumulated plastic strain rate is given by the following expression:

$$\dot{p}(t) = \sqrt{\frac{2}{3}\dot{\varepsilon}_{ij}^{p}\dot{\varepsilon}_{ij}^{p}} \tag{6}$$

In (6) $\dot{\varepsilon}_{ij}^{p}$ is the plastic strain rate, obtained after decomposition of the total strain into elastic and plastic part. It is assumed that damage begins when the plastic strain reaches the value corresponding to the ultimate stress (Figure 2) and its critical value is given by:

$$D_c = \left(\frac{\sigma_u^2}{2ES}\right)\left(\varepsilon_p - \varepsilon_{pD}\right) \tag{7}$$

where ε_p is the accumulated plastic strain and ε_{pD} is the plastic strain corresponding to the damage threshold. Damage is accumulated only if $\varepsilon_p > \varepsilon_{pD}$.

$$\begin{aligned} \varepsilon_p > \varepsilon_{pD} &\rightarrow \dot{D} \neq 0 \\ \varepsilon_p \leq \varepsilon_{pD} &\rightarrow \dot{D} = 0 \end{aligned} \tag{8}$$

3.3 Rubber

For rubber, a Neo-Hookean model is used. Strain energy potential is defined by using the following equation.

$$\mathrm{W} = \frac{\mu}{2}\left(\bar{\mathrm{I}}_1 - 3\right) + \frac{1}{\mathrm{d}}\left(\mathrm{J}-1\right)^2 \tag{9}$$

In Eq. (9) μ stands for the initial shear modulus of the material; d is the material incompressibility parameter, and $\bar{I}_1$ is the first invariant of the isochoric part of the right Cauchy-Green deformation tensor. According to [7] and [8], J is the ratio of the deformed elastic volume to the undeformed reference volume of the material. J can be evaluated by calculating the determinant of the Lagrangian strain tensor:

$$J = \det\left[F_{ij}\right] \tag{10}$$

In Eq. (10) F_{ij} denotes the components of the Lagrangian strain tensor. Furthermore, $\bar{I}_1$ can be obtained as

$$\bar{I}_1 = I_1 J^{-2/3} \tag{11}$$

where I_k is the k^{th} invariant of the right Cauchy-Green deformation tensor, and is given by

$$I_1 = \lambda_1^2 + \lambda_2^2 + \lambda_3^2 \tag{12}$$

where λ_i are the principal stretches. The material incompressibility parameter d is related to the material bulk modulus K as follows:

$$K = \frac{2}{d} \tag{13}$$

and the Young's modulus of the material is defined as:

$$E = 2\mu(1+\nu) \tag{14}$$

Based on experimental data, the following values are chosen for the material parameters μ and d [[1]]: μ=0.73MPa and d=0.001mm^2/N.

4 FINITE ELEMENT MODEL

A detailed 3-D finite element model is created. All elements of the bearing device are explicitly modeled in terms of geometry. Volumes are created for the rubber layers, steel shims, the lead-core and the thick top and bottom steel plates. Advantage is taken of the existing symmetries. Only half of the bearing device is modelled. Appropriate symmetry boundary conditions are defined on the plane of symmetry (Figure 3).

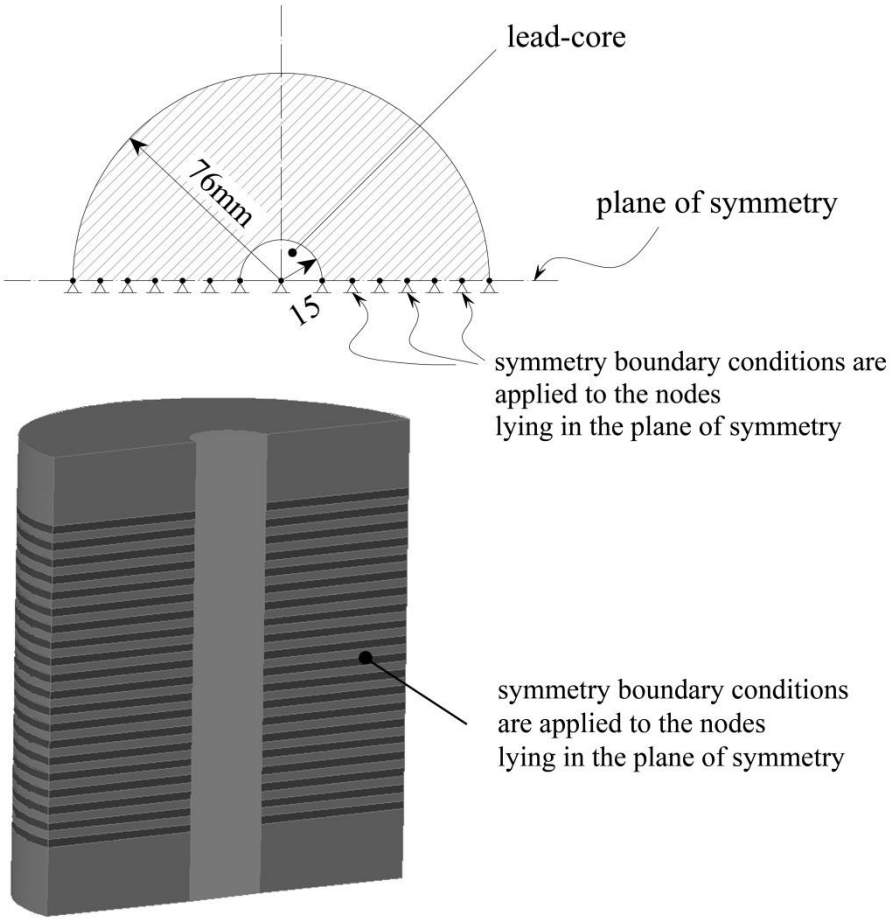

Figure 3: The half-space model and symmetry boundary conditions

For the finite element mesh 20-nodes 3-D structural solids are used (**Figure 4**). Components in steel are meshed with Solid 95 [9]. The lead-core and the rubber layers are meshed with Solid 185 [9]. Full integration option is used to avoid spurious stress hardening.

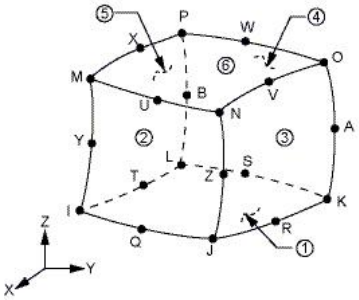

Figure 4: A 20-node 3-D structural finite element [9]

The finite element mesh is displayed in Figure 5. A total of 10290 Solid185 are employed to mesh the volumes of the lead-core, the thick steel plates, the rubber layers and the steel shims. All the interfaces are assumed to give have bonds.

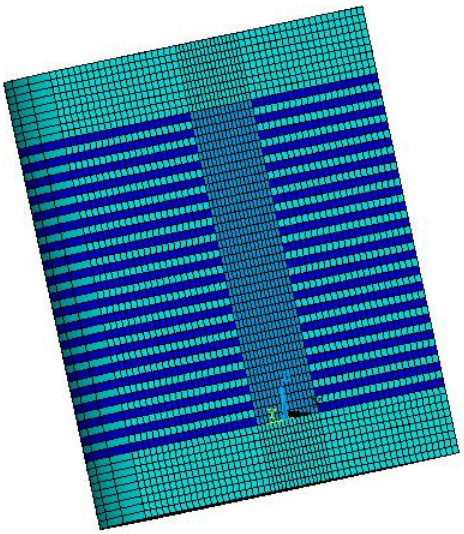

Figure 5: Half-space finite element model: finite element mesh

5 FINITE ELEMENT SIMULATION

The response of the lead-core bearing device is obtained by performing an explicit dynamic transient analysis. The equation of motion has the form:

$$[M]\{\ddot{u}\}+[D]\{\dot{u}\}+[K]\{u\}=\{F(t)\} \tag{15}$$

where [M] is the mass matrix; [D] is the damping matrix; [K] is the stiffness matrix; $\{\ddot{u}\}$ is the nodal acceleration vector; $\{\dot{u}\}$is the nodal velocity vector, and $\{u\}$ is the nodal displacement vector, and $\{F(t)\}$ is the time- dependent loading vector. All the nodes on the 'bottom' surface of the bearing device (Z = -25mm) are restrained against all possible displacements (nodal translations along X-, Y- and Z-axis). Both constant vertical loads and time-dependent horizontal loads are applied to the nodes on the 'top' surface of the bearing device (Z = 142mm). The vertical load is applied along the direction parallel to the global Z-axis in the model space. The time-dependent horizontal load is simulated by applying displacements to the top-surface-nodes in a direction parallel to the global X-axis. The boundary conditions defined for the simulation

of the characterization test are shown in Figure 6. In order to obtain the 'force-displacement' relationship, the evolution of the shear stresses in the lead-core along the global X-direction is monitored.

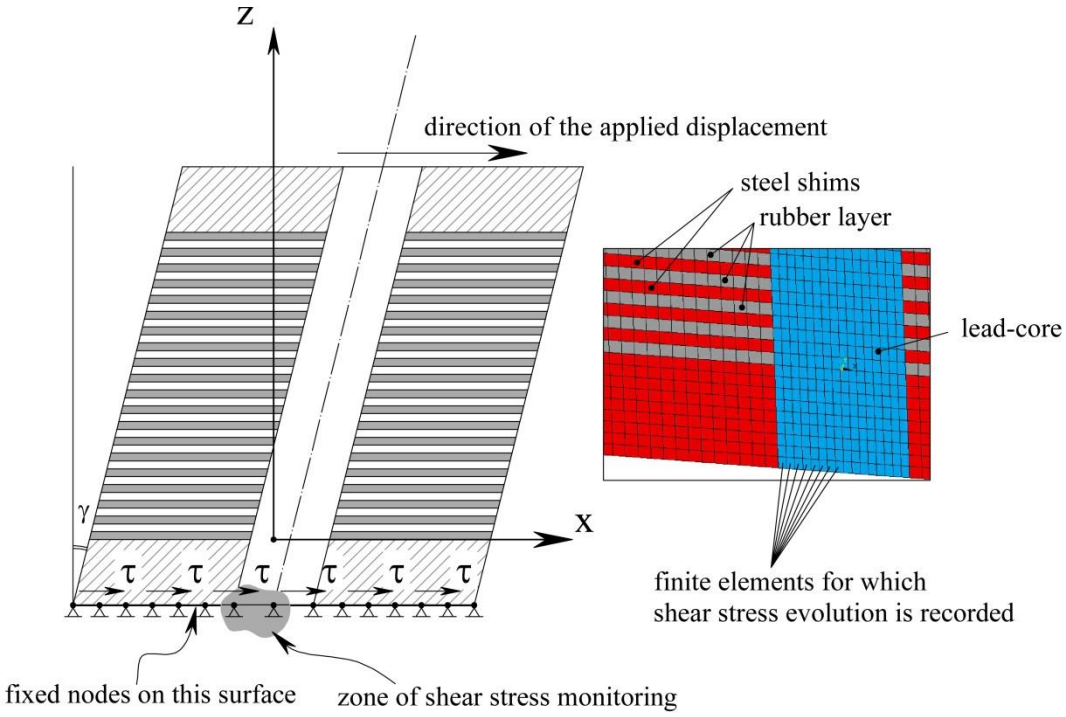

Figure 6: Schematization of the characterization test simulation

The shear strain γ in its turn is conventionally defined as the ratio between the relative horizontal displacement between the top and bottom surfaces of the bearing device- d_h and the total height of the rubber H_r (H_r =60 mm).

$$\gamma = \frac{d_h}{H_r} \tag{16}$$

One of the strain loading paths is visualized in Figure 7.

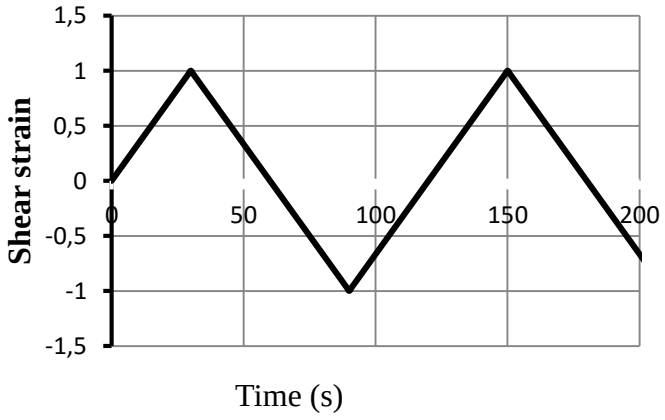

Figure 7: cyclic strain paths

6 RESULTS OBTAINED BY FINITE ELEMENT SIMULATION

In this section shear strain- displacement curves obtained for different shear strain amplitudes and shear strain rates are shown. The numerical procedure reproduces the typical hysteresis behavior exhibited by a bearing device in common identification test. All simulations contain three full hysteresis loops and the ascending branches of the fourth loop. It should be noted that these results should be further validated through comparison with experimental data.

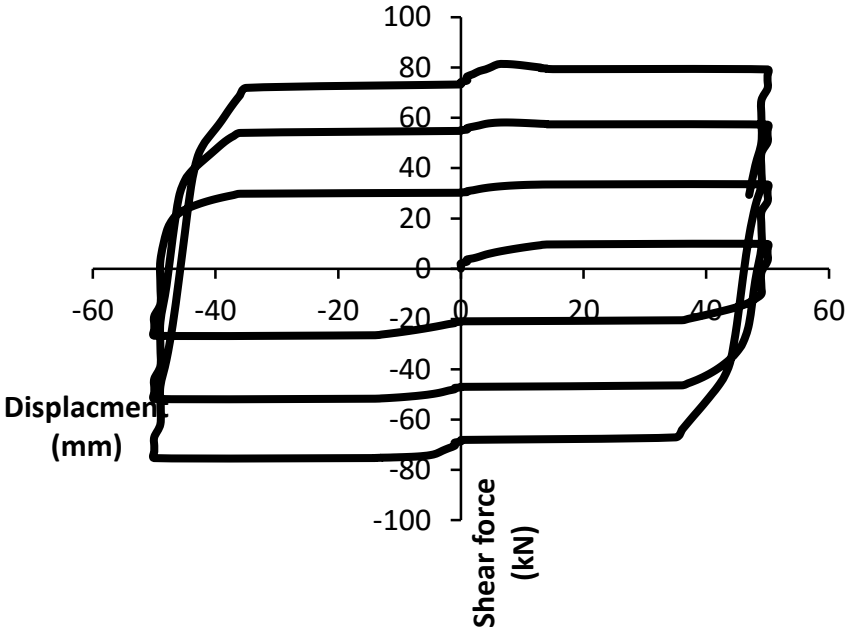

Figure 8: Shear force-displacement hysteresis loops for maximum shear strain γ=0.835 and shear strain rate $d\gamma/dt$=0.083

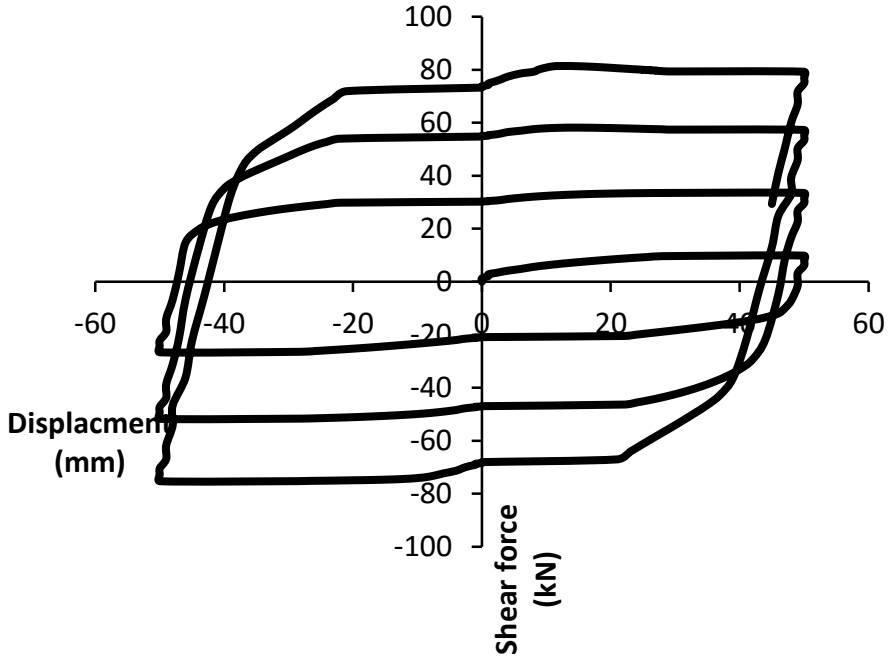

Figure 9: Shear force-displacement hysteresis loops for maximum shear strain γ=0.835 and shear strain rate $d\gamma/dt$=0.042

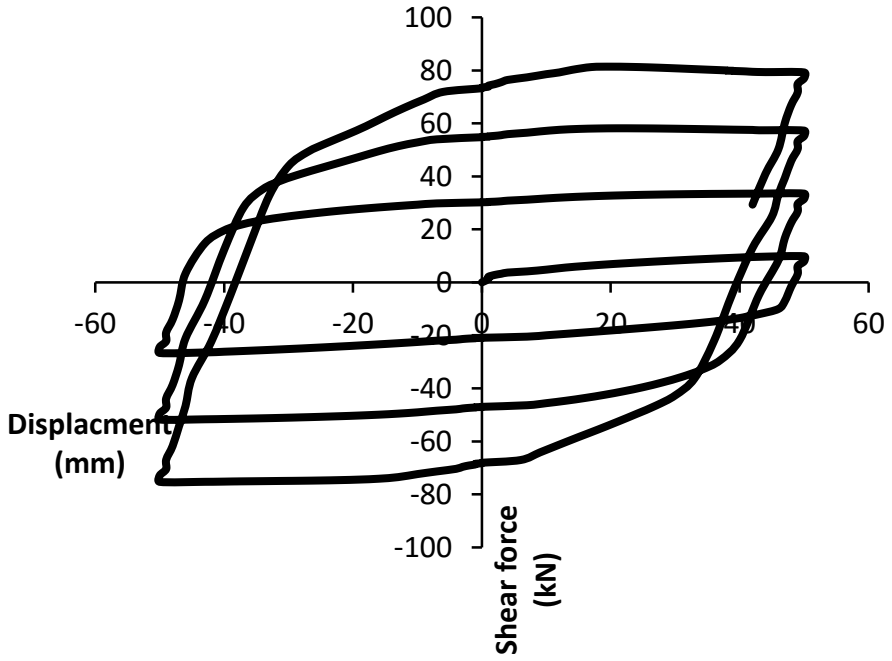

Figure 10: Shear force-displacement hysteresis loops for maximum shear strain γ=0.835 and shear strain rate dγ/dt=0.028

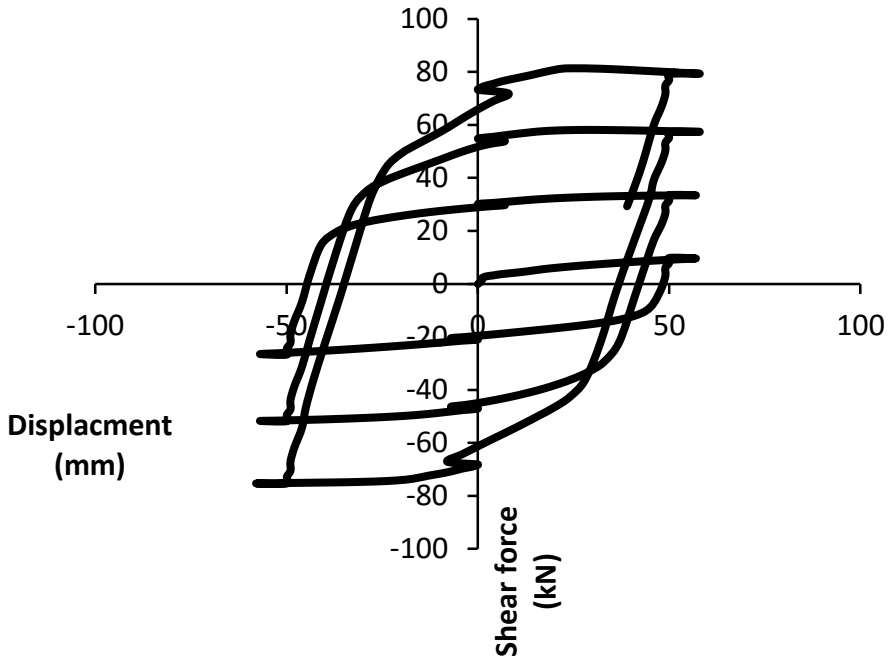

Figure 11: Shear force-displacement hysteresis loops for maximum shear strain γ=0.835 and shear strain rate dγ/dt=0.021

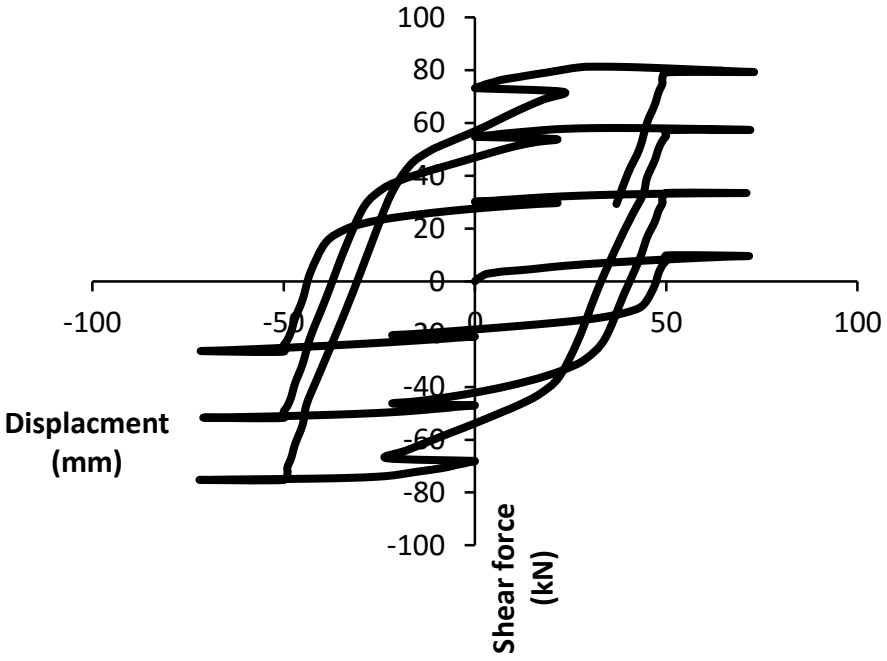

Figure 12: Shear force-displacement hysteresis loops for maximum shear strain γ=0.835 and shear strain rate $d\gamma/dt$=0.017

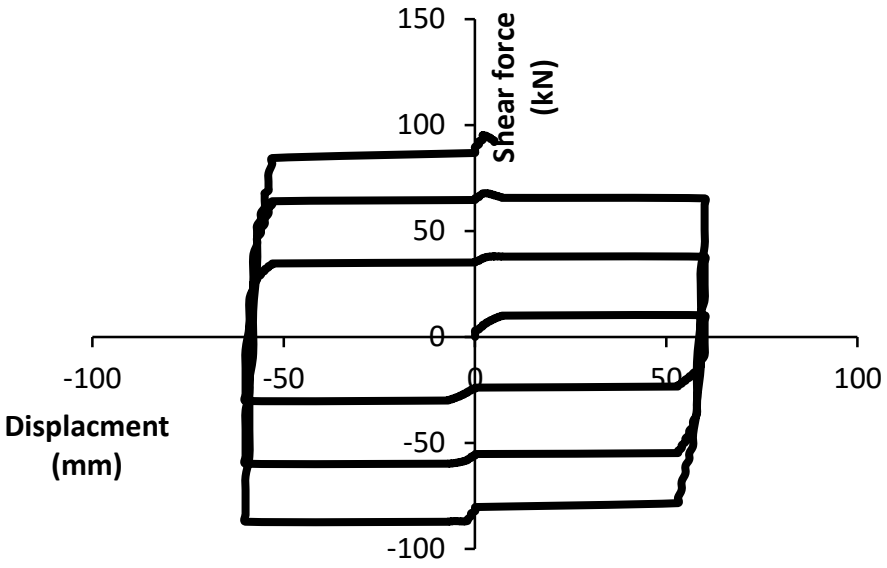

Figure 13: Shear force-displacement hysteresis loops for maximum shear strain γ=1.00 and shear strain rate $d\gamma/dt$=0.2

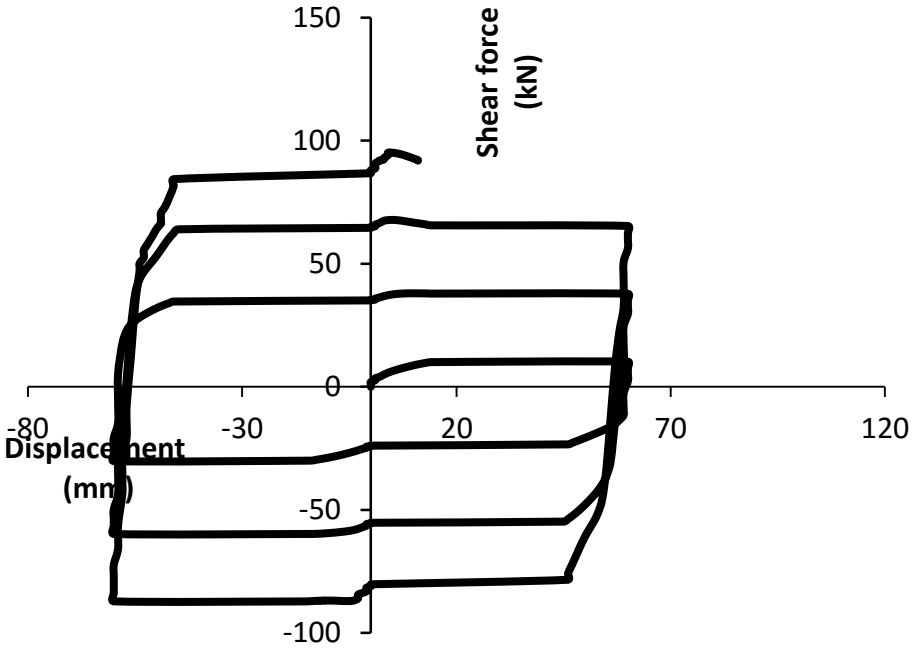

Figure 14: Shear force-displacement hysteresis loops for maximum shear strain γ=1.00 and shear strain rate $d\gamma/dt$=0.1

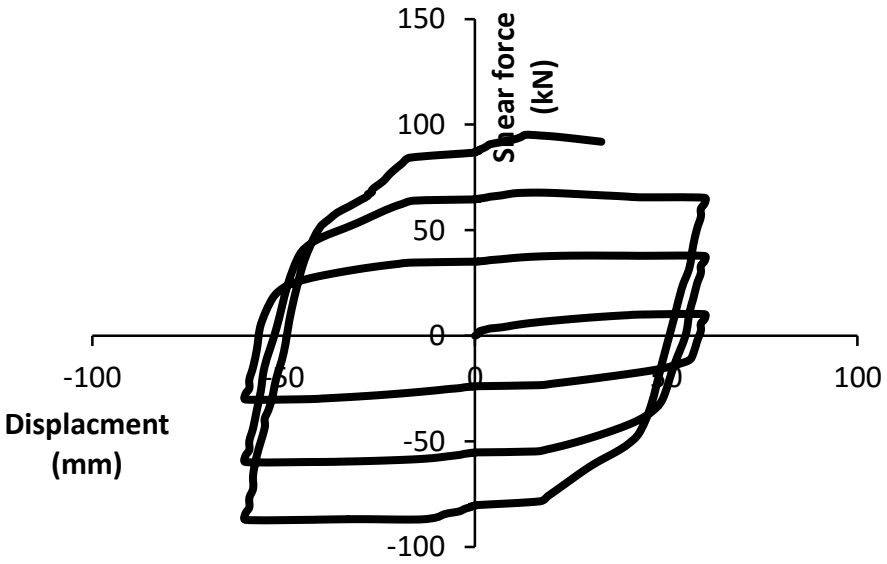

Figure 15: Shear force-displacement hysteresis loops for maximum shear strain γ=1.00 and shear strain rate $d\gamma/dt$=0.033

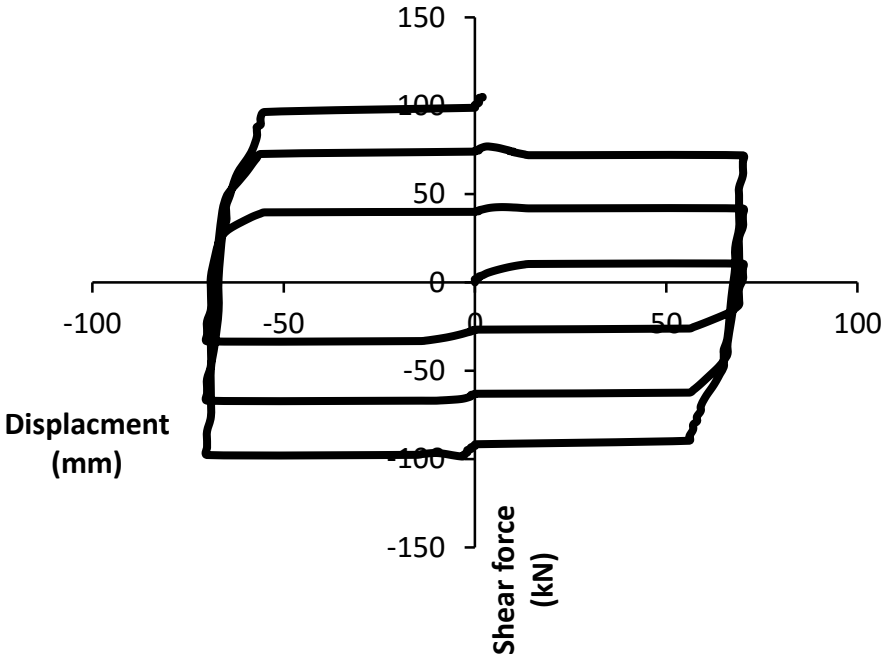

Figure 16: Shear force-displacement hysteresis loops for maximum shear strain γ=1.165 and shear strain rate $d\gamma/dt$=0.117

Qualitative comparison between different 'displacement-shear force' curves obtained by finite element analysis shows that the shear strain rate decrease results in hardening in the ascending branch of each hysteresis loop (compare Figure 8, Figure 9, Figure 10). For further decrease in shear strain rate this trend is conserved. Additionally a sharp discontinuity in the transition between ascending and descending branches as well as at the 'zero-shear strain point' can be observed (see Figure 11 and Figure 12). The latter observation should be addressed again when relevant experimental data is available.

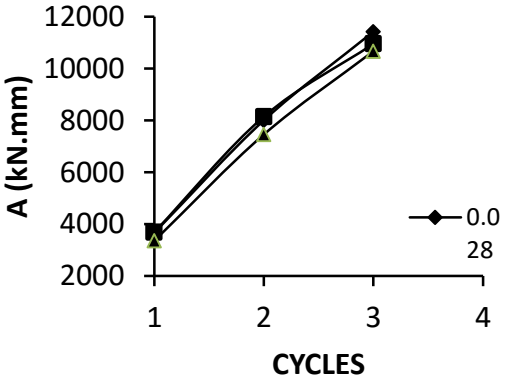

Figure 17: predicted dissipation capacity for different shear strain rates (0.028; 0.021; 0.017)

Furthermore, comparing numerical results obtained for various shear strain rates, it can be concluded that the model predicts a slight decrease in dissipation capacity with the strain rate decrease. This is visualized in Figure 17 which shows an estimate of the dissipation capacity based on results of three finite element simulations. For the three simulations the maximum imposed shear strain is the same whereas the shear strain rate differs.

7 CONCLUSIONS

- This paper presents preliminary results of the study of mechanical response of bearing devices used in passive seismic isolation carried out at the Earthquake Engineering Research Center of the University of Iceland. The study will be further extended by experimental investigation in order to furnish relevant data for model validation.
- Lead-core bearing is modelled as a multiple component system. Appropriate constitutive laws and failure criteria are defined for each material: lead, rubber and steel.
- An explicit and accurate finite element model of a lead-core bearing device is presented. Results obtained by finite element analysis reproduce the hysteresis response of a lead-core bearing device usually exhibited in a common identification test.
- Results obtained by finite element simulation can be further used as a basis for tuning of an analytical differential equation model (curve fitting) aiming a subsequent implementation of the calibrated single-degree-of freedom model into a numerical models of a damped large-scale structures.

Abstract. *Structural damage identification is a scientific field that has attracted a lot of interest in the scientific community during the recent years. There have been many studies intending to find a reliable method to identify damage in structural elements both in location and extent. Most damage identification methods are based on the changes of dynamic characteristics and static responses, but the incompleteness of the test data is a great obstacle for both. In this paper, the performance of different modal correlation criteria in structural damage identification is investigated. The structural damage identification problem is treated as an optimization problem which is solved using the differential evolution search algorithm. The objective functions used in the optimization process are based on different modal correlation criteria, providing a measure of consistency and correlation between estimations of modal vectors. The performance of each of the objective functions is evaluated by a number of damage scenarios for a simply supported beam. Although the results of the various criteria on the different damage scenarios vary, it is clearly shown that some modal correlation criteria exhibit excellent performance in detecting the structural damage even in the case of strong incompleteness of the modal data.*

1. INTRODUCTION

Structural damage identification has drawn increasing academic literature, as witnessed by the number of relevant journal and conference papers, during the recent years. There have been many studies intending to find a reliable method to identify damage in structural elements both in location and extent [1]. Most damage identification techniques are based on the changes of dynamic characteristics and static responses, but the incompleteness of the test data is a great obstacle for both.

Generally speaking, the existing methods of damage identification techniques based on modal testing can be clarified into two major categories: direct and inverse methods. The direct methods utilize the change in modal measurement to instantly detect structural damage without the need of iterative computational procedures. In contrast, the second category of damage identification techniques poses the whole process as inverse problems [2-9], in which the structural damage is identified via optimizing the correlation between the theoretical and the experimental modal parametric change, respectively. In order to determine the level of correlation between the measured and the predicted natural frequencies or mode shapes modal correlation criteria are used as a simple mathematical tools, providing a measure of consistency and correlation between estimations of modal vectors.

In this paper, the performance of different modal correlation criteria in structural damage identification is investigated. The structural damage identification problem is treated as an optimization problem which is solved using the differential evolution optimization algorithm. The objective functions used in the optimization process are based on different modal correlation criteria to identify the location and the extent of structural damage. The performance of each of the objective functions is evaluated in a number of damage scenarios for a simply supported beam. It is shown that the results of the different modal correlation criteria vary, while certain criteria exhibit excellent performance in detecting the structural damage even in the case of strong incompleteness of the modal data.

2. STRUCTURAL DAMAGE IDENTIFICATION

The problem of damage identification is classified into four levels [10]: (A) detection, (B) localization, (C) quantification, and (D) prediction of future damage (damage prognosis). At the level of damage detection (Level A), the existence of damage can be detected, while its location and severity are unknown. Information about location of the damage can be provided by localization techniques at Level B. At the damage quantification level (Level C), both the location and severity of damage are estimated. Finally, at the prediction level (Level D), the remaining life of the structure is estimated based on the (identified) current damage state and future loads and damage propagation. This study reaches the third level of damage identification, which means it investigates the ability to detect, localize as well as estimate the severity of damage in structures.

It is proven that changes in the dynamic characteristics of a structure are related to damage occurrence. Specifically changes in the modal parameters, namely natural frequencies and mode shapes, can provide an accurate indication of damage in a structure. Since modal parameters are dependent on the physical properties of the structure, i.e. stiffness and mass, the FEM may be used as a tool for locating and quantifying damaged elements in a structure through the update of modal parameters, even in large-scale structures.

2.1. Damage identification model

If a structure is properly modeled using the FEM, structural damage mathematically affects its stiffness and physically its dynamic properties, such as natural frequencies and mode shapes [11]. It can be assumed that the global mass matrix remains the same in both the undamaged and the damaged structure. This assumption is considered quite accurate for the majority of real applications. The eigenvalue problem of a structure with n active degrees of freedom (DOFs) can be written as follows:

$$\left(\mathbf{K} - \omega_{(i)}^2 \mathbf{M}\right)\left\{\boldsymbol{\varphi}^{(i)}\right\} = 0, \quad i = \{1,\ 2, \ldots,\ m\} \tag{1}$$

where $\mathbf{K}$ is the global stiffness matrix of the structure ([$n \times n$]), $\mathbf{M}$ is the global mass matrix ([$n \times n$]), $\{\boldsymbol{\varphi}^{(i)}\}$ is the i-th natural mode vector of the structure ([$n \times 1$]) corresponding to the $\omega_{(i)}$ natural frequency and m is the total number of natural modes to be obtained ($m \leq n$).

Eq. (1) forms the basis of the damage identification method used in the present study. An inverse procedure is used, where the natural frequencies and natural modes of the damaged structure are measured and they are supposed to be known quantities (to a certain extent), while the damage of the structure is unknown and needs to be calculated through an optimization procedure.

2.2. Modal correlation criteria

We consider two structures A and B with n active degrees of freedom (DOFs) each, with eigenvalues $\lambda_{A(i)} = \omega_{A(i)}^2$ and $\lambda_{B(i)} = \omega_{B(i)}^2$, natural frequencies $\omega_{A(i)}$ and $\omega_{B(i)}$ ($i = 1, 2, \ldots, m$), where m is the total number of natural modes obtained ($m \leq n$). The corresponding mode shape vectors are $\{\boldsymbol{\varphi}^{(i)}\}$ and $\{\boldsymbol{\psi}^{(i)}\}$ ([$n \times 1$] each), for structures A and B, respectively.

In order to compare two sets of values for the two structures, the use of modal correlation criteria is imperative. The following criteria have been used in this study, as useful mathematical tools providing a measure of consistency and correlation between estimations of modal vectors:

1. The Modal Assurance Criterion (MAC)
2. The Modified Total Modal Assurance Criterion (MTMAC)
3. The Co-ordinate Modal Assurance Criterion (CoMAC)
4. The Modal Flexibility Assurance Criterion (MACFLEX)

An example of two structures

In the next sections we will show the mathematical formulation of each criterion and also provide numerical values for a given example of two structures, for better comprehension and in order to exhibit the different criteria used. We consider two example structures, A and B. Each structure has $n = 9$ active DOFs and up to $m = 4$ eigenvalues and eigenmodes are taken into consideration (are supposed to be known, for both structures A and B).

Structures A and B correspond to the example which is examined in the numerical results section of the present study. Specifically, Structure A is the structure of the example with no damage, while Structure B is the same structure but in a damaged state where the damage vector is [0.0, 0.0, 0.0, 0.2, 0.3, 0.4, 0.6, 0.6, 0.3, 0.0], i.e. damage 20%, 30%, 40%, 60%, 60%, 30% at the 4^{th}, 5^{th}, 6^{th}, 7^{th}, 8^{th}, 9^{th} element, respectively. The eigenproperties of structures A and B are shown in Table 1 and Table 2. Figure 1 shows the four eigenmodes of the two structures.

2.2.1. The Modal Assurance Criterion (MAC)

The Modal Assurance Criterion (MAC) [12, 13] is one of the most popular tools for the quantitative comparison of modal vectors. The purpose of this criterion is to indicate the correlation between two sets of natural modes. Considering two mode shapes vectors $\{\boldsymbol{\varphi}^{(i)}\}$ ([n×1]) and $\{\boldsymbol{\psi}^{(j)}\}$ ([n×1]), for structures A and B, respectively, the term MAC_{ij} of the **MAC** matrix ([m×m]) is given by:

$$MAC_{ij} = \frac{\left(\{\varphi^{(i)}\}^T\{\psi^{(j)}\}\right)^2}{\left(\{\varphi^{(i)}\}^T\{\varphi^{(i)}\}\right)\left(\{\psi^{(j)}\}^T\{\psi^{(j)}\}\right)}, \quad i, j = \{1,\ 2,\ldots,\ m\} \tag{2}$$

or

$$MAC_{ij} = \frac{\left(\sum_{k=1}^{n}\varphi_k^{(i)}\psi_k^{(j)}\right)^2}{\sum_{k=1}^{n}\left[\left(\varphi_k^{(i)}\right)^2\right]\cdot\sum_{k=1}^{n}\left[\left(\psi_k^{(j)}\right)^2\right]}, \quad i, j = \{1,\ 2,\ldots,\ m\} \tag{3}$$

MAC_{ij} takes values from zero, representing no consistent correspondence, to one, representing a consistent correspondence between the two mode shapes vectors. In this manner, if the modal vectors under consideration, $\{\boldsymbol{\varphi}^{(i)}\}$ and $\{\boldsymbol{\psi}^{(j)}\}$, truly exhibit a consistent relationship, the modal assurance criterion element MAC_{ij} approaches unity. By calculating MAC_{ij} for all i, j = {1, 2,…, m} we obtain the **MAC** matrix. In our example, considering all four eigenmodes, we obtain:

$$\mathbf{MAC}(\mathrm{A},\mathrm{A}) = \mathbf{MAC}(\mathrm{B},\mathrm{B}) = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{4}$$

$$\mathbf{MAC}(\mathrm{A},\mathrm{B}) = \mathbf{MAC}(\mathrm{B},\mathrm{A})^T = \begin{bmatrix} 0.9950 & 0.0049 & 0.0001 & 0.0000 \\ 0.0049 & 0.9853 & 0.0077 & 0.0018 \\ 0.0000 & 0.0082 & 0.9765 & 0.0107 \\ 0.0001 & 0.0009 & 0.0121 & 0.9609 \end{bmatrix} \tag{5}$$

If we consider a lower number of eigenmodes *m*, then the size of the MAC matrix decreases accordingly but in any case, it corresponds to the upper left part of the above full matrix (which corresponds to 4 eigenmodes). In other words, the above matrix contains (as sub-matrices) the [1×1], [2×2], [3×3] **MAC** matrices that would have been calculated for a lower number of known eigenmodes (1, 2 or 3, respectively).

$\mathbf{\hat{MAC}}$ ([1×*m*]) is a vector holding the diagonal terms of **MAC** matrix and it can be easily calculated by setting $i = j$ in Eq. (2) or Eq. (3). $\mathbf{\hat{MAC}}$ is a vector with as many values as the number of known eigenmodes (*m*). In our example, considering all four eigenmodes, we obtain:

$$\mathbf{\hat{MAC}}(\mathrm{A},\mathrm{A}) = \mathbf{\hat{MAC}}(\mathrm{B},\mathrm{B}) = \begin{bmatrix} 1 & 1 & 1 & 1 \end{bmatrix} \tag{6}$$

$$\mathbf{\hat{MAC}}(\mathrm{A},\mathrm{B}) = \mathbf{\hat{MAC}}(\mathrm{B},\mathrm{A}) = \begin{bmatrix} 0.9950 & 0.9853 & 0.9765 & 0.9609 \end{bmatrix} \tag{7}$$

By multiplying the *m* individual values of the $\mathbf{\hat{MAC}}$ vector, we obtain the final *MAC* scalar value as follows:

$$MAC = \prod_{i=1}^{m} \hat{\mathrm{MAC}}_i \tag{8}$$

The table below shows the values of *MAC* for various values of the number of known eigenmodes, for our example.

No of known modes	**1**	**2**	**3**	**4**
MAC(A, B)	0.9950	0.9803	0.9573	0.9199

Table 3. *MAC* values for 1, 2, 3 or 4 known eigenmodes.

2.2.2. The modified total modal assurance criterion (MTMAC)

One limitation of the MAC criterion is that it does not take into account the eigenvalues of the different mode shapes of the structures. It takes into account only the eigenvectors, but not the eigenvalues. This means that in case of uniform damage, the MAC criterion will not be able to detect any change, as in this case, the structure becomes more flexible (the eigenperiod increases), but there is no difference in the eigenvectors which remain the same as before. The natural frequencies provide global information of the structure and they can be accurately identified through dynamic measurements.

Another criterion, the modified total modal assurance criterion (MTMAC) [14], is based on the MAC criterion but it takes also the eigenvalues into account. The MTMAC vector $\mathbf{MT\hat{M}AC}$ ([1×*m*]) is defined as follows:

$$\mathrm{MT\hat{M}AC}_i = \frac{\mathrm{M\hat{A}C}_i}{1+\left|\dfrac{\omega_{A(i)}^2 - \omega_{B(i)}^2}{\omega_{A(i)}^2 + \omega_{B(i)}^2}\right|}, \quad i = \{1,\ 2, \ldots,\ m\} \tag{9}$$

It should be noted that the MTMAC can be easily defined also as a matrix ([*m*×*m*]), whose diagonal is again the $\mathbf{MT\hat{M}AC}$ vector, as was the case with MAC. $\mathbf{MT\hat{M}AC}$ is a row vector with as many values as the number of natural modes considered (*m*). In our example, considering all four eigenmodes:

$$\mathbf{MT\hat{M}AC}(\mathrm{A,A}) = \mathbf{MT\hat{M}AC}(\mathrm{B,B}) = \begin{bmatrix} 1 & 1 & 1 & 1 \end{bmatrix} \tag{10}$$

$$\mathbf{MT\hat{M}AC}(\mathrm{A,B}) = \mathbf{MT\hat{M}AC}(\mathrm{B,A}) = \begin{bmatrix} 0.7889 & 0.8220 & 0.8395 & 0.8195 \end{bmatrix} \tag{11}$$

By multiplying the *m* individual values of the $\mathbf{MT\hat{M}AC}$ vector, we obtain the *MTMAC* scalar value as follows:

$$MTMAC = \prod_{i=1}^{m} \mathrm{MT\hat{M}AC}_i \tag{12}$$

The table below shows the values of *MTMAC* for various values of the number of known eigenmodes, for our example.

No of known modes	**1**	**2**	**3**	**4**
MTMAC(A, B)	0.7889	0.6484	0.5444	0.4461

Table 4. *MTMAC* values for 1, 2, 3 or 4 known eigenmodes.

2.2.3. The co-ordinate modal assurance criterion (CoMAC)

In the comparison of two sets of modal vectors, one of the issues of interest is the influence of individual DOFs on the vector resemblance. The spatial dependence of the MAC correlation criterion can be misleading. The co-ordinate modal assurance criterion (CoMAC) [15] is an extension of the modal assurance criterion which is used to detect differences between two modal vectors at the DOF level. It is basically a row-wise correlation of two sets of compatible vectors, while in MAC this is done column-wise.

Although we can also define a **COMAC** matrix ([*n*×*n*]), in the same way as we defined **MAC** earlier, this time we will go straight to the definition of the $\mathbf{CO\hat{M}AC}$ vector ([1×*n*]) which is most relevant and important. The off-diagonal terms of **MAC** were the ones giving the relationship between different mode shape vectors of the two structures, for example the element (2, 1) of **MAC** is the one which gives the relationship between the 2nd eigenmode of structure A and the 1st eigenmode of structure B. In the case of **COMAC**, in a similar manner, the off-diagonal terms are the ones giving the relationship between different DOFs of the two structures. For example the element (2, 1) of **COMAC** is the one which gives the relationship

between the 2nd DOF of structure A and the 1st DOF of structure B, for the various eigenvectors considered.

Hence, the $\mathbf{COM\hat{A}C}$ for the k-th DOF of the structure (k = 1, 2,…, n) is defined as follows:

$$\mathrm{COM\hat{A}C}_k = \frac{\left(\sum_{i=1}^{m}\left|\varphi_k^{(i)}\psi_k^{(i)}\right|\right)^2}{\sum_{i=1}^{m}\left[\left(\varphi_k^{(i)}\right)^2\right]\cdot\sum_{i=1}^{m}\left[\left(\psi_k^{(i)}\right)^2\right]}, \quad k=\{1,\ 2,\ldots,\ n\} \tag{13}$$

Unlike the MAC, the COMAC can compare modes that are close in frequency by detecting local differences between two sets of modal vectors. It does not identify modeling errors, because their location can be different from the areas where their consequences are felt. Another limitation is the fact that COMAC weights all DOFs equally, irrespective of their magnitude in the modal vector.

By calculating $\mathrm{COM\hat{A}C}_k$ for all k = {1, 2,…, n} we obtain the $\mathbf{COM\hat{A}C}$ vector ([1×n]). In case of full consistency between $\{\boldsymbol{\varphi}^{(i)}\}$ and $\{\boldsymbol{\psi}^{(i)}\}$ ($\{\boldsymbol{\varphi}^{(i)}\}=\{\boldsymbol{\psi}^{(i)}\}$ for all i = {1, 2,…, m}), all elements of the $\mathbf{COM\hat{A}C}$ vector will be equal to 1. By multiplying the n individual values of the $\mathbf{COM\hat{A}C}$ vector, we obtain the *COMAC* scalar value as follows:

$$COMAC = \prod_{i=1}^{n}\mathrm{COM\hat{A}C}_i \tag{14}$$

In our example:

$$\mathbf{COM\hat{A}C}(\mathrm{A},\mathrm{A}) = \mathbf{COM\hat{A}C}(\mathrm{B},\mathrm{B}) = \begin{bmatrix}1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1\end{bmatrix}^T \tag{15}$$

The table below shows the values of the various elements of $\mathbf{COM\hat{A}C}$ vector together with the corresponding values of *COMAC* scalar, for various values of the number of known eigenmodes, for our example.

No of known modes	**1**	**2**	**3**	**4**
1st DOF	1.0000	0.9999	0.9997	0.9997
2nd DOF	1.0000	0.9995	0.9979	0.9905
3rd DOF	1.0000	0.9970	0.9804	0.9509
4th DOF	1.0000	0.9850	0.9623	0.9754
5th DOF	1.0000	0.9678	0.9837	0.9421
6th DOF	1.0000	0.9892	0.9760	0.9814
7th DOF	1.0000	0.9987	0.9934	0.9906
8th DOF	1.0000	0.9991	0.9993	0.9992
9th DOF	1.0000	0.9980	0.9983	0.9990
COMAC	**1.0000**	**0.9356**	**0.8955**	**0.8395**

Table 5. $\mathbf{COM\hat{A}C}$ (A, B) and corresponding *COMAC* scalar value for 1, 2, 3 or 4 known eigenmodes.

2.2.4. The modal flexibility assurance criterion (MACFLEX)

It is well known that damage affects the stiffness matrix of the structure and more specifically it reduces the stiffness of the individual damaged elements. A reduction in stiffness is equivalent to an increase in the structural flexibility.

Flexibility matrix

In structural health monitoring it is advantageous to use changes in flexibility as an indicator of damage rather than using stiffness perturbations. This is due to the following reasons [16]:

1. The flexibility matrix is dominated by the lower modes and so good approximations can be obtained even when only a few lower modes are employed.
2. The flexibility matrices are directly attainable through the modes and mode shapes, determined by the system identification process.
3. Iterative algorithms usually converge the fastest to high eigenvalues.
4. In flexibility-based methods, these eigenvalues correspond to the dominant low-frequency components in structural vibrations.

Therefore, the dynamically measured flexibility matrix which is calculated from the identified modal parameters, can be used as a damage identification measure [7]. The flexibility matrix $\mathbf{F}_A$ ([$n \times n$]) for structure A is given by

$$\mathbf{F}_A = \mathbf{\Phi} \cdot \mathbf{\Lambda}_A^{-1} \cdot \mathbf{\Phi}^T \tag{16}$$

where $\mathbf{\Phi}$ is a matrix ([$n \times m$]) containing all the m mode shape vectors $\{\boldsymbol{\varphi}^{(i)}\}$ ([$n \times 1$] each) and $\mathbf{\Lambda}_A$ is a diagonal matrix ([$m \times m$]) which holds the eigenvalues $\lambda_{A(i)} = \omega_{A(i)}^2$ (i = 1, 2,…, m) on its diagonal. The individual elements of matrix $\mathbf{F}_A$ can also be obtained separately using the following formula:

$$F_{A,ij} = \sum_{k=1}^{m} \frac{1}{\omega_{(k)}^2} \varphi_k^{(i)} \varphi_k^{(j)} \tag{17}$$

The two figures below, show graphical representations of the flexibility matrices $\mathbf{F}_A$ and $\mathbf{F}_B$ of the two structures of our example, for 1 and for 4 known eigenmodes, respectively.

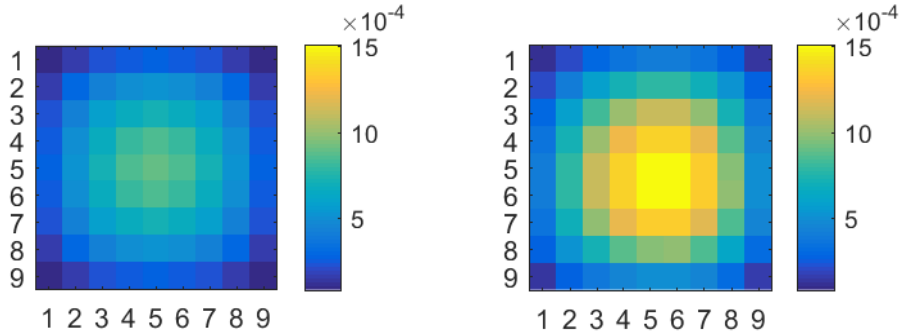

Figure 2. Flexibility matrices for structure A (left) and B (right), for one known eigenmode.

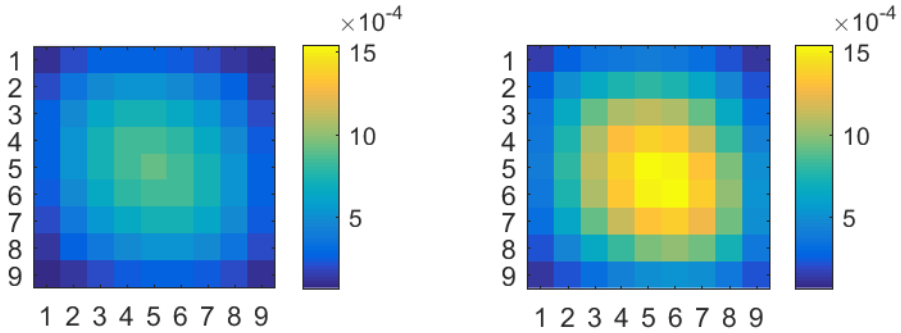

Figure 3. Flexibility matrices for structure A (left) and B (right), for 4 known eigenmodes.

Each column of the flexibility matrix represents the displacement pattern of a structure associated with a unit force applied to the associated degree of freedom. As shown in Eq. (17), as the value of frequency decreases (i.e. the eigenperiod increases) the modal contribution to the flexibility matrix increases also. As a result, a good estimate of the flexibility matrix can be calculated with a small number of the first low-frequency modes, which is also evidenced in the two figures above.

The MACFLEX criterion definition

In order to compare the values of the flexibility matrix of the two structures A and B, the modal flexibility assurance criterion (MACFLEX) is applied. The individual elements of the $\mathbf{MAC\hat{F}LEX}$ vector ([1×n]) can be calculated as follows:

$$\mathrm{MAC\hat{F}LEX}_i = \frac{\left(\hat{\mathbf{F}}_{\mathrm{A}}^{(i)T}\hat{\mathbf{F}}_{\mathrm{B}}^{(i)}\right)^2}{\left(\hat{\mathbf{F}}_{\mathrm{A}}^{(i)T}\hat{\mathbf{F}}_{\mathrm{A}}^{(i)}\right)\left(\hat{\mathbf{F}}_{\mathrm{B}}^{(i)T}\hat{\mathbf{F}}_{\mathrm{B}}^{(i)}\right)} \tag{18}$$

where $\hat{\mathbf{F}}_{\mathrm{A}}^{(i)}$ and $\hat{\mathbf{F}}_{\mathrm{B}}^{(i)}$ are the i-th column vectors ([n×1]) of the flexibility matrices $\mathbf{F}_{\mathrm{A}}$ and $\mathbf{F}_{\mathrm{B}}$, for structures A and B, respectively. $\mathbf{MAC\hat{F}LEX}$ is a vector with as many values as the number of columns in the flexibility matrices. Again, we could consider a full **MACFLEX** matrix by taking different vectors into account, instead of the i-th vector for both structures, but there is no point in that as again the diagonal terms of the **MACFLEX** matrix are the important ones.

By multiplying the n individual values of the $\mathbf{MAC\hat{F}LEX}$ vector, we obtain the *MACFLEX* scalar value as follows:

$$MACFLEX = \prod_{i=1}^{n} \mathbf{MAC\hat{F}LEX}_i \tag{19}$$

In our example, for any number of known modes (1, 2, 3 or 4), it is:

$$\mathbf{MAC\hat{F}LEX}(\mathrm{A},\mathrm{A}) = \mathbf{MAC\hat{F}LEX}(\mathrm{B},\mathrm{B}) = \begin{bmatrix}1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1\end{bmatrix} \tag{20}$$

However, the $\mathbf{MAC\hat{F}LEX}(\mathrm{A},\mathrm{B})$ = $\mathbf{MAC\hat{F}LEX}(\mathrm{B},\mathrm{A})$ vector changes depending on the number of the known eigenmodes, as shown in the table below (shown as the transpose, in column format).

No of known modes	1	2	3	4
1st DOF	0.9950	0.9929	0.9932	0.9933
2nd DOF	0.9950	0.9936	0.9939	0.9939
3rd DOF	0.9950	0.9947	0.9948	0.9948
4th DOF	0.9950	0.9957	0.9956	0.9956
5th DOF	0.9950	0.9963	0.9962	0.9962
6th DOF	0.9950	0.9965	0.9965	0.9965
7th DOF	0.9950	0.9967	0.9967	0.9967
8th DOF	0.9950	0.9972	0.9973	0.9973
9th DOF	0.9950	0.9978	0.9980	0.9979
MACFLEX	**0.9557**	**0.9621**	**0.9628**	**0.9629**

Figure 4 shows the values of MTMAC and MACFLEX criteria for different number of known eigenmodes (1, 2, 3 or 4), for our example.

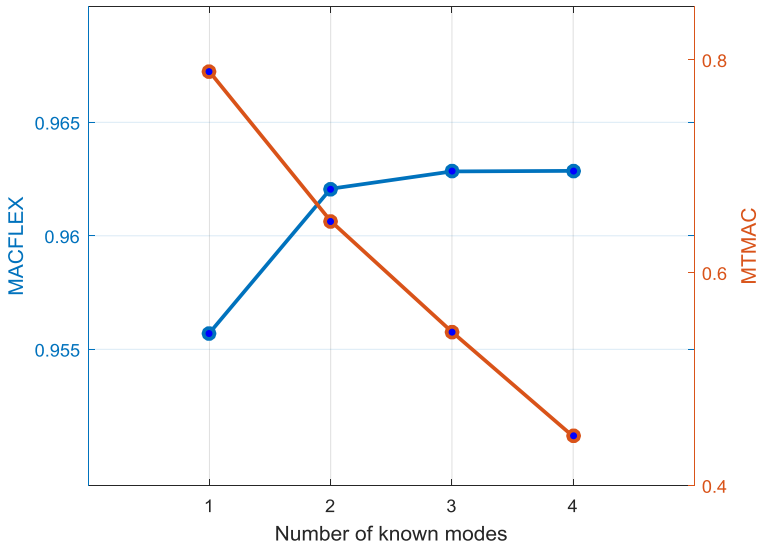

Figure 4. Comparison of *MACFLEX* and *MTMAC* scalar values for 1, 2, 3, and 4 known eigenmodes.

3. DAMAGE IDENTIFICATION AS AN OPTIMIZATION PROBLEM

3.1. Problem formulation

Setting-up an objective function, selecting the updating parameters and using robust optimization algorithms are three crucial steps in structural identification. They require deep physical insight and usually trial-and-error procedures have to be used. In our case, the damage identification problem is considered as an unconstrained optimization problem where the design variables denote the extent of damage of every single element of the structure. In this sense, the number of design variables is equal to the number of elements in the structure. Single beam elements are used to represent the structure of the numerical example. It has been assumed that no alteration occurs before and after damage related to the mass, which is acceptable in most real applications. Therefore, the parameterization of the damage has been represented by a reduction factor or damage index of the element bending stiffness. This damage index, d_e, for a damaged element e represents the relative variation of the damaged element bending stiffness, $(EI)_{e,d}$ to the initial (undamaged) bending stiffness $(EI)_e$, as follows:

$$d_e = 1 - \frac{(EI)_{e,d}}{(EI)_e} \tag{21}$$

This definition of a damage index for each element of the structure allows estimating not only the damage extent but also the damage location since the damage identification is carried out at the element level. The damage index can take values between 0 (no damage) and 1 (100% damage, no stiffness), although for numerical stability purposes, the maximum damage has to be limited to a value slightly below 1 (i.e. 0.999) or the structure can become a mechanism that cannot be analyzed and numerical instabilities will occur.

The objective function has to reflect the deviation between the numerical prediction and the real behavior of the structure. For this reason, an objective function may be formulated in terms of the discrepancy between FE and experimental quantities. The following four objective functions have been considered in this study, corresponding to the four different modal correlation criteria (MAC, MTMAC, CoMAC and MACFLEX respectively) between the real damage (according to each examined damage scenario) and the damage which is estimated by the finite element model:

- $F_1 = 1 - \text{MAC}$
- $F_2 = 1 - \text{MTMAC}$
- $F_3 = 1 - \text{COMAC}$
- $F_4 = 1 - \text{MACFLEX}$

The minimum value (target value) for each objective function is zero. At this point it has to be noted that in real life, the dynamics properties (eigenvalues and eigenmodes) of the real damaged structure would have to be determined (measured) by experiment. In our case, these properties are also calculated numerically using a FE "real damage" model, which is perfectly acceptable for the purposes of the present study and does not cause any problems or limitations to the procedure.

3.2. The differential evolution algorithm

Choosing the proper search algorithm for solving an optimization problem is not a straightforward procedure. In the past a number of studies have been published where structural optimization are solved using the metaheuristic search algorithms and especially those based on

adopting Darwinian principles of evolutionary process. These algorithms achieve efficient performance for a wide range of combinatorial optimization problems. Among the plethora of such algorithms, the differential evolution (DE) algorithm is adopted in this study to solve the optimization problem of Section 3.1.

Differential evolution (DE) is a stochastic population-based evolutionary algorithm for global optimization, introduced by Storn & Price [17]. It follows the standard evolutionary algorithm flow with some significant differences in mutation and selection process. The simplicity of DE algorithm is based on only three tunable parameters, the mutation factor $F \in [0,2]$, the crossover probability $CR \in [0,1]$ and the total number or particles (population size) *NP*. The fundamental idea behind DE is the use of vector differences by choosing randomly selected vectors, and then taking their difference as a means to perturb the parent vector with a special kind operator and probe the search space. Several variants of DE have been proposed so far [18], but this study is focused on the nominal approach (DE/rand/1/bin). According to this, each of the members of the population undergoes mutation and crossover. Once crossover occurs, the offspring is compared to the parent, and whichever fitness is better moves to the next generation (selection process). In more detail:

We consider an optimization problem with *D* dimensions. First, all individuals $\boldsymbol{x}$ are initialized at random positions in the search-space. After initialization each member of the population $\boldsymbol{x}$ undergoes mutation and a donor vector $\boldsymbol{v}$ is generated such as:

$$\boldsymbol{v} = \boldsymbol{a} + F \cdot (\boldsymbol{b} - \boldsymbol{c}) \tag{22}$$

where $\boldsymbol{a}$, $\boldsymbol{b}$ and $\boldsymbol{c}$ are three individuals from the population at random, which must be distinct from each other as well as from individual $\boldsymbol{x}$ ($\boldsymbol{x} \neq \boldsymbol{a} \neq \boldsymbol{b} \neq \boldsymbol{c}$).

In the next step the crossover operator is applied by generating the trial vector $\boldsymbol{u}$ which is defined either from the *i*-th component (v_i) of $\boldsymbol{v}$ or the *i*-th component (x_i) of $\boldsymbol{x}$, with probability *CR* as follows:

$$u_i = \begin{cases} v_i & \text{if } r_i \leq CR \text{ or } i = R \\ x_i & \text{otherwise} \end{cases} \qquad i = \{1, 2, ..., D\} \tag{23}$$

where r_i is a random number with uniform distribution, $r_i \in U[0,1]$, and *R* is a random integer in [1, 2, …, *D*] which ensures that in any case, after the crossover operation it is $\boldsymbol{u} \neq \boldsymbol{x}$. The last step of the generation procedure is the implementation of the selection operator where the target vector $\boldsymbol{x}$ is compared to the trial vector $\boldsymbol{u}$. If the trial vector $\boldsymbol{u}$ has a better fitness value, then the individual $\boldsymbol{x}$ is replaced in the population with the trial vector $\boldsymbol{u}$ as follows:

$$\boldsymbol{x}' = \begin{cases} \boldsymbol{u} & \text{if } f(\boldsymbol{u}) < f(\boldsymbol{x}) \\ \boldsymbol{x} & \text{otherwise} \end{cases} \tag{24}$$

where *f* is the objective function to be minimized and $\boldsymbol{x}'$ is the new design vector for the next generation. The optimization procedure finished when the maximum number of generations has been reached.

4. NUMERICAL EXAMPLES

A simply supported beam [19] is analyzed in this section to illustrate the performance of the proposed methodology and the different criteria. The geometry, boundary conditions and finite element mesh of the beam are shown in Figure 5. The beam has a total length of 6 m and it is discretized by 10 equal length beam elements of rectangular cross section b (width) x h (height)

= 0.25 m × 0.20 m. The beam is considered to have a Young's modulus E equal to 30 GPa and a density ρ equal to 2500 kg/m^3.

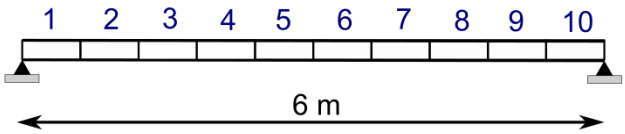

Figure 5. The beam structure under investigation.

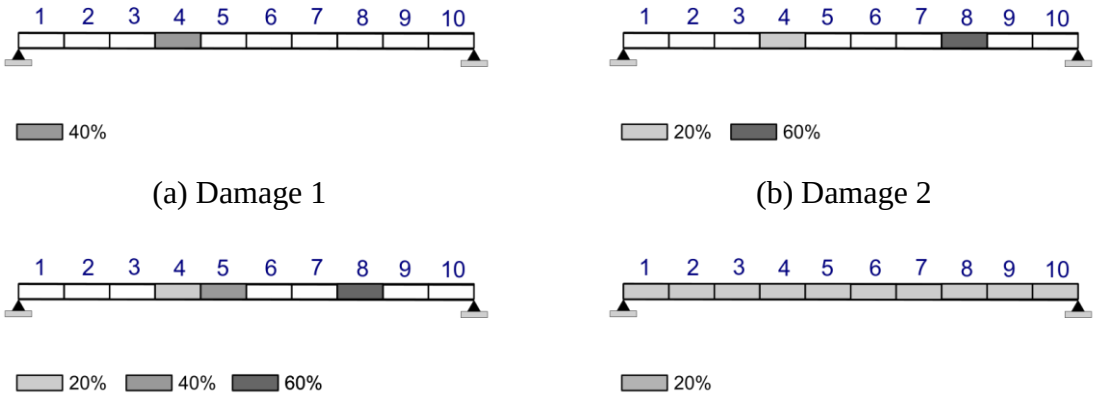
The parameters of the DE optimization problem are the following:

- D = 10 (dimension of the problem)
- NP = 40 (population size)
- F = 0.6 (mutation factor)
- CR = 0.9 (crossover probability)
- MAXGEN = 3000 (maximum numbers of generations)

Four different damage scenarios are considered: (1) A single-element damage scenario (Figure 6a); (2) a two-element damage case (Figure 6b); (3) a three-element damage case (Figure 6c); and (4) a uniform damage case (Figure 6d). The finite element model of the beam is based on Euler–Bernoulli assumption of the planar elements with two degrees of freedom per node (the axial deformation is ignored).



(a) Damage 1 (b) Damage 2

(c) Damage 3 (d) Damage 4

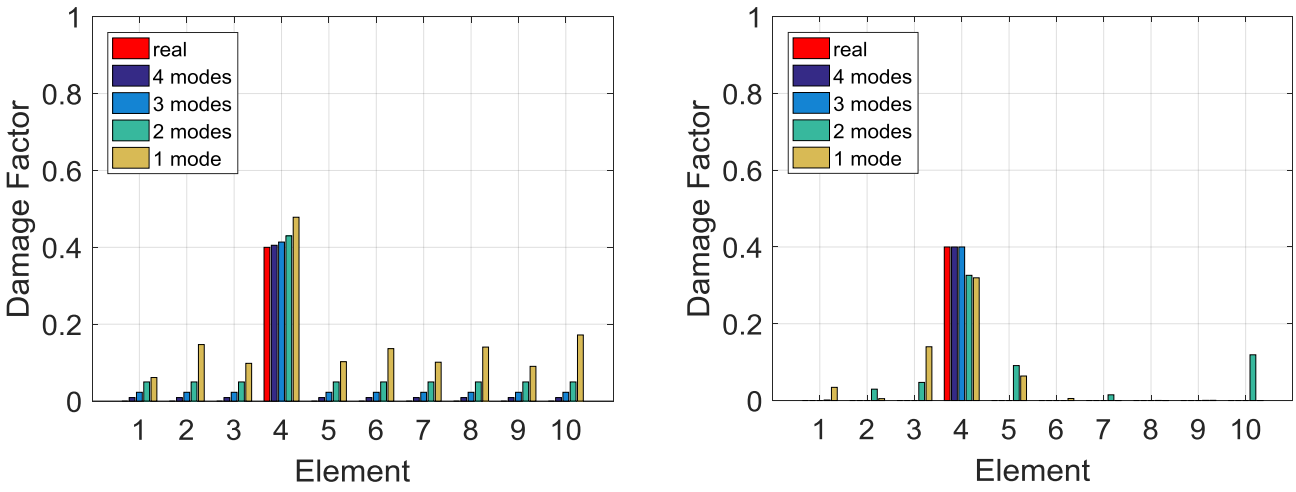
Figure 6. The four different damage scenarios.

4.1. Results

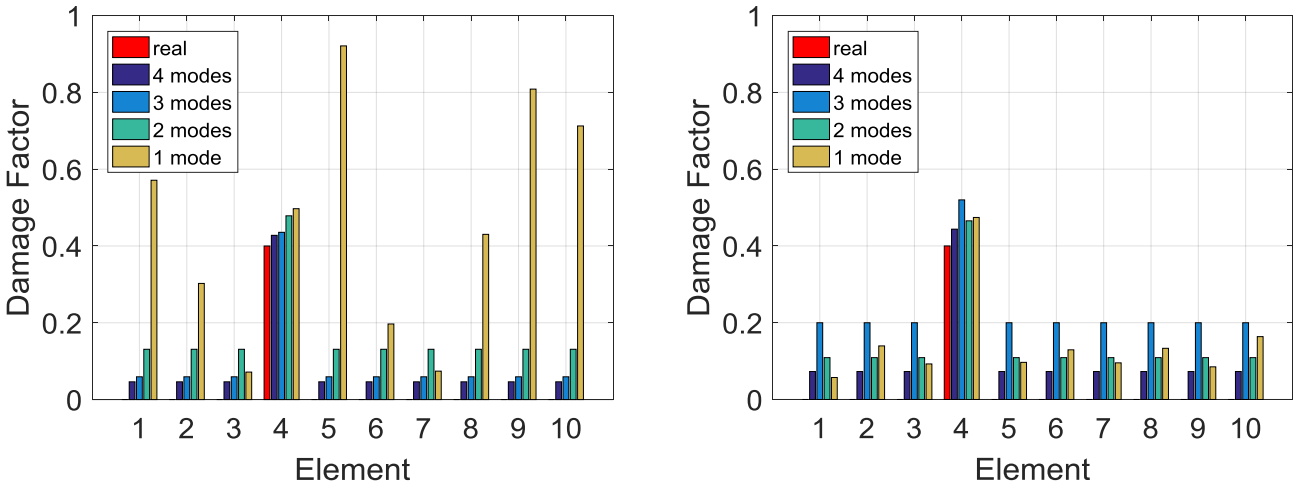
The same optimization algorithm has been applied to all damage scenarios. For each damage scenario, the four different modal correlation criteria have been used for the formulation of the objective function. For each criterion, the number of known eigenmodes varies from 1 to 4. The results are presented in bar charts, where the target damage (real damage) is always denoted in red color and the other colored bars denoted the damage estimation by the optimization procedure.

4.1.1. Damage 1 scenario (single-element damage)

Figure 7 shows the performance of the four different criteria for the first damage scenario. We see that the MTMAC criterion shows very good performance, since it manages to identify the damage almost 100% in the cases where 3 or 4 eigenmodes are known, while a good performance is also recorded for the difficult cases of 2 or even only 1 known eigenmode. The MAC criterion shows also good performance, but again it cannot be compared to the performance of the MTMAC criterion.



(a) MAC (b) MTMAC

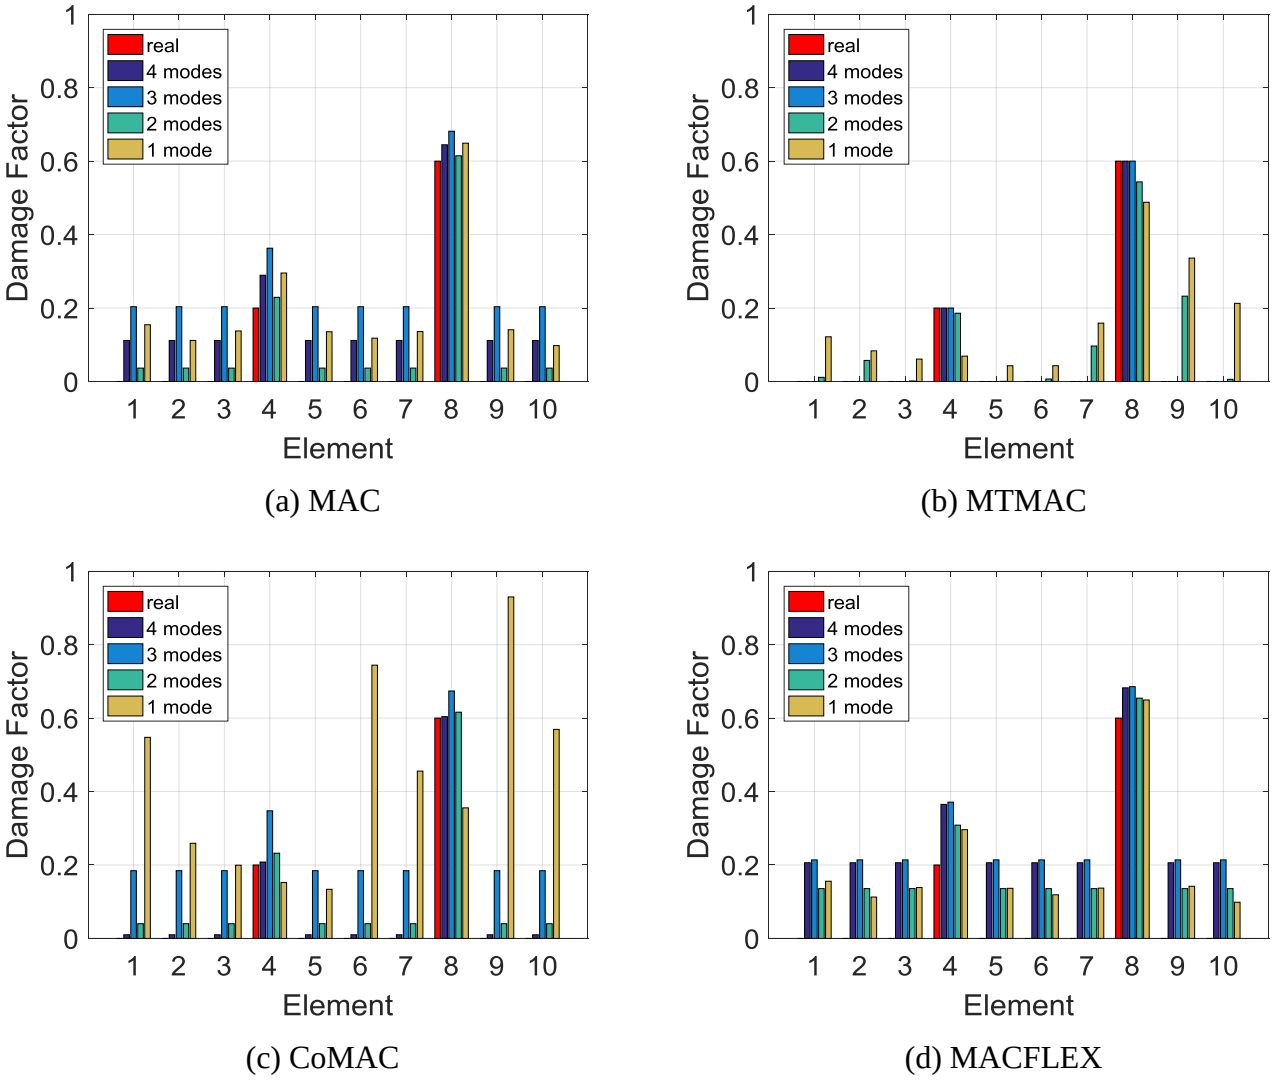


(c) CoMAC (d) MACFLEX

Figure 7. Performance of the four different criteria for the single-element damage scenario (Damage 1).

4.1.2. Damage 2 scenario (two-element damage)

Figure 8 shows the performance of the four different criteria for the second damage scenario. This damage scenario appears to be more difficult than the first one. Again, we see that the MTMAC criterion shows exceptional performance in the cases where 3 or 4 eigenmodes are known. The other criteria appear not to exhibit a very good performance, even in the cases where 4 eigenmodes are known.



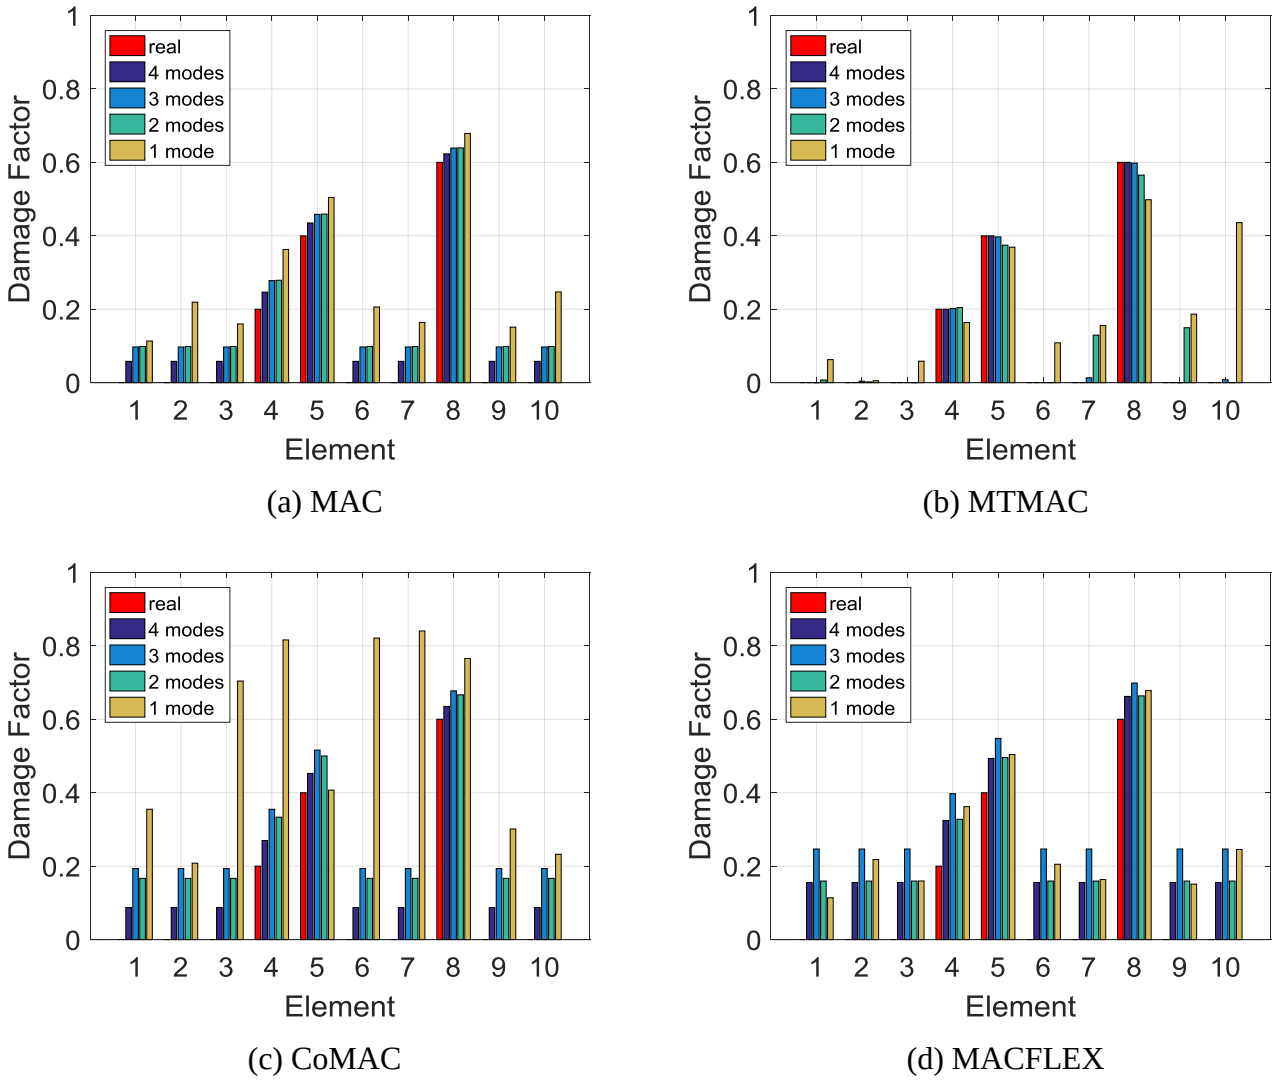
(a) MAC (b) MTMAC

(c) CoMAC (d) MACFLEX

Figure 8. Performance of the four different criteria for the two-element damage scenario (Damage 2).

4.1.3. Damage 3 scenario (three-element damage)

Figure 9 shows the performance of the four different criteria for the third damage scenario. Again the trend is the same. Only the MTMAC shows excellent performance, especially in the cases of 3 or 4 known eigenmodes, while the other criteria fail to identify the location and extent of damage adequately, even in the cases where 4 eigenmodes are known.



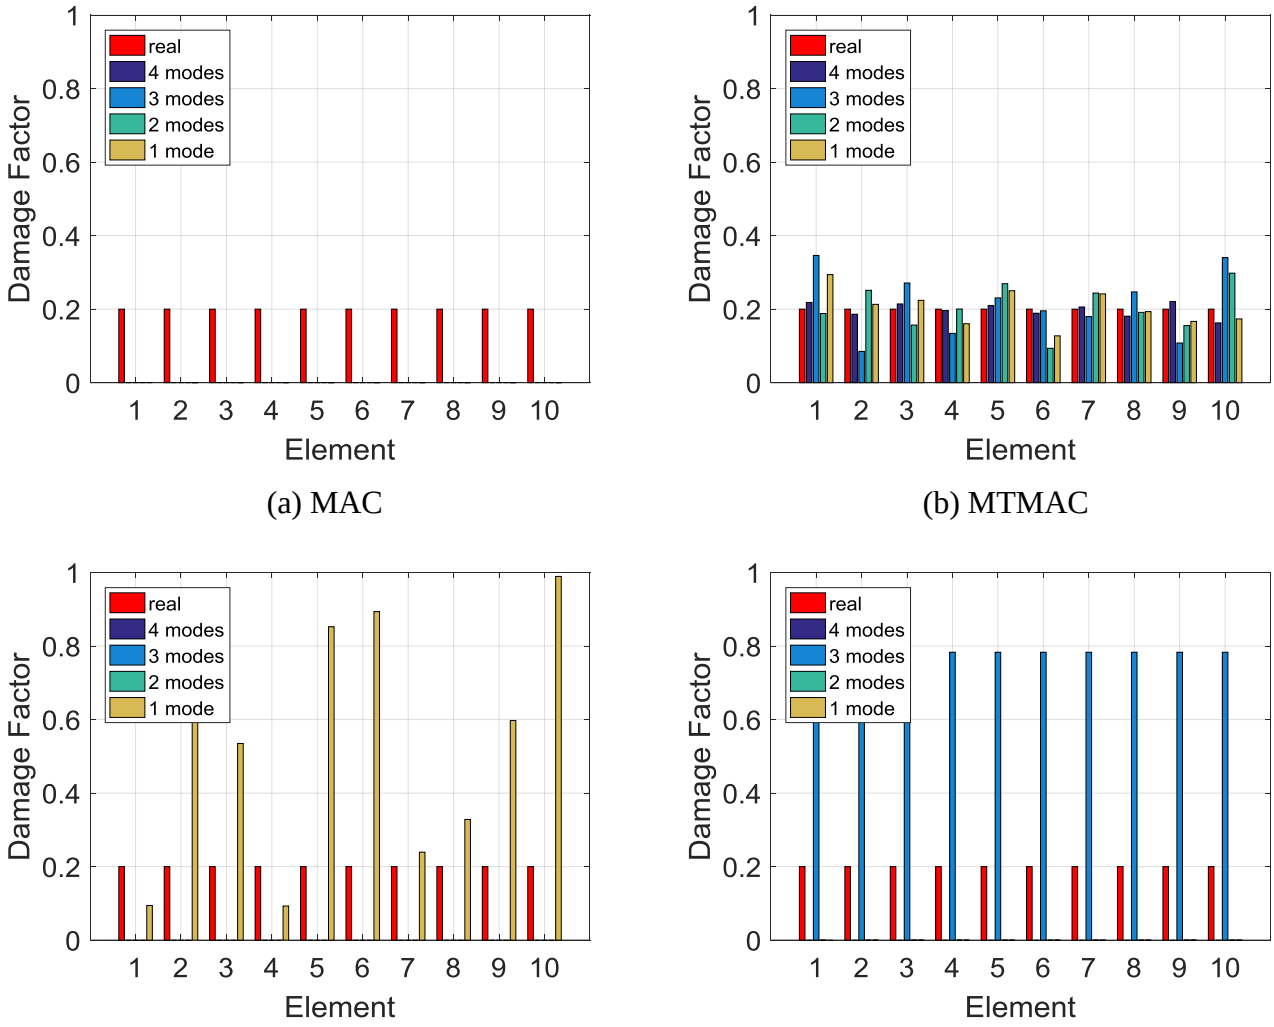
(a) MAC (b) MTMAC

(c) CoMAC (d) MACFLEX

Figure 9. Performance of the four different criteria for the three-element damage scenario (Damage 3).

4.1.4. Damage 4 scenario (uniform damage)

Figure 10 shows the performance of the four different criteria for the last damage scenario. The uniform damage appears to be the most difficult scenario. With the exception of MTMAC, the three other criteria completely fail to identify the location or extent of damage and they seem to just not be working at all. On the other hand, MTMAC shows very good performance when 4 eigenmodes are known, while its performance in the case where 3 eigenmodes are known can be still considered as acceptable. The overall performance of MTMAC is good but it is not as good as in the three other damage scenarios.



(a) MAC (b) MTMAC

(c) CoMAC (d) MACFLEX

Figure 10. Performance of the four different criteria for the uniform damage scenario (Damage 4).

The reason that the other three criteria (MAC, CoMAC and MACFLEX) fail completely is that only the MTMAC criterion contains also information about the eigenvalues (or eigenperiods) of the structure. The other criteria take into account only information about the eigenmodes. It is known that in the special case of uniform damage, the eigenmodes of the structure themselves do not change and the only property that changes is the eigenperiod which becomes larger (the structure becomes more flexible). As a result, only the MTMAC criterion manages to identify this special kind of damage and can be trustworthy for such damage cases.

5. CONCLUSIONS

- In this paper, the performance of different modal correlation criteria in structural damage identification was investigated. The structural damage identification problem was treated as an optimization problem which was solved using the differential evolution optimization algorithm.
- The DE algorithm proved to be very efficient and robust in all cases, while the four correlation criteria exhibited different performances for each damage case.
- In general, the MTMAC criterion showed excellent performance, managing to identify almost 100% the location and extent of damage for all damage cases, when 3 or 4 eigenmodes were known. In the cases were limited data were available (1 or 2 known eigenmodes), this criterion showed also an acceptable performance which was the best among the different criteria.
- The other criteria showed good performance only in some individual damage cases, but their general performance was not reliable, especially when a smaller number of eigenmodes were considered (1, 2 or 3).
- Some damage scenarios were more difficult than others. The most difficult was the uniform damage (4^{th}) scenario. Only the MTMAC criterion managed to give a good estimation for this damage case and again, the quality of the solution was not perfect, even in the case of 4 known eigenmodes.

e-mail: ierimonti@strutture.unipg.it

Keywords: Active Control, Model-Reference Adaptive Control, Multiple Hazards, Multiple Reference Model, Control force.

Abstract. *Flexible structures like tall buildings are often equipped with active control systems which allow the reduction of structural vibration induced by wind and earthquakes. Wind gusts and earthquakes are different in terms of intensity level, frequency and duration of the excitation. In particular, wind induced vibrations are usually moderate and require a continuously operating control system whose main goal is to provide occupants' comfort in serviceability conditions. Conversely, earthquakes of significant intensity are rarely experienced by the structure and may produce structural damage that leads to deterioration in structural stiffness.*
The use of Model-Reference Adaptive Control (MRAC) has recently been considered for structural applications for its capability of dealing with systems's uncertainties and time dependence of parameters. The adaptive controller has two loops: the inner loop consists of an ordinary feedback control process while the outer loop adjusts the controller parameters through an adaptation rule in order to minimize the difference between measured output and model output. In this paper the use of MRAC in conjunction with a Lyapunov-based adaptation rule is investigated for the response mitigation of a tall building equipped on top with an active device and subjected to both wind and seismic hazards. Since the required structural performances in case of wind and earthquake-excited vibrations are different, in order to optimize the control effectiveness, a modified MRAC algorithm based on multiple reference models (M-MRAC) is proposed in which the switch between the targets is performed based on the measured feedback information. The main advantage of the proposed methods is its capability of providing power saving and limitation of the peak control force. Parametric analyses allow to identify proper threshold levels for the switching condition and optimal reference models providing a compromise between safety and economy. Results of the numerical analyses on a benchmark tall building show the effectiveness of the control strategy for several loading conditions.

1 INTRODUCTION

Active control is an appealing technique, already adopted in many tall buildings for mitigation of wind- and earthquake-induced vibrations. The effectiveness of active control is closely linked to the selected control algorithm. The most widespread strategies are those based on linear optimal control or robust control [1, 2] but they can not fully manage uncertainties in modal parameters evaluation, loads variability, system's non-linearities and physical limits of actuators [3]. For these reasons adaptive control strategies recently have started to be used for structural control.

Model Reference Adaptive Control is an adaptive algorithm which updates the parameters of the controller for tracking the response of a reference model. The actual system's response is compared to the target response and the control parameters are modified as a function of the error. While many applications of MRAC are available in the mechanical and aeronautical fields, still a few studies exist for civil structures [4, 5, 6].

Tall buildings can experience different vibration levels when subjected to earthquake and wind hazards. Consequently, active control has to allow satisfaction of serviceability requirements under wind load and to avoid occurrence of severe damage under seismic load.

In this paper a modified MRAC algorithm based on multiple reference models (M-MRAC) is proposed, capable of switching between targets depending on the measured feedback information. The idea of switching between different models has recently been proposed in literature [7] but never exploited for civil engineering applications. A preliminary parametric analysis on a tall building equipped with an AMD on top and subjected to both seismic and wind loads allows to define the characteristics of multiple reference models. Analysis results demonstrate the effectiveness of the method in optimizing the control performance and in reducing the required control force.

2 ADAPTIVE CONTROL WITH MRAC

2.1 Dynamics of the structure and the reference model

The considered structure is a tall building modeled as a multi-degrees of freedom dynamic system, subjected to external excitation $\mathbf{f}$ and to a control force $\mathbf{u}$. The equation of motion is:

$$\mathbf{M}_s\ddot{\mathbf{z}}_s + \mathbf{C}_s\dot{\mathbf{z}}_s + \mathbf{K}_s\mathbf{z}_s = \bar{\mathbf{E}}_s\mathbf{f} + \bar{\mathbf{B}}_s\mathbf{u} \tag{1}$$

where $\mathbf{M}_s$, $\mathbf{C}_s$ and $\mathbf{K}_s$ are the mass, damping and stiffness matrices of the building, $\bar{\mathbf{E}}_s$ and $\bar{\mathbf{B}}_s$ are the location matrices of the external excitation and the control force, respectively. In MRAC, a reference model is defined that is subjected to the same external disturbance $\mathbf{f}$ whose dynamic behavior is the target. The equation of motion of the reference system is:

$$\mathbf{M}_r\ddot{\mathbf{z}}_r + \mathbf{C}_r\dot{\mathbf{z}}_r + \mathbf{K}_r\mathbf{z}_r = \bar{\mathbf{E}}_r\mathbf{f} \tag{2}$$

where $\mathbf{M}_r$, $\mathbf{C}_r$ and $\mathbf{K}_r$ are the mass, damping and stiffness matrices of the reference model, $\bar{\mathbf{E}}_r$ is the location matrix of the external excitation.

In state-space formulation, the equations of motion become:

$$\dot{\mathbf{x}}_s = \mathbf{A}_s\mathbf{x}_s + \mathbf{E}_s\mathbf{f} + \mathbf{B}_s\mathbf{u} \tag{3}$$

$$\dot{\mathbf{x}}_r = \mathbf{A}_r\mathbf{x}_r + \mathbf{E}_r\mathbf{f} \tag{4}$$

where

$$\mathbf{x}_s = [\mathbf{z}_s, \dot{\mathbf{z}}_s]^T \tag{5}$$

$$\mathbf{x}_r = [\mathbf{z}_r, \dot{\mathbf{z}}_r]^T \tag{6}$$

$\mathbf{A}_s$, $\mathbf{A}_r$ are the system matrices of the structure and the reference model respectively, $\mathbf{E}_s$, $\mathbf{E}_r$ and $\mathbf{B}_s$ are the location matrices.

A linear feedback control law is adopted for computing the control force:

$$\mathbf{u} = \mathbf{K}\mathbf{x}_s \tag{7}$$

where $\mathbf{K}$ is the vector collecting the states' gains.

2.2 Adaptation law

In MRAC control scheme both the structure and the reference model are subjected to the same external excitation $\mathbf{f}$ which is supposed to be measured. To derive the adaptation law, the error vector $\mathbf{e}$ is computed as follows:

$$\mathbf{e} = \mathbf{x}_s - \mathbf{x}_r \tag{8}$$

The knowledge of the states of the structure is considered available and the target response is computed through the reference model.

A stable adaptation law used to adjust the controller's parameters is computed based on the definition of a Lyapunov function as follows:

$$V = \mathbf{e}^T\mathbf{P}\mathbf{e} + \boldsymbol{\phi}^T\boldsymbol{\Gamma}^{-1}\boldsymbol{\phi} \tag{9}$$

where $\boldsymbol{\phi}$ is the parameter error vector, $\mathbf{P}$ is a positive definite symmetric matrix, $\boldsymbol{\Gamma}$ is the positive definite adaptation gain matrix. In order to obtain an asymptotically stable adaptive system, the time derivative of the Lyapunov function $\dot{V}$, must be negative definite. Differentiating V yields:

$$\dot{V} = \mathbf{e}^T(\mathbf{A}_r^T\mathbf{P} + \mathbf{P}\mathbf{A}_r)\mathbf{e} + 2\mathbf{e}^T\mathbf{P}\mathbf{b}_I\boldsymbol{\phi}^T\mathbf{x}_s + 2\boldsymbol{\phi}^T\boldsymbol{\Gamma}^{-1}\boldsymbol{\phi}\mathbf{P}\mathbf{e} + \boldsymbol{\phi}^T\boldsymbol{\Gamma}^{-1}\boldsymbol{\phi} \tag{10}$$

By applying the Lyapunov's equation ($\mathbf{A}_r^T\mathbf{P}+\mathbf{P}\mathbf{A}_r = -\mathbf{Q}$), positive definite symmetric matrices $\mathbf{P}$ and $\mathbf{Q}$ can be found such that the first part of Equation 10 is negative definite. By putting the last two terms of Equation 10 to zero, the adaptive law is obtained:

$$\dot{\boldsymbol{\phi}} = -\boldsymbol{\Gamma}\mathbf{e}^T\mathbf{P}\mathbf{b}_I\mathbf{x}_s \tag{11}$$

$$\dot{\mathbf{K}} = \dot{\boldsymbol{\phi}}\mathbf{M}_s^{-1} \tag{12}$$

The adaptive control gain vector $\mathbf{K}$ is obtained by time integration.

3 MULTIPLE-MODEL REFERENCE ADAPTIVE CONTROL (M-MRAC)

Structures subjected to multiple hazards with different levels of excitation exhibit different performance. In order to guarantee the respect of various limit states under multiple hazard, it is convenient to define multiple reference models providing different target performance. The choice of the reference models is important for the determination of the best compromise between structural performance and power saving.

The reference model is a dynamic system described by the following equation:

$$\dot{\mathbf{x}}_r = \mathbf{A}_r(\sigma)\mathbf{x}_r + \mathbf{E}_r\mathbf{f} \tag{13}$$

where the state matrix $\mathbf{A}_{r\sigma}$ is a piecewise continuous function of time depending on the parameter characterizing switching conditions $\sigma(t)$. The multiple reference models' state matrix is defined as follows:

$$\mathbf{A}_r(\sigma) = \begin{cases} \mathbf{A}_{r,0} & \text{for } \sigma(t) < \sigma_1 \\ \mathbf{A}_{r,1} & \text{for } \sigma_1 \leq \sigma(t) < \sigma_2 \\ \dots & \\ \mathbf{A}_{r,n} & \text{for } \sigma(t) \geq \sigma_n \end{cases} \tag{14}$$

where $\sigma_1, ..., \sigma_n$ are switching thresholds. The parameter σ can be a measured state of the system or a generic response parameter.

In the simplified case of two reference models, the switching rule becomes:

$$\mathbf{A}_{r,\sigma} = \begin{cases} \mathbf{A}_{r,0} & \text{for } \sigma(t) < \bar{\sigma} \\ \mathbf{A}_{r,1} & \text{for } \sigma(t) \geq \bar{\sigma} \end{cases} \tag{15}$$

where $\bar{\sigma}$ is the switching threshold.

In order to obtain good performance of the control system, the switching rule must be properly selected. Repeated switching may potentially lead to optimized performance but a too high commutation frequency can lead to improper system's behavior [8]. Nevertheless, due to the high natural periods of structures under investigation the critical dwell time is usually reasonably well below the switching time intervals.

4 THE CASE STUDY

4.1 Description of the tall building

The structure chosen as case study is the 76-story building, 306 meters high, proposed as a benchmark problem for response control under wind load [9]. It is a reinforced concrete building consisting of a concrete core, designed to resist lateral loads and concrete frames mainly devoted to support gravity loads. The building has a square cross section with chamfer at two corners, constant along the height. A simplified dynamic model of the building with 1DOF for each floor is considered in the analyses. Damping ratio for all modes is 1% and the first natural frequency is 0.16 Hz. Figure 1 shows the plan and elevation views of the structure.

4.2 Wind and seismic loads modeling

Wind loads adopted for the analyses were obtained by tests performed in the boundary layer wind tunnel facility at the Department of Civil Engineering at University of Sidney, Australia [10]. The rigid model of the building had a length scale of 1:400. Wind pressures were recorded for 27 seconds, corresponding to about 1 hour in prototype scale. Pressure coefficients were integrated and converted into across-wind forces at each story. The mean wind velocity at the top of the building was 47.25 m/s corresponding to a reference wind velocity $V_{ref} = 13.5$ m/s at 10 m above ground, representing serviceability conditions at which occupant's comfort and motion perception are important design criteria.

In order to consider uncertainties on measurement variability and to characterize statistically the wind load, 7 sets of time histories each one having a duration of 10 minutes are extracted from the measured time histories of the lateral wind forces and used to compute the structural response.

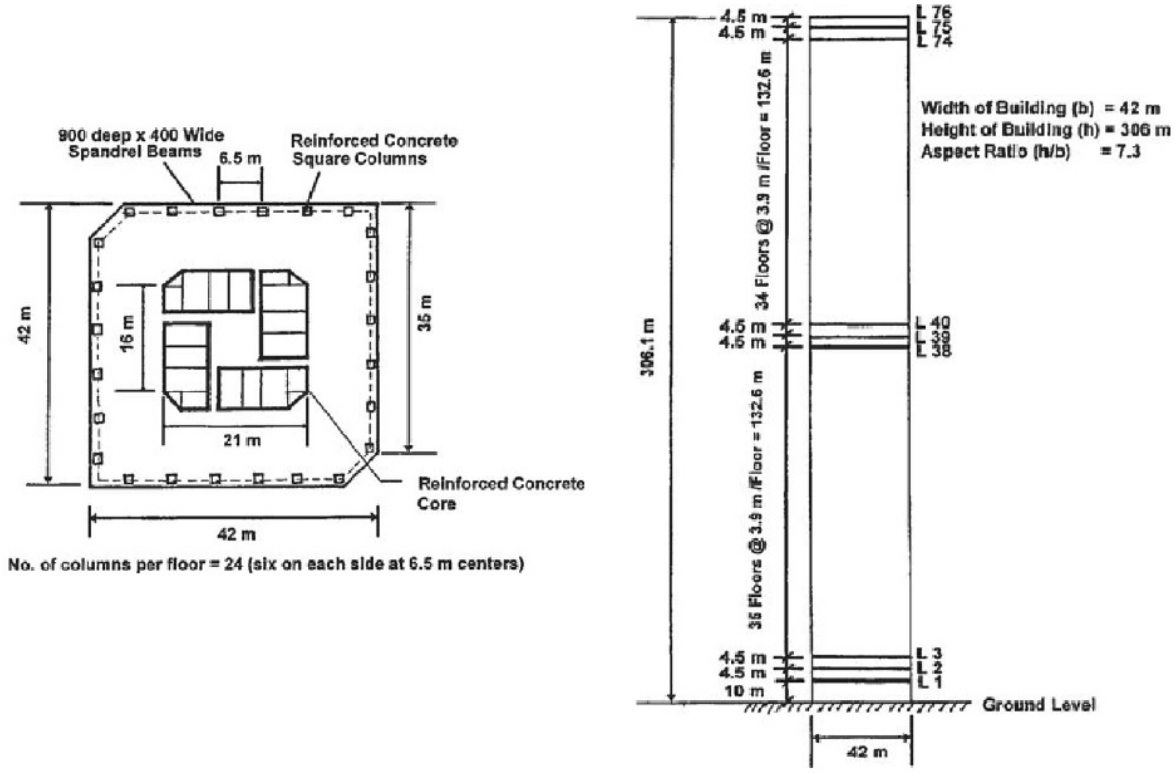

Figure 1: Plan and elevation views of the building [9].

To characterize the seismic load, 7 accelerograms relative to the Los Angeles area, with a 10% probability of exceedance in 50 years, are taken from the PEER-NISEE online library [12]. The accelerograms are preliminary scaled to have the same reference value of peak ground acceleration PGA_{ref}, which is the mean value (among the 7 accelerograms) of the PGA.

5 NUMERICAL RESULTS

5.1 Sensitivity analysis on the choice of the reference models

Tall buildings must satisfy different performance requirements under wind and earthquake. Therefore control systems have the dual purpose of guaranteeing occupants' comfort under ordinary wind conditions and limiting damage under extreme seismic events. The possibility of adopting multiple reference models is exploited with the aim of reducing costs associated with elevated power supply.

In order to characterize reference models, a parametric analysis by varying the target system damping is carried out. Without loss of generality, the investigated reference dynamic systems have mass and stiffness matrices equal to the corresponding nominal matrices of the real structure and damping ratio of all modes varying from 1% to 15%.

Proper performance indices are defined in order to have quantitative comparison between the

results:

$$J_1(\%) = \frac{\max|\text{IDR}|_r}{\max|\text{IDR}|_{lim}} \tag{16}$$

$$J_2(\%) = \frac{\max|\ddot{\mathbf{z}}|_r}{\max|\ddot{\mathbf{z}}|_{lim}} \tag{17}$$

$$J_3(\%) = \frac{\max|\text{M}_b|_r}{\max|\text{M}_b|_{lim}} \tag{18}$$

where IDR is the interstory drift ratio, $\ddot{\mathbf{z}}$ is the structural acceleration, M_b is the bending moment at the base of the building. Subscript r refers to the reference model and subscript lim refers to the acceptable threshold levels.

The most important response components to limit in order to ensure comfort and avoid damage to non-structural components are interstory drifts and accelerations. For serviceability, according to [13], 1/400 of the story height can be set as the limit state threshold for maximum interstory drift. For the motion perception acceleration threshold, the following relation can be adopted [14]:

$$\ddot{\mathbf{z}}_{lim} = \frac{a_0}{{f_0}^{0.56}} \tag{19}$$

where f_0 is the dominant natural frequency, $a_0 = 6$ cm/s^2, for office buildings.

Regarding the strength limit state, the threshold value of maximum bending moments at the base of the internal core is obtained as follows:

$$\text{M}_{b,lim} = \varphi_{lim} EI \tag{20}$$

where EI is the flexural stiffness and φ_{lim} is the curvature at the elastic limit of the reinforced concrete central core. Since the control system is supposed to maintain the central core below its yielding limit, the hypothesis of linear elastic behavior is justified and the structural response is computed by linear analysis with time domain integration.

Table 1 shows mean values and standard deviations of the peak response components. Results are obtained for damping ratio equal to the 1% (the nominal value for the building), under wind and seismic loads. Results show that interstory drifts and base bending moments due to wind load are one order of magnitude smaller than those due to seismic load. Moreover, earthquake-induced accelerations are much higher than wind-induced ones. This results is in keeping with full scale observations. High accelerations in tall buildings were observed in response to the 2011 Tohoku earthquake, and shown to be due to higher mode effects [15].

	Wind		Earthquake	
	Mean value	Standard deviation	Mean value	Standard deviation
IDR_{max} (m)	1.70e-3	0.61e-3	1.72e-2	1.12e-2
$\ddot{\mathbf{z}}_{max}$ (m/s^2)	0.25	0.02	26.19	7.45
$\text{M}_{b,max}$ (Nm)	5.39e6	1.85e6	6.06e7	3.39e7

Table 1: Mean values and standard deviations of peak response components for damping ratio of 1%.

Figure 2 reports the mean values of performance indices (computed adopting the 7 accelerograms and the 7 wind load time histories) for different values of damping ratio (1%, 5%, 10%,

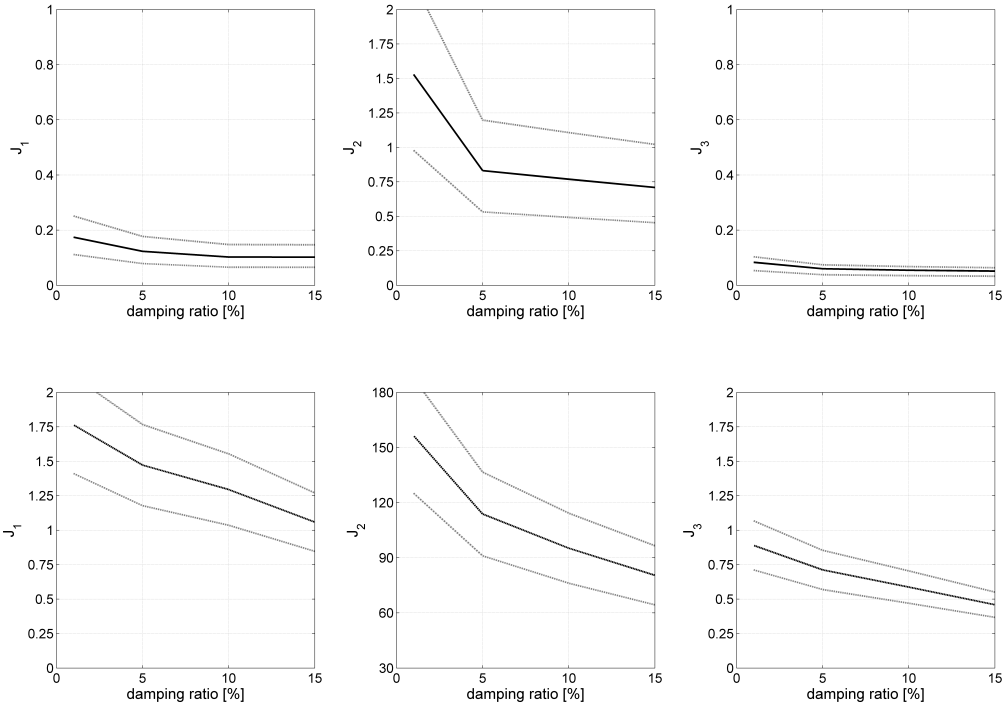

Figure 2: Performance indices as a function of damping ratio computed using wind load (top) and seismic load (bottom)

and 15%). The three top diagrams show response under wind load and the bottom ones show response obtained using the set of earthquakes. The grey dotted lines represent the performance indices obtained by varying PGA_{ref} and V_{ref} by the 40% ($\pm 20\%$) to account for randomness of the seismic intensity and the reference wind speed. Values of performance indices larger than unity indicate limit state crossing. Results show that index J_1 on interstory drifts ratio is smaller that unity for wind load and higher than unity for earthquake, unless damping ratios higher than 15% are adopted. Index J_2 on peak accelerations is significantly higher than unity for earthquake load, meaning that in seismic conditions limit state on motion perception is always exceeded and occupants comfort condition cannot be satisfied. In case of wind load, index J_2 can be reduced below unity for values of damping ratio higher than about 5%. Index J_3 related to yielding of the central core is smaller than unity for both wind and seismic load.

In order to ensure occupants' comfort, a reference model with 5% damping ratio can be used but to the extent of reducing drift-dependent damage to non-structural elements a reference model with 15% damping ratio must be adopted. Although the choice of reference models' damping con not be generalized (as it depends on the building's dynamic characteristics and the specific site's conditions), the sensitivity analyses demonstrate that the optimal target damping is not unique for different limit states.

5.2 Analysis with M-MRAC

In order to evaluate the effectiveness of the modified MRAC procedure (M-MRAC), several analysis are carried out on a simplified 1 degree of freedom model having mass equal to the first

modal mass and natural period equal to the one of the selected tall building.

The two reference models are chosen on the basis of the preliminary analyses presented in Section 5.1. In particular, in order to ensure occupants' comfort in serviceability conditions, an uncontrolled target system with 5% damping ratio is adopted. In order to avoid damage to drift-sensitive non-structural elements, an uncontrolled target system with 15% damping ratio is selected.

The response component $\sigma(t)$ which determines the switching condition is the building's peak displacement that is related to drift dependent damage. In the present analyses, without loss of generality, the switch between different models is activated when the structural displacement is $\bar{\sigma} = 0.5$ m.

Figure 3(a) shows the response of the uncontrolled system (U), the reference model (R) and the controlled system with M-MRAC to a step loading with a short ramp. The reference model has no control system and a damping of 15%. In this case the applied load does not activate the switching condition. Structural responses and load are normalized with respect to their maximum absolute values. Results show very good matching between the target model and the real system. Figures 3(b) and (c) show the states errors and control force, normalized with respect to their maximum absolute values, which tend to zero with time. Figure 4 shows

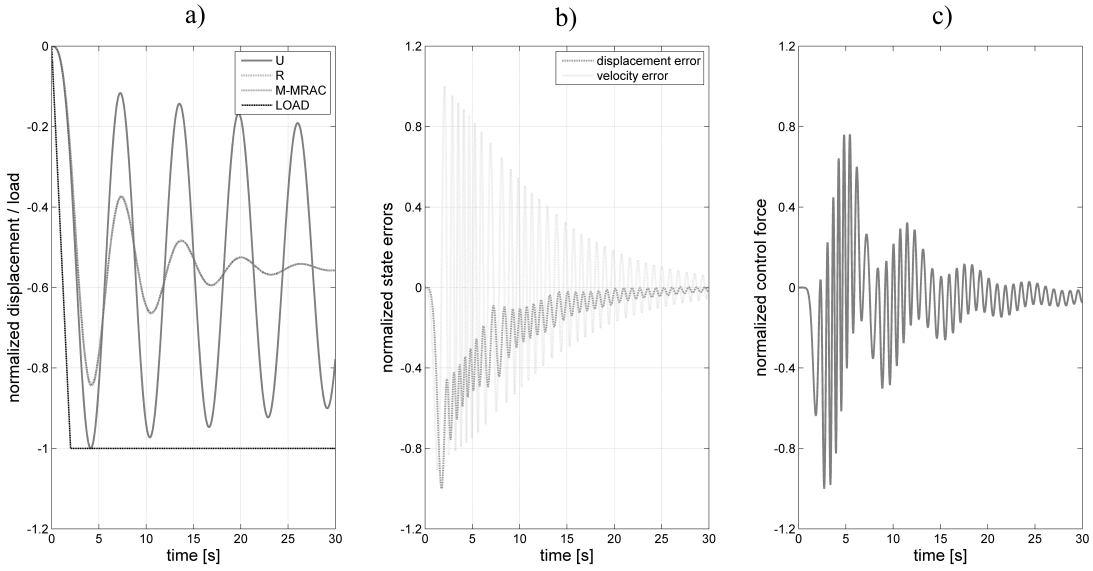

Figure 3: Controlled response obtained with M-MRAC to a step loading if reference model switching is not activated.

the performance of M-MRAC to a sinusoidal loading with natural frequency of 0.4 Hz and amplitude which increases up to its maximum value and after a slight impulsive variation is kept constant. Figure 4a shows the uncontrolled response (U), the response of the reference model (R) and the controlled response obtained with M-MRAC. Displacements are normalized with respect to $\bar{\sigma}$, showing that reference model switching is activated repeatedly. It can be observed that there is a very good matching between responses of the reference model and the controlled structure and that the system properly reduces peak displacements with respect to the uncontrolled case. Figure 4(b) compares normalized displacements obtained with the proposed M-MRAC and traditional MRAC. In this latter case, the reference model that the

system has to track is unique and has a damping ratio equal to 15%, corresponding to the damping required in case of seismic events. Figures 4(c) and (d) show the displacement error and control forces, normalized with respect to their maximum absolute values. It is possible to observe that state errors are kept limited and have the tendency to decrease with time. The control force required by M-MRAC is smaller than the one required by traditional MRAC, demonstrating the advantage of adopting multiple reference models.

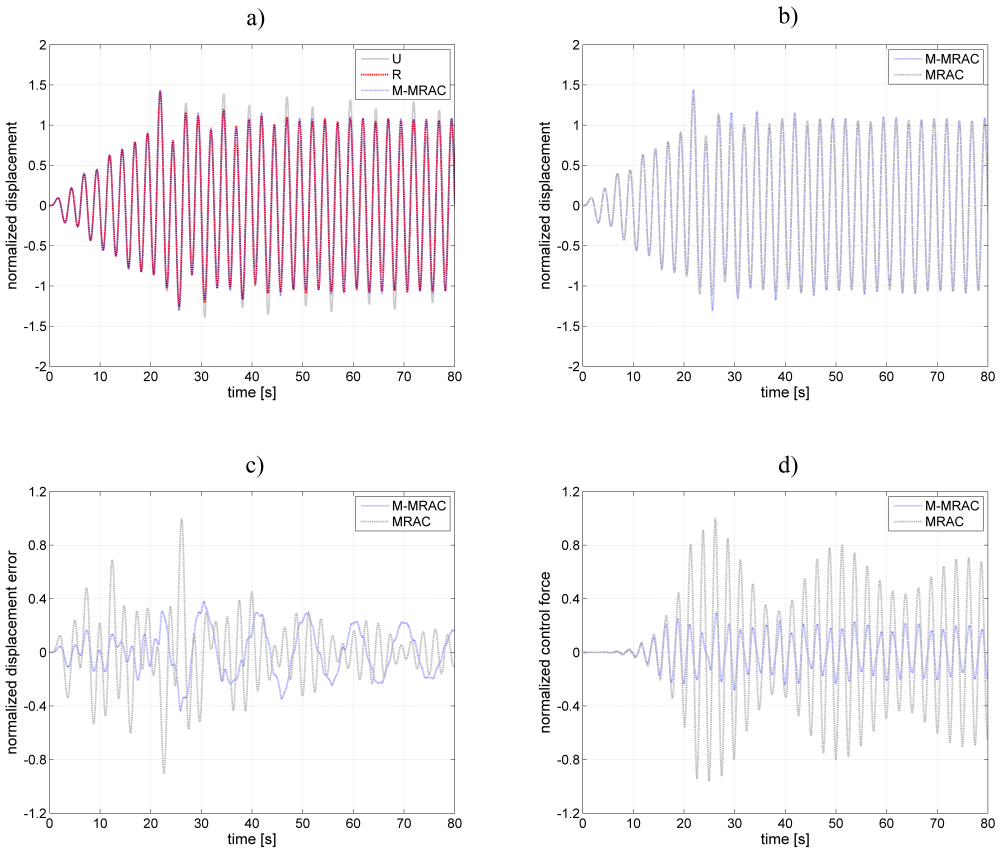

Figure 4: Performance of M-MRAC under sinusoidal loading.

In order to investigate the M-MRAC performance to real loading conditions, an erthquake capable of activating switching condition for several cycles is applied to the structure. Figure 5 shows the performance of M-MRAC to a base seismic accelerogram (represented in Figure 5(a)). Figure 5(b) shows the uncontrolled response and the response of the controlled systems with the proposed M-MRAC and traditional MRAC. Figures 5(c) and (d) show the displacement error and control forces, normalized with respect to their maximum absolute values. Also in case of extreme seismic loading, state errors tend to decrease with time and the control force required by M-MRAC is smaller than the one required by MRAC.

The effect of excitation frequency on M-MRAC performance is investigated by computing systems' responses to harmonic loads with frequency varying between 0.05 Hz and 1.00 Hz. As system's maximum response depends on frequency, the displacement threshold establishing switching condition is set equal to the 80% of the peak uncontrolled value. Figure 6(a) shows

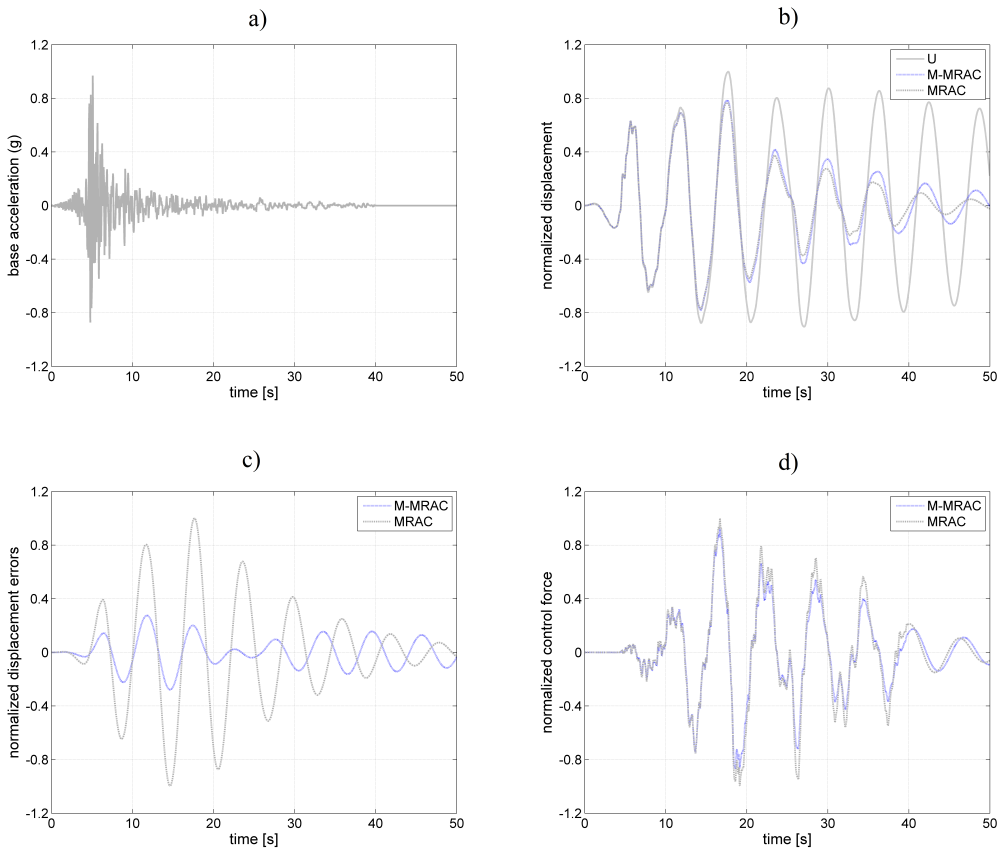

Figure 5: Performance of M-MRAC under seismic loading.

the peak displacements of the uncontrolled system and the controlled systems with M-MRAC and MRAC, normalized with respect to the maximum uncontrolled peak response. Figure 6(b) shows the peak control forces required by M-MRAC and MRAC normalized with respect to maximum peak control force. Results show that M-MRAC provides a significant reduction of the maximum required control force at the expense of an increase in structural response. This limited growth in structural response, which is less important in case of non-harmonic excitation (Figure 5), can be partially compensated by properly varying the gap between reference models' dampings.

6 CONCLUSIONS

The paper exploits the possibility of adopting multiple reference models for adaptive control of tall buildings subjected to multiple hazards. With this aim, the standard Model Reference Adaptive Control algorithm is modified through the adoption of multiple reference models. The motivation of the proposed algorithm enhancement is that flexible buildings require various damping levels to avoid the occurrence of different limit states. This problem is also more important when the tall building is subjected to multiple hazards, like wind and earthquake, having different characteristics in terms of frequency, amplitude and duration of load.

A benchmark tall building is chosen as case study to examine the effectiveness of the pro-

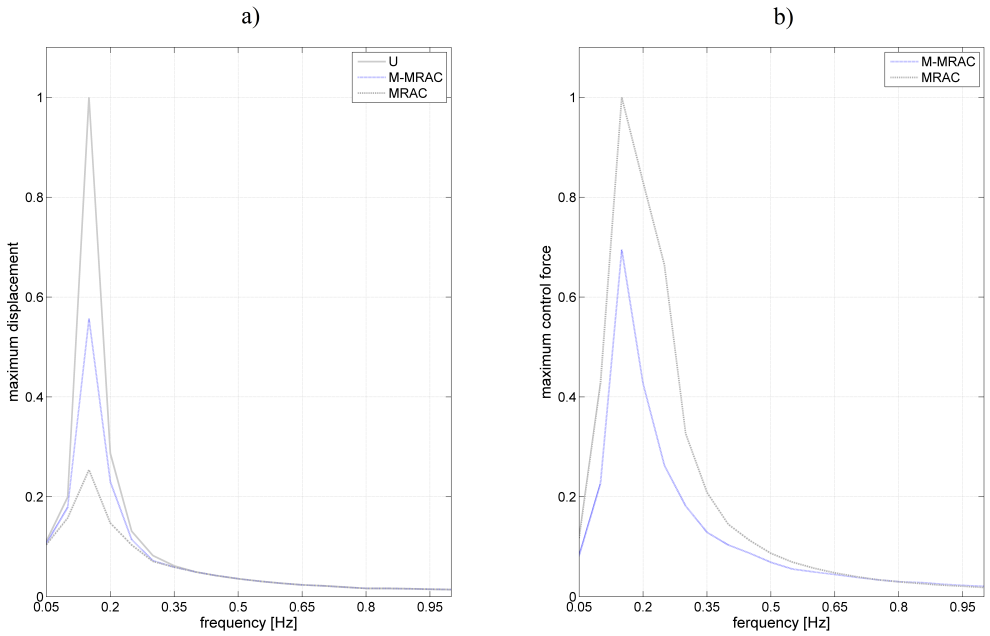

Figure 6: Peak displacements and control forces as a function of the harmonic excitation frequency.

posed control strategy. After preliminary parametric analyses for choosing the optimal reference systems, several investigations on the performance of M-MRAC are carried out. Results show the capacity of M-MRAC in tracking the target system and in reducing the structural response. Comparison between results obtained with traditional MRAC demonstrates that the main advantage of M-MRAC is the reduction of the required control force, at the expense of a slight reduction of control effectiveness.

Future developments of the work will deepen the effects of dwell time, reference models' characteristics, system's uncertainties and non-linearities.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge Prof. Oren Lavan, from Technion, Israel Institute of Technology, for suggestions on seismic response of tall buildings and Prof. Mario Luca Fravolini, from University of Perugia for advice on adaptive control methods.

Keywords: Auxetic materials, Wave propagation, Resonators, Meta-materials, Passive control

Abstract. *Periodic anti-tetrachiral materials are strongly characterized by a marked auxeticity, the unusual and fascinating mechanical property mathematically expressed by negative values of the Poisson's ratio. The auxetic behavior is primarily provided by pervasive rolling-up mechanisms developed by the doubly-symmetric micro-structure of the periodic cell, composed by a regular pattern of rigid rings connected by tangent flexible ligaments. Adopting a beam-lattice model to describe the linear free dynamics of the elementary cell, the planar wave propagation along the bi-dimensional material domain can be studied according to the Floquet-Bloch theory. Parametric analyses of the dispersion curves, carried out with numerical or asymptotic tools, typically reveal a highly-dense spectrum, with persistent absence of total band-gaps in the low-frequency range. The paper analyses the wave propagation in the meta-material developed by introducing rigid massive inserts, locally housed by all the rings and working as undamped linear oscillators with assigned inertia and/or stiffness properties. The elastic coupling between the cell microstructure and the oscillators, if properly tuned (inertial resonators), is found to significantly modify the Floquet-Bloch spectrum of the material. The effects of the resonator parameters (tuning frequency and mass ratio) on the low-frequency band structure of the meta-material are discussed, with focus on the valuable possibility to (i) open total band gaps, by either the widening of an existing partial band gap or the avoidance of a crossing point between adjacent dispersion curves, (ii) finely control the total band-gap amplification, in order to assess the maximum achievable performance of the meta-material against the vibration propagation.*

1 INTRODUCTION

Auxetic materials are characterized by the unconventional and fascinating ability to develop transversal expansions in response to a longitudinal stretching. This physical peculiarity, which is described by negative Poisson's ratios in solid mechanics, is rarely observable in nature, but can be smoothly obtained by artificial synthesis [1–3]. The recent and increasing interest in auxetic materials is being strongly catalyzed by the compelling demand for advanced applications in aerospace, chemical, naval, nuclear, biomedical, sport engineering fields. Indeed, auxetic sheets and solids are potentially featured by a variety of functional super-capacities, including higher fracture toughness and indentation resistance, as well as augmented properties of acoustic damping and energy absorption, with respect to their conventional counterparts [4–6].

Artificial realizations of auxetic materials include polymeric or metallic foams and laminates, on the one hand, and micro-structured composites, which typically possess periodic cellular geometries (namely reticular networks, chiral lattices, re-entrant honeycombs and origami folds), on the other hand [8–10]. Leveraging their intrinsic periodicity, obeying to the well-established Floquet-Bloch theory, a promising theoretical and technological research challenge concerns the employment of chiral auxetic media as versatile elastic guides for planar optical and acoustic waves. Indeed, a proper tuning of their mechanical properties may allow the effective design of such materials as tailor-made signal propagators or – especially – selective passive filters for noise reduction and vibration mitigation [11–14]. In this respect, the high performance and versatility ensured by tunable arrays of light and flexible resonant subsystems is a promising trend coming from a multi-disciplinary cross-fertilization [15–21].

Among different chiral topologies, the anti-tetrachiral material is gaining major attention, due to its strong auxeticity, accompanied by a marked anisotropy [9, 14, 22–24]. Employing a linear beam-lattice model of the cell microstructure, the wave propagation properties of this material have been studied by means of both numerical and asymptotic tools [30]. Parametric analyses of the dispersion curves typically reveal a highly-dense spectrum, with persistent absence of band-gaps in the low-frequency range. Such shortcomings, confirmed also by continuum models and in presence of soft matrices [14] may actually limit the practical efficiency of the anti-tetrachiral materials as adjustable passive controllers against the free propagation of vibration waves with target frequencies, wavenumbers, or polarization modes.

The paper explores the possibility to develop a meta-material by introducing rigid massive inserts, locally housed by all the rings and working as undamped linear oscillators with assigned inertia and/or stiffness properties. The elastic coupling between the cell microstructure and the oscillators, if properly tuned (inertial resonators), has the potential to significantly modify the Floquet-Bloch spectrum of the material [25–28]. A suited design of this purely-mechanical behavior opens the valuable perspective to passively control the wave propagation by, first, artificially regulating the tailored opening or closure of one or more frequency band-gaps, and, second, maximizing their respective amplitudes according to optimal criteria [29].

According to this leading idea, the beam-lattice model of the anti-tetrachiral material is enriched by coupling the global dynamics of the periodic cell with the local dynamics of the resonators (Section 2). Then the coupled eigenproblem governing the wave propagation in the meta-material is formulated (Section 2.2). The effects of the resonator key-parameters (mass ratio and frequency tuning) on the dispersion curves and frequency band gaps are discussed (Section 3). These parametric studies pave the way for the analytical, although approximate, description of the enriched Floquet-Bloch spectrum by means of asymptotic perturbation techniques, suited to carry out explicit design criteria. Concluding remarks are finally drawn.

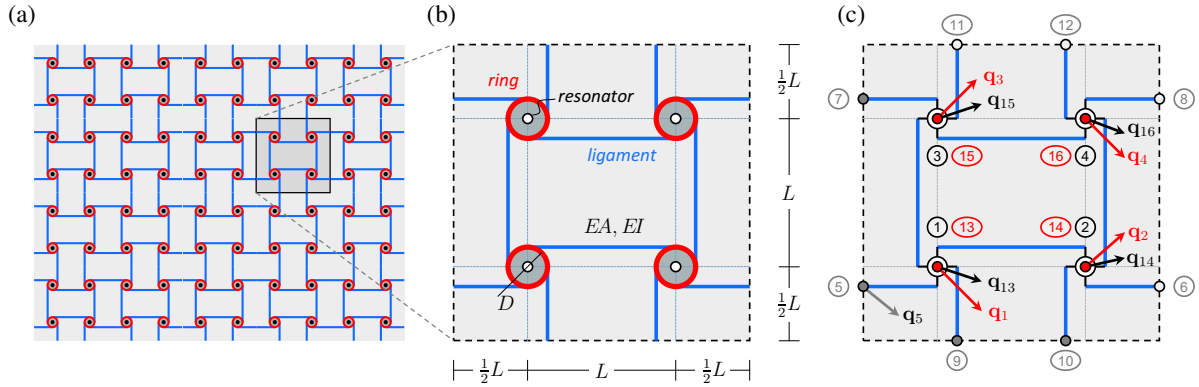

Figure 1: Anti-tetrachiral cellular meta-material: (a) pattern, (b) periodic cell, (c) beam lattice model.

2 BEAM LATTICE MODEL

Focusing on the microscopic scale, a cellular meta-material characterized by a square periodic cell, fully tiling a two-dimensional infinite domain, is considered (Figure 1a). A beam lattice model is formulated to describe the linear elasto-dynamic response of the unit cell, featured by a double geometric symmetry which realizes an anti-tetrachiral topology (Figure 1b). The internal structure, or *microstructure*, of the elementary cell is composed by four circular rings connected by twelve tangent ligaments. The *rolling-up* mechanism, responsible for the auxetic behavior, consists in the opposite-sign, iso-amplitude rotations developed by any pair of adjacent disks in-a-row (or column), when the cell is stretched along one of the symmetry axes.

A rigid body model is assumed for the massive and highly-stiff rings, possessing identical mean diameter D. The ring centers are located at the four corners of an ideal internal square, concentric with the external cell boundary. The ring small width S is considered a free parameter, allowing the independent assignment of the rigid body mass M and moment of inertia J. A linear, extensible, unshearable model of massless beam is employed for all the identical light and flexible ligaments, in the small-deformation range. As long as the beam-ring connections nominally realize perfectly-rigid joints, the natural length L of the *inner* horizontal and vertical ligaments coincide with half the side of the square cell. By virtue of the periodicity, the cell boundary crosses the midspan – and halves the natural length – of all the *outer* ligaments. Assuming the same linear elastic material (with Young's modulus E) and cross-section shape (with area A and second area moment I) for each ligament, all the beams have identical extensional EA and flexural rigidity EI. The effects of a homogeneous soft matrix, which may likely embed the microstructure [14], are neglected as first approximation.

Moving from this structural layout, a novel meta-material can be realized by supplying each ring with a light soft annular filler, hosting a central heavy circular inclusion, serving as inertial resonator with adjustable mechanical properties. All the identical inclusions are modelled as rigid disks, co-centered with the respective housing rings, with body mass M_r and moment of inertia J_r. As long as the internal coupling provided by the filler can be assumed linearly elastic, the ring-resonator differential displacements are affected by equivalent translational and rotational stiffnesses [28]. Therefore, the local (translational and rotational) motion of each resonator is essentially characterized by two natural frequencies Ω_r and Ω_θ.

Introducing a certain circular frequency Ω_c of the cellular solid as known dimensional reference, a suited minimal set of independent nondimensional parameters, sufficient to describe the inertial, elastic and geometric properties of the square periodic cell, is

$$\delta = \frac{D}{L}, \qquad \varrho^2 = \frac{I}{AL^2}, \qquad \omega_c^2 = \frac{EA}{M\Omega_c^2 L}, \qquad \chi^2 = \frac{J}{ML^2} \tag{1}$$

where ω_c stands for a frequency characterizing the beam lattice. The geometric parameter δ roughly expresses the material compositeness, measured as the linear density of the circular rings. The nondimensional form ϱ of the gyration radius of inertia accounts for the (inverse) slenderness of the ligaments. Finally, χ^2 is the rotational-to-translational mass ratio of the disks.

Together with the microstructural parameters, the meta-material is further characterized by additional nondimensional parameters, describing the properties of the local resonators

$$\gamma = \frac{\Omega_r}{\omega_c\,\Omega_c}, \qquad \alpha = \frac{M_r}{M}, \qquad \gamma_\theta = \frac{\Omega_\theta}{\omega_c\,\Omega_c}, \qquad \chi_r^2 = \frac{J_r}{M_r L^2}$$

where γ and γ_θ can be recognized as *tuning* parameters for the two resonator frequencies, α accounts for the resonator-to-ring mass ratio and χ_r^2 is the rotational-to-translational mass ratio of the resonator.

2.1 Equations of motion

According to the mechanical assumptions, the linear dynamics of the unit cell is governed by a multi-degrees-of-freedom discrete model, referred to a full set of 16 configurational nodes, located by the position vectors $\mathbf{x}_i$ (with $i = 1, ..., 16$) in the natural configuration. The actual configuration of the i-th node is described by three time-dependent components of motion, corresponding to the horizontal displacement $U_i(t)$, the vertical displacement $V_i(t)$ and the in-plane rotation $\phi_i(t)$. The nondimensional variables can be introduced

$$u_i = \frac{U_i}{L_r}, \qquad v_i = \frac{V_i}{L_r}, \qquad \tau = \Omega_r t \tag{2}$$

where L_r stands for a reference length L_r which preserves the smallness of the displacements. All the nondimensional configuration variables can be collected in the 48-by-one displacement column-vector $\mathbf{q} = (\mathbf{q}_1, ..., \mathbf{q}_i, ..., \mathbf{q}_{16})$, where the i-th nodal subvector $\mathbf{q}_i = (u_i, v_i, \phi_i)$.

Depending on the position of the lumped masses in the discrete model and with reference to the labels in Figure 1c, the model nodes can conveniently be distinguished into three subsets

i. four *internal* nodes located at the ring centroids (red nodes ①...④), whose 12 *active* displacements can be collected in the subvector $\mathbf{q}_a = (\mathbf{q}_1, \mathbf{q}_4)$

ii. eight *external* nodes located at the outer ligament midspans (gray nodes ⑤...⑫), whose 24 *passive* displacements can be cast in the subvector $\mathbf{q}_p = (\mathbf{q}_5, \mathbf{q}_{12})$

iii. four *inner* nodes located at the disk centroids (black nodes ⑬...⑯), whose 12 *resonant* displacements can be collected in the subvector $\mathbf{q}_r = (\mathbf{q}_{13}, \mathbf{q}_{16})$

The distinction remarks that the internal and inner nodes develop both nondimensional elastic $(\boldsymbol{\sigma}_a, \boldsymbol{\sigma}_r)$ *and* inertial forces $(\mathbf{f}_a, \mathbf{f}_r)$, which actively participate in the dynamic cell equilibrium. On the contrary, the external nodes can develop only elastic forces $\boldsymbol{\sigma}_p$, which partially depend on the stiffness coupling with the internal nodes, and quasi-statically balance the reactive forces $\mathbf{f}_p$ transferred by the adjacent cells. Due to the geometric assumptions, the positions of the *internal* and *inner* node sets (nodes ①...④ and ⑬...⑯) coincide in the undeformed configuration.

According to displacement/force decomposition, the nondimensional equilibrium equation governing the undamped free oscillations of the discrete model has the matrix form

$$\begin{pmatrix} \mathbf{f}_r \\ \mathbf{f}_a \\ \mathbf{0} \end{pmatrix} + \begin{pmatrix} \boldsymbol{\sigma}_r \\ \boldsymbol{\sigma}_a \\ \boldsymbol{\sigma}_p \end{pmatrix} = \begin{pmatrix} \mathbf{0} \\ \mathbf{0} \\ \mathbf{f}_p \end{pmatrix} \tag{3}$$

or, making explicit the force dependence on the nodal acceleration or displacements

$$\begin{bmatrix} \mathbf{M}_r & \mathbf{O} & \mathbf{O} \\ \mathbf{O} & \mathbf{M}_a & \mathbf{O} \\ \mathbf{O} & \mathbf{O} & \mathbf{O} \end{bmatrix} \begin{pmatrix} \ddot{\mathbf{q}}_r \\ \ddot{\mathbf{q}}_a \\ \ddot{\mathbf{q}}_p \end{pmatrix} + \begin{bmatrix} \mathbf{K}_r & -\mathbf{K}_r & \mathbf{O} \\ -\mathbf{K}_r & \mathbf{K}_{aa}+\mathbf{K}_r & \mathbf{K}_{ap} \\ \mathbf{O} & \mathbf{K}_{pa} & \mathbf{K}_{pp} \end{bmatrix} \begin{pmatrix} \mathbf{q}_r \\ \mathbf{q}_a \\ \mathbf{q}_p \end{pmatrix} = \begin{pmatrix} \mathbf{0} \\ \mathbf{0} \\ \mathbf{f}_p \end{pmatrix} \tag{4}$$

where dot indicates differentiation with respect to the τ-time and $\mathbf{O}$ stands for empty matrices.

Focusing on the micro-structural matrices, the *global* mass submatrix $\mathbf{M}_a$ is diagonal, as far as a lumped mass description is assumed. The symmetric submatrices $\mathbf{K}_{aa}$ and $\mathbf{K}_{pp}$ account for the *global* stiffness of the internal and external nodes, respectively. The rectangular submatrix $\mathbf{K}_{ap} = \mathbf{K}_{pa}^{\top}$ expresses the elastic *global* coupling among the internal and external nodes. A parametric expression of these matrices can be found in [30]. Focusing on the resonators, both the *local* mass and stiffness submatrices $\mathbf{M}_r$ and $\mathbf{K}_r$ are diagonal. The submatrix $\mathbf{K}_r$ accounts also for the *global-local* coupling between the inner and internal nodes.

2.2 Free wave propagation

The free wave propagation along the bi-dimensional cell domain can be studied according to the Floquet-Bloch theory [31–33]. Moving in the $\mathbf{k}$-transformed space the active ($j = 1...4, 13...16$) and passive displacements and passive force vectors assume the representations

$$\mathbf{q}_j = \tilde{\mathbf{q}}_j \, \mathrm{e}^{\mathrm{i}\,\mathbf{k}\cdot\mathbf{x}_j}, \qquad \mathbf{q}_p = \mathbf{F}_p \tilde{\mathbf{q}}_p, \qquad \mathbf{f}_p = \mathbf{F}_p \tilde{\mathbf{f}}_p \tag{5}$$

where i denotes the imaginary unit, $\mathbf{k} = (k_1, k_2)$ is the (dimensional) wavevector and the block diagonal matrix $\mathbf{F}_p = \mathrm{diag}[\,\mathbf{I}\,\mathrm{e}^{\mathrm{i}\,\mathbf{k}\cdot\mathbf{x}_5}, ..., \mathbf{I}\,\mathrm{e}^{\mathrm{i}\,\mathbf{k}\cdot\mathbf{x}_{12}}\,]$ with $\mathbf{I}$ being the three-by-three unit matrix.

The passive displacement and force vector can be ordered and partitioned as $\mathbf{q}_p = (\mathbf{q}_p^-, \mathbf{q}_p^+)$, $\mathbf{f}_p = (\mathbf{f}_p^-, \mathbf{f}_p^+)$ to separate the variable pairs $(\mathbf{q}_p^-, \mathbf{f}_p^-)$ belonging to the left/bottom cell boundary (composed by the external nodes ⑤,⑦,⑨,⑩) from the variable pairs $(\mathbf{q}_p^+, \mathbf{f}_p^+)$ belonging to the right/top boundary (composed by the external nodes ⑥,⑧,⑪,⑫). Extending the same partition to the respective transformed variables, the equation (5) can be written

$$\mathbf{q}_p^- = \mathbf{F}_p^- \tilde{\mathbf{q}}_p^-, \qquad \mathbf{q}_p^+ = \mathbf{F}_p^+ \tilde{\mathbf{q}}_p^+, \qquad \mathbf{f}_p^- = \mathbf{F}_p^- \tilde{\mathbf{f}}_p^-, \qquad \mathbf{f}_p^+ = \mathbf{F}_p^+ \tilde{\mathbf{f}}_p^+, \tag{6}$$

where, based on the decomposition, the matrices $\mathbf{F}_p^- = \mathrm{diag}[\,\mathbf{I}\,\mathrm{e}^{\mathrm{i}\,\mathbf{k}\cdot\mathbf{x}_5}, \mathbf{I}\,\mathrm{e}^{\mathrm{i}\,\mathbf{k}\cdot\mathbf{x}_7}, \mathbf{I}\,\mathrm{e}^{\mathrm{i}\,\mathbf{k}\cdot\mathbf{x}_9}, \mathbf{I}\,\mathrm{e}^{\mathrm{i}\,\mathbf{k}\cdot\mathbf{x}_{10}}]$ and $\mathbf{F}_p^+ = \mathrm{diag}[\,\mathbf{I}\,\mathrm{e}^{\mathrm{i}\,\mathbf{k}\cdot\mathbf{x}_6}, \mathbf{I}\,\mathrm{e}^{\mathrm{i}\,\mathbf{k}\cdot\mathbf{x}_8}, \mathbf{I}\,\mathrm{e}^{\mathrm{i}\,\mathbf{k}\cdot\mathbf{x}_{11}}, \mathbf{I}\,\mathrm{e}^{\mathrm{i}\,\mathbf{k}\cdot\mathbf{x}_{12}}\,]$.

Imposing the periodicity conditions on the transformed variables ($\tilde{\mathbf{q}}_p^+ = \tilde{\mathbf{q}}_p^-$ and $\tilde{\mathbf{f}}_p^+ = -\tilde{\mathbf{f}}_p^-$), the free wave propagation throughout the cell domain between the two complementary boundaries is governed by the quasi-periodicity conditions on the anti-transformed variables

$$\mathbf{q}_p^+ = \mathbf{L}\mathbf{q}_p^-, \qquad \mathbf{f}_p^+ = -\mathbf{L}\mathbf{f}_p^- \tag{7}$$

where, following from the equations (6), the block diagonal transfer matrix reads

$$\mathbf{L} = \mathrm{diag}\left[\mathrm{e}^{\mathrm{i}\,\mathbf{k}\cdot\mathbf{d}_{56}}\,\mathbf{I}, \mathrm{e}^{\mathrm{i}\,\mathbf{k}\cdot\mathbf{d}_{78}}\,\mathbf{I}, \mathrm{e}^{\mathrm{i}\,\mathbf{k}\cdot\mathbf{d}_{911}}\,\mathbf{I}, \mathrm{e}^{\mathrm{i}\,\mathbf{k}\cdot\mathbf{d}_{1012}}\,\mathbf{I}\right] \tag{8}$$

and $\mathbf{d}_{ij} = \mathbf{x}_j - \mathbf{x}_i$ represents the vector connecting the i-th and the j-th external nodes.

Consistently with the passive displacement and force decomposition, and imposing the quasi-periodicity conditions (8), the lower (quasi-static) part of equation (4) reads

$$\begin{bmatrix} \mathbf{K}_{pa}^{-} \\ \mathbf{K}_{pa}^{+} \end{bmatrix} \mathbf{q}_a + \begin{bmatrix} \mathbf{K}_{pp}^{=} & \mathbf{K}_{pp}^{\mp} \\ \mathbf{K}_{pp}^{\pm} & \mathbf{K}_{pp}^{\#} \end{bmatrix} \begin{bmatrix} \mathbf{I} \\ \mathbf{L} \end{bmatrix} \mathbf{q}_p^{-} = \begin{bmatrix} \mathbf{I} \\ -\mathbf{L} \end{bmatrix} \mathbf{f}_p^{-} \tag{9}$$

with $\mathbf{I}$ being now the twelve-by-twelve unit matrix. This equation can be solved to express the passive variables as slave functions of the master active displacements, yielding

$$\mathbf{q}_p^{-} = \mathbf{R}\big(\mathbf{K}_{pa}^{+} + \mathbf{L}\mathbf{K}_{pa}^{-}\big)\mathbf{q}_a, \qquad \mathbf{f}_p^{-} = \big(\mathbf{K}_{pa}^{-} + \big(\mathbf{K}_{pp}^{=} + \mathbf{K}_{pp}^{\mp}\mathbf{L}\big)\mathbf{R}\big(\mathbf{K}_{pa}^{+} + \mathbf{L}\mathbf{K}_{pa}^{-}\big)\big)\mathbf{q}_a \tag{10}$$

where the $\mathbf{k}$-dependent matrix $\mathbf{R} = -\big(\mathbf{L}\mathbf{K}_{pp}^{\mp}\mathbf{L} + \mathbf{L}\mathbf{K}_{pp}^{=} + \mathbf{K}_{pp}^{\#}\mathbf{L} + \mathbf{K}_{pp}^{\pm}\big)^{-1}$ is diagonal.

Similarly, the imposition of the quasi-periodicity conditions to the upper (dynamic) part of the equation (4) leads to a coupled equation which, after *condensation* of the passive variables by virtue of the enslaving relations (11), depends on the active variables only

$$\begin{bmatrix} \mathbf{M}_r & \mathbf{O} \\ \mathbf{O} & \mathbf{M}_a \end{bmatrix} \begin{pmatrix} \ddot{\mathbf{q}}_r \\ \ddot{\mathbf{q}}_a \end{pmatrix} + \begin{bmatrix} \mathbf{K}_r & -\mathbf{K}_r \\ -\mathbf{K}_r & \mathbf{K}_r + \mathbf{K}_a \end{bmatrix} \begin{pmatrix} \mathbf{q}_r \\ \mathbf{q}_a \end{pmatrix} = \begin{pmatrix} \mathbf{0} \\ \mathbf{0} \end{pmatrix} \tag{11}$$

where the condensed stiffness matrix $\mathbf{K}_a = \mathbf{K}_{aa} + (\mathbf{K}_{ap}^{-} + \mathbf{K}_{ap}^{+}\mathbf{L})\mathbf{R}(\mathbf{K}_{pa}^{+} + \mathbf{L}\mathbf{K}_{pa}^{-})$, with the symmetries $\mathbf{K}_{ap}^{-} = (\mathbf{K}_{pa}^{-})^{\top}$ and $\mathbf{K}_{ap}^{+} = (\mathbf{K}_{pa}^{+})^{\top}$ is known to be Hermitian and is derived in [30].

As brief discussion, the upper part of equation (11) can still be recognized to govern the local resonator dynamics, whereas the lower part governs the global dynamics of the cell microstructure. It is worth noting that the passive variable condensation, including the enforcement of the quasi-periodicity, is not mathematically affected by the resonator presence. Indeed, the condensed *global* stiffness matrix $\mathbf{K}_g = (\mathbf{K}_r + \mathbf{K}_a)$ of the meta-material is not formally different from the matrix $\mathbf{K}_a$ governing the wave propagation in the resonator-free material, apart for the mere addiction of the *local* stiffness term $\mathbf{K}_r$. Conversely, the uncoupled global dynamics the resonator-free material can be restored by simply zeroing the local matrices $\mathbf{M}_r$ and $\mathbf{K}_r$. Physically, this remark can immediately be justified by the absence of any internal coupling between the resonant active variables $\mathbf{q}_r$ and the condensed passive variables $\mathbf{q}_p$.

Denoting ω the unknown nondimensional frequency, the harmonic monofrequent solution $\mathbf{q}_a = \mathbf{F}_a\boldsymbol{\psi}_a\,\mathrm{e}^{\mathrm{i}\,\omega\tau}$ and $\mathbf{q}_r = \mathbf{F}_r\boldsymbol{\psi}_r\,\mathrm{e}^{\mathrm{i}\,\omega\tau}$ can be imposed in the equation (11). Eliminating the dependence on time, an eigenproblem in the unknown eigenvalues $\lambda = \omega^2/\omega_c^2$ and eigenvectors $\boldsymbol{\psi} = (\boldsymbol{\psi}_r, \boldsymbol{\psi}_a)$ can be stated in the non-standard form $(\mathbf{K} - \lambda\mathbf{M})\,\mathbf{F}\boldsymbol{\psi} = \mathbf{0}$, or more explicitly

$$\left(\begin{bmatrix} \mathbf{K}_r & -\mathbf{K}_r \\ -\mathbf{K}_r & \mathbf{K}_a \end{bmatrix} - \lambda \begin{bmatrix} \mathbf{M}_r & \mathbf{O} \\ \mathbf{O} & \mathbf{M}_a \end{bmatrix}\right) \begin{bmatrix} \mathbf{F}_r \\ \mathbf{F}_a \end{bmatrix} \boldsymbol{\psi} = \begin{pmatrix} \mathbf{0} \\ \mathbf{0} \end{pmatrix} \tag{12}$$

where the diagonal block matrices $\mathbf{F}_r = \mathbf{F}_a = \mathrm{diag}[\,\mathbf{I}\,\mathrm{e}^{\mathrm{i}\,\mathbf{k}\cdot\mathbf{x}_1}, ..., \mathbf{I}\,\mathrm{e}^{\mathrm{i}\,\mathbf{k}\cdot\mathbf{x}_4}\,]$.

The eigenproblem solution gives twenty-four real-valued eigenvalues λ_i (or frequencies ω_i), sorted in ascending order. It is worth remarking that, owing to the Hermitian property, the $\mathbf{K}$-matrix is certainly non-defective, that is, possesses a complete eigenspace spanned by twenty-four proper eigenvectors. Therefore, each eigenvalue λ_i has coincident algebraic and geometric multiplicity m_i and corresponds to a complex-valued eigenvector $\boldsymbol{\psi}_i$, collecting the non-passive eigencomponents $\boldsymbol{\psi}_{ri}$ and $\boldsymbol{\psi}_{ai}$ only. The passive eigencomponents depend on the active eigencomponents through the quasi-static relations $\boldsymbol{\psi}_{pi}^{-} = \mathbf{R}\big(\mathbf{K}_{pa}^{+} + \mathbf{L}\mathbf{K}_{pa}^{-}\big)\boldsymbol{\psi}_{ai}$ and $\boldsymbol{\psi}_{pi}^{+} = \mathbf{L}\boldsymbol{\psi}_{pi}^{-}$.

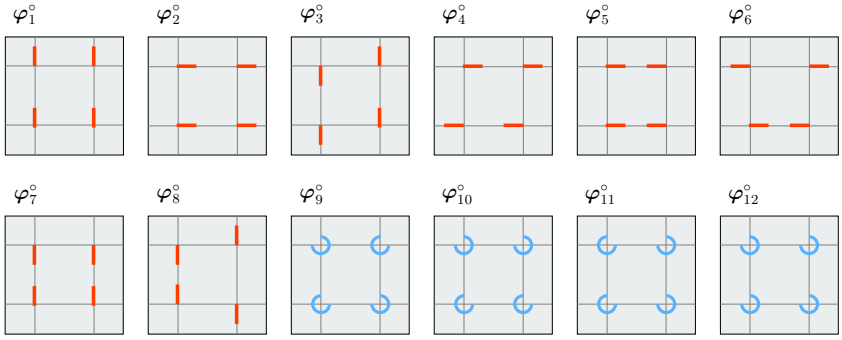

Figure 2: Stationary translational (red) or rotational (blue) modes $\boldsymbol{\psi}_{ai}$ of the anti-tetrachiral material (a omitted).

3 FLOQUET-BLOCH SPECTRUM

Fixed certain parameter values for the beam-lattice model and the resonators, the twenty-four eigenvalues (or frequencies) and the corresponding eigenvectors can be determined under variation of the nondimensional wavevector $\mathbf{b} = (\beta_1, \beta_2)$, composed of the wavenumbers

$$\beta_1 = \mathbf{k} \cdot \mathbf{d}_{56} = \mathbf{k} \cdot \mathbf{d}_{78}, \qquad \beta_2 = \mathbf{k} \cdot \mathbf{d}_{911} = \mathbf{k} \cdot \mathbf{d}_{1012} \tag{13}$$

in the square Brillouin domain $\mathcal{D} = [-\pi, \pi] \times [-\pi, \pi]$. According to the Floquet-Bloch theory [31–33], this investigation can be focused on the two edges

$$\mathcal{B}_1 = \{\beta_1 \in [0, \pi], \beta_2 = 0\}, \qquad \mathcal{B}_{12} = \{\beta_1 = \beta_2 \in [0, \pi]\} \tag{14}$$

which bound the irreducible triangular zone of the $\mathcal{D}$-domain and are spanned by the abscissae β_1 and $\beta_{12} = (\beta_1^2 + \beta_2^2)^{1/2}$, respectively. The corresponding ω-frequent vibration waves propagate through the periodic material along the horizontal direction (with β_1-wavenumber ranging in $[0, \pi]$) and diagonal direction (with β_{12}-wavenumber ranging in $[0, \sqrt{2}\pi]$).

The frequency loci versus the variable wavenumber constitute the Floquet-Bloch spectrum, composed of twenty-four dispersion curves for the meta-material or twelve dispersion curves for the resonator-free material (as can be carried out by setting $\mathbf{M}_r = \mathbf{K}_r = \mathbf{O}$). The curve *roots*, located at the $\mathcal{D}$-origin ($\beta_1 = \beta_2 = 0$), correspond to the quasi-periodicity conditions (7) degenerating into conditions of standard periodicity. Therefore, the corresponding eigenpairs $(\lambda^\circ, \boldsymbol{\varphi}^\circ)$ can be interpreted as the natural frequencies, possibly null, and (real-valued) vibration modes of the single elementary cell in the free stationary harmonic oscillation of the periodic system. In the absence of resonators, these modes are participated only by an homogeneous subset of active displacements (Figure 2). so that they can be classified as *translational modes*, if contributed by the four horizontal or the four vertical components, or *rotational modes*, if contributed by the four rotation components. With minor abuse of nomenclature, the same classification can be extended to the $\mathbf{b}$-dependent eigenvectors, which can be interpreted as polarization modes of the propagating wave, characterized by a certain (not null) wavenumber.

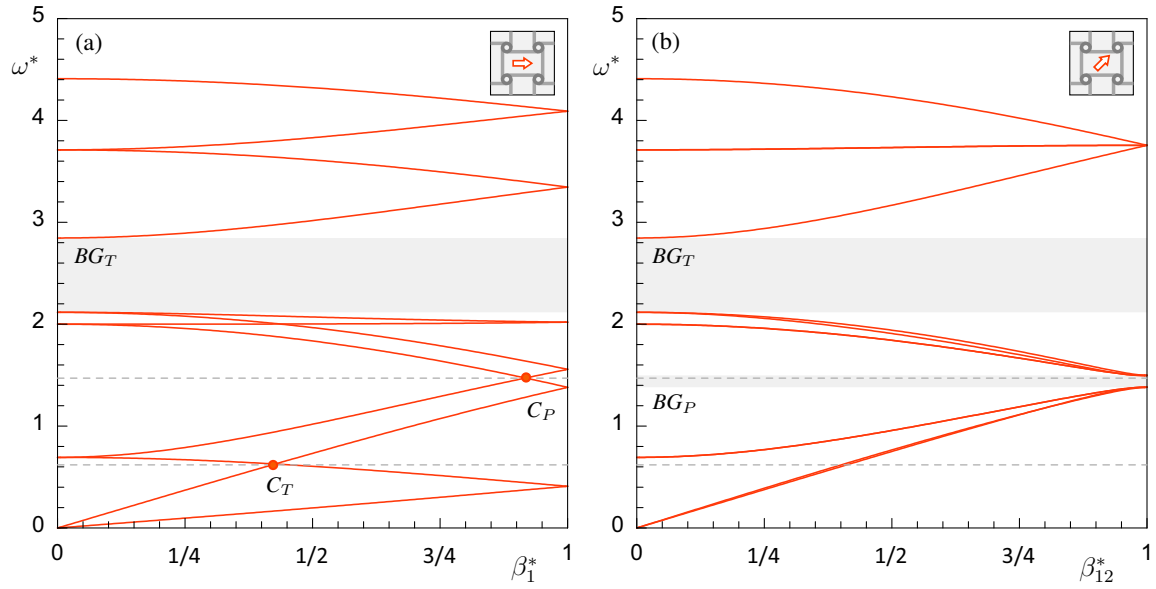

Figure 3: Floquet-Bloch spectrum ($\omega* = \omega/\omega_c$) of the anti-tetrachiral material (without resonators): (a) horizontal and (b) diagonal direction of wave propagation ($\beta_1^* = \beta_1/\pi$, $\beta_{12}^* = \beta_{12}/(\sqrt{2}\pi)$).

3.1 Parametric analysis

In the absence of resonators, the Floquet-Bloch spectrum is presented in Figure 3 for a set of parameter values ($\chi^2 = 1/81, \delta = 1/10, \varrho^2 = 1/100$). For both the propagation directions, the low-frequency (namely ω_1-ω_8) and high-frequency (namely ω_9-ω_{12}) ranges are separated from each other by the total band gap BG_T, and the respective polarizations are systematically dominated by translational and rotational modes, respectively. Some parametric analyses show that, as long as the two frequency ranges remains well-separated, the translational frequency curves (rigorously, the curves related to the frequencies of translational modes) undergo only minor qualitative and quantitative changes for slight variations of the parameter set $(\varrho^2, \chi^2, \delta)$. On the contrary, the rotational frequencies (rigorously, the curves related to the frequencies of rotational modes) strongly depend on the δ and χ parameters, with an approximately linear law of direct and inverse proportionality, respectively. Physically, this remark states that the amplitude of the total band gap BG_T can be amplified/reduced by modifying the ring density (higher/lower δ-values) or their rotational-to-translational mass ratio (lower/higher χ^2-values). For instance, the band gap can be verified to close (null amplitude) for $\chi^2 \geq 1/36$.

As major remark, the material does not present low-frequency total band gaps, neither they can be obtained for a different, generic parameter set. This persistent scenario is a direct consequence of the high spectral density characterizing the translational frequencies, together with the large number of crossing points between their dispersion curves. Looking at waves propagating along the diagonal direction (Figure 3b), the small-amplitude partial band-gap BG_P can be found at low-frequencies, ranging between two translational-translation curves. It can be verified that this gap occurs in the direction of minimum auxeticity of the material, consistently with the findings of [14]. Fixed the other parameter, the gap amplitude A_{12} can be moderately increased by an increment of the δ-parameter, up to $A_{12} \simeq 0.250$.

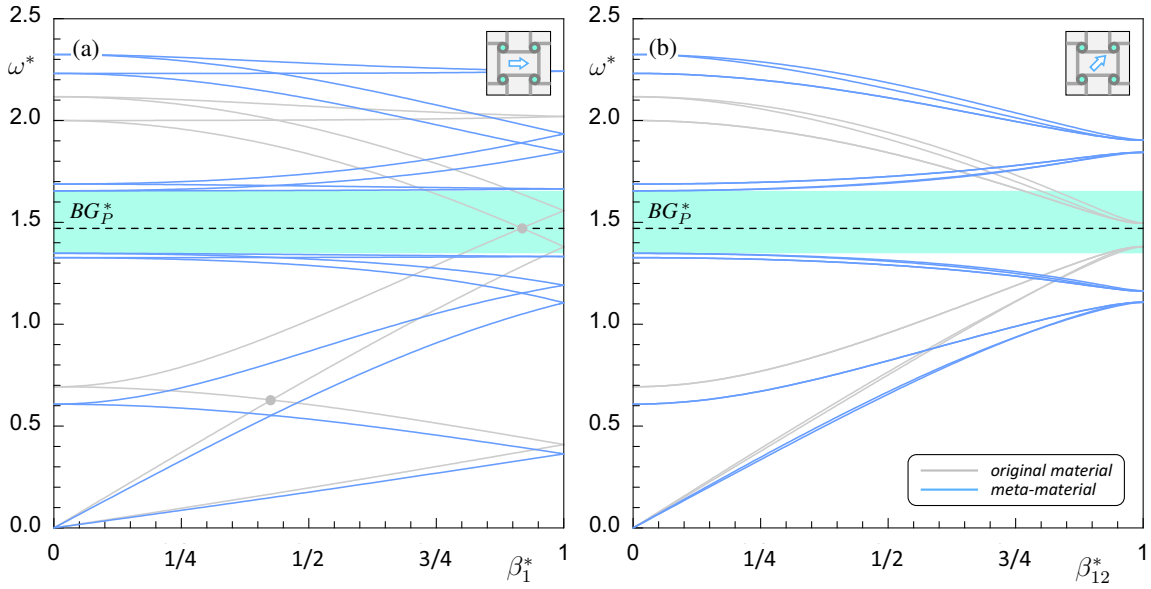

Figure 4: Low-frequency Floquet-Bloch spectrum ($\omega* = \omega/\omega_c$) of the meta-material ($\gamma = 148/100$): (a) horizontal and (b) diagonal direction of wave propagation ($\beta_1^* = \beta_1/\pi$, $\beta_{12}^* = \beta_{12}/(\sqrt{2}\pi)$).

3.2 Effects of the local resonators

The strong potential recognized to micro-oscillator arrays in preventing the wave propagation through periodic lattices can be explained by the effective negative values of mass density achievable in the equivalent elastic continua [25, 26]. Inter-oscillator distances lower than the typical wavelengths let the meta-material internally resonate in the low-frequency range, where band gaps may open in the Floquet-Bloch spectrum, in correspondence with the tunable natural frequencies of the oscillators (resonators). The present study is focused on two different tasks

i. check whether a proper tuning of the meta-material resonators (through the γ-parameter) allow the opening of total band gaps, by either the widening of an existing partial band gap or the transformation of a crossing point into a veering between adjacent curves,

ii. verify the possibility to finely control (through the α-parameter) the total band-gap amplification/deamplification, in order to quantitatively evaluate the meta-material potential in terms of achievable performance range against undesired wave propagation.

To the former task, the oscillator-to-ring mass can be tentatively assigned to the reference value $\alpha = 1/2$, which optimizes the resonator performance in similar chiral meta-materials [29]. First, the partial-to-total widening of the low-frequency band gap BG_P is challenged. The crossing C_P between the forth and fifth dispersion curves, which closes the band gap in the horizontal propagation direction, is pointed as target frequency by tuning $\gamma = 148/100$ (corresponding to the upper dashed line in Figure 3). The efficiency of the resonator action is confirmed by the low-frequency Floquet-Bloch spectrum of the meta-material (Figure 4). Indeed, a new total band BG_P^*, with almost $\mathbf{b}$-independent amplitude $A_1 = A_{12} \simeq 0.300$, rises up and lies just across the tuned frequency. The original crossing point is removed by a strong softening/hardening effect, consisting in the downward/upward frequency shifting of the previously intersecting curves (gray lines). The band gap opening is not compromised by the local densification of the spectrum owing to the doubled dimension of the meta-material model.

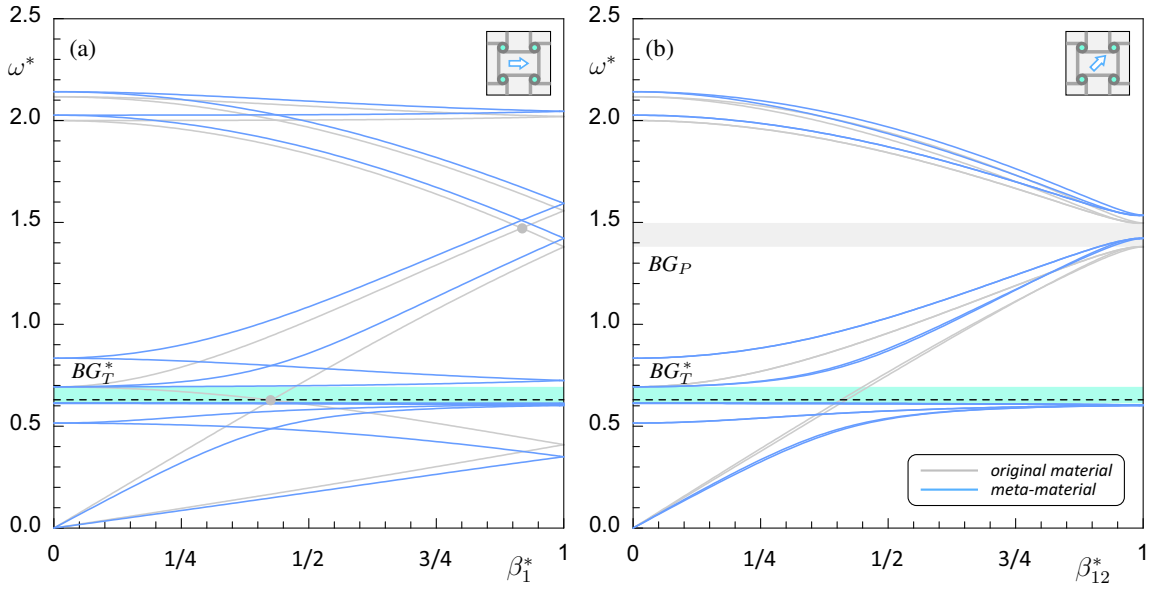

Figure 5: Low-frequency Floquet-Bloch spectrum of the anti-tetrachiral meta-material ($\gamma = 62/100$): (a) horizontal and (b) diagonal direction of wave propagation ($\beta_1^* = \beta_1/\pi$, $\beta_{12}^* = \beta_{12}/(\sqrt{2}\pi)$).

Second, the crossing C_T between the second and third dispersion curves, which characterizes the horizontal propagation direction, is pointed as target frequency by tuning $\gamma = 62/100$ (corresponding to the lower dashed line in Figure 3). Again, the resonator action successes in opening a low-frequency total band BG_P^*, with almost $\mathbf{b}$-independent amplitude $A_1 = A_{12} \simeq 0.037$, lying across the tuned frequency (Figure 5). The band gap is provided by a strong linear interaction among the new spectrum curves and the previously intersecting curves (gray lines), which are forced to veer away form their original crossing point.

To the latter task, a few parametric analyses have been carried out under variation of the resonator-to-ring mass, without changes in the tuning parameters (Table 1). The results tend to confirm that the total band gap amplitudes are $\mathbf{b}$-independent ($A_1 = A_{12}$) and that – fixed the resonator mass – larger band gap are achievable at higher tuning frequencies. Finally, the band gap amplitudes are found to grow up with the increments of the resonator mass. In this respect, the trend of the mass-to-amplitude ratios suggests an underlying quadratic relationship which could be investigated by means of local analyses based on perturbation methods.

Table 1: Amplitudes of the low-frequency band-gaps obtainable in the anti-tetrachiral meta-material.

4 CONCLUSIONS

A parametric beam-lattice model has been formulated to describe the linear planar dynamics of the unit cell which characterizes the periodic microstructure of the auxetic anti-tetrachiral material. The persistent absence of low-frequency band gaps in the Floquet-Bloch spectrum has been verified. This lack limits the smart functionalities of passive noise suppression and vibration filtering of the material, when it is used as elastic waveguide. The transformation into a meta-material, by introducing local undamped resonators with flexible properties of tunable *frequency* and selectable *mass* ratio, has demonstrated its potential in strongly modifying the original low-frequency band structure. In particular, a tailor-made design of the resonator parameters has allowed the widening of an existing partial band gap, as well as the opening of a new band gap across the tuned frequency, with adjustable amplitude depending on the selected mass.

Keywords: flexible model, vibration complex system, extreme moving load, closed-form solution.

Abstract. *In this paper the dynamic response of a complex double-string system traversed by extreme moving load is considered. The paper includes the study of a dynamic behavior of a finite, simply supported double-string flexible complex system subject to moving forces with a constant velocity on the top string. The strings are identical, parallel one upon the other and continuously coupled by a linear Winkler elastic element. The moving loads are around an extreme position of the shear wave velocity of the strings. The classical solution of the response of complex systems subjected to forces moving with a constant velocity has a form of an infinite series. But also it is possible to show that in the considered case part of the solution can be presented in a closed, analytical form instead of an infinite series. The presented method to search for a solution in a closed, analytical form is based on the observation that the solution of the system of partial differential equations in the form of an infinite series is also a solution of an appropriate system of ordinary differential equations. The closed solutions take different forms depending if the velocity of a moving force is smaller, equal or larger than the shear wave velocity of the strings. This follows from the fact that in string wave phenomena may occur. The solution for the dynamic response of the composite strings under moving force is important because it can be used also in order to find the solution for other types of moving loads. The double string connected in parallel by linear elastic elements can be studied as a theoretical model of composite system or prestressed structure in which coupling effects and transverse wave effects are taken into account.*

1 INTRODUCTION

Flexible complex systems have a wide range of applications to civil, military, mechanical, transport, naval, aeronautical and aircraft as structural members with high strength to weight ratios. One of the most important issues in the dynamics of structures is moving load problems witch have been studied by many authors for many years [2-22]. Modeling of movement is very difficult in its complications and generates many mathematical problems [1,3,7,21]. Even simply models give very complex and unpredicted solutions of structural in dynamical and stability meaning. Thusly different types of structures and girders like beams, plates, shells, and frames also membranes, strings and cables have been considered. As well different models of moving loads have been assumed [3]. The paper includes the study of a dynamic behavior of a finite, simply supported double-string flexible complex system subject to moving force with a constant velocity on the top string. The strings are identical, parallel one upon the other and continuously coupled by a linear Winkler elastic element. The most critical situation is when moving loads are around an extreme position of the shear wave velocity of the strings. Responses of structures to extreme speed of load are often complex and difficult to understand, especially because of the complex nature of vibration repeatedly complicated systems. For instance, it is possible to observe some anomalies while the aircraft reaching speed of sound. The Prandtl–Glauert singularity [Fig.1] is the prediction by the Prandtl–Glauert transformation that infinite pressures would be experienced by an aircraft as it approaches the speed of sound. A certain similarity can be expected in the solid body, which can be proved by a closed-form solution of a string with a load moving at the speed of the transverse wave propagating in the string.

Figure 1: A F/A-18 Hornet during transonic flight, a Prandtl–Glauert singularity [NASA].

A string as a simple model of a one-dimensional continuous system resistant to tension but not to bending is often used in analysis of numerous engineering structures and has been a subject of great scientific interest for a considerable time. This follows from the fact that the vibrations of a string are described by the wave differential equation. This allows one to see the wave effect in a string, contrary to many more complex systems for example structural elements where it might be either not present or not clearly visible. The analogies between a string and the beams have been considered in papers [5,6,11]. Various aspects of the dynamics response of a string under a moving load have been considered, among others, in the papers [2,4,8,10,12-15,18-20,22]. The classical solution of the response of complex systems subjected to forces moving with a constant velocity has a form of an infinite series. But also it

is possible to show that in the considered case part of the solution can be presented in a closed, analytical form instead of an infinite series. Using the method, of superposed deflections Kączkowski [9] has shown for a simply supported Euler-Bernoulli beam that, in the case of undamped vibration, the aperiodic part of the solution can be presented in a closed-form. Next, Reipert obtained a closed form solutions for a beam with arbitrary boundary conditions [16] and for a frame [17]. In this paper, we use a different method to obtain the solutions in a closed form. The presented method to search for a solution in a closed, analytical form is based on the observation that the solution of the system of partial differential equations in the form of an infinite series is also a solution of an appropriate system of ordinary differential equations. The closed solutions take different forms depending if the velocity of a moving force is smaller, equal or larger than the shear wave velocity of the strings. This follows from the fact that in string wave phenomena may occur. The presented solutions can be also used in axial and torsional vibration of the rod. Using this method, the closed solutions for undamped vibration of string and beam due to moving force have been obtained in the papers [18-21]. The solution for the dynamic response of the composite strings under moving force is important because it can be used also in order to find the solution for other types of moving loads. The double string connected in parallel by linear elastic elements can be studied as a theoretical model of composite system or prestressed structure in which coupling effects and transverse wave effects are taken into account.

2 MATHEMATICAL MODEL AND GOVERNING EQUATION

Consider the problem of a dynamic behavior of flexible complex system consist of a finite, simply supported double-string. The strings are identical, parallel one upon the other and continuously interfaced by a linear Winkler elastic element with *k* coefficient. The strings are under axial compression *N* and the system are excited by a load *p(x,t)* moving with a constant velocity *v* on a top string as on Fig.2.

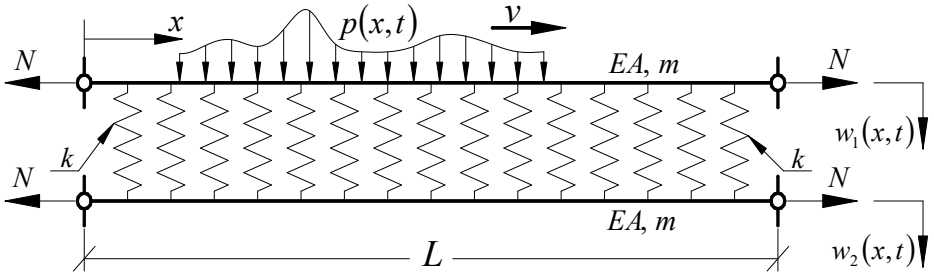

Figure 2: Double-string system under a moving force.

Vibrations describe functions $w_1(x,t)$ and $w_2(x,t)$ which solution in the classical-forms and closed-form is investigated. Hence an equation of motion of double-string system is governed by two conjugate partial differential equations:

$$-N\frac{\partial^2 w_1(x,t)}{\partial x^2}+m\frac{\partial^2 w_1(x,t)}{\partial t^2}+k\left[w_1(x,t)-w_2(x,t)\right]=p(x,t), \tag{1}$$

$$-N\frac{\partial^2 w_2(x,t)}{\partial x^2}+m\frac{\partial^2 w_2(x,t)}{\partial t^2}+k\left[w_2(x,t)-w_1(x,t)\right]=0, \tag{2}$$

where *m* is the mass per unit length ρA of each string, *k* denotes the stiffness modulus of a springs system, and furthermore, *EA* is the axial rigidity of the strings, *E* denotes Young's

modulus of elasticity and A is the area of the cross-section of the strings. The load function in expression (1) and from figure 2 has a form:

$$p(x,t) = P\,\delta(x - vt), \tag{3}$$

where P is the intensity value of the load and $\delta(.)$ denotes Dirac delta. After introducing the dimensionless variables:

$$\xi = x/L, \quad T = vt/L, \quad \xi \in [0,1], \quad T \in [0,1], \tag{4}$$

the differential equations of motion of the string-string system have the form:

$$-\frac{\partial^2 w_1(\xi,T)}{\partial \xi^2} + \eta^2 \frac{\partial^2 w_1(\xi,T)}{\partial T^2} + k_o\left[w_1(\xi,T) - w_2(\xi,T)\right] = P_o\,\delta(\xi - T), \tag{5}$$

$$-\frac{\partial^2 w_2(\xi,T)}{\partial \xi^2} + \eta^2 \frac{\partial^2 w_2(\xi,T)}{\partial T^2} + k_o\left[w_2(\xi,T) - w_1(\xi,T)\right] = 0. \tag{6}$$

The parameters from equations (5) and (6) have the following designations:

$$v_s = \sqrt{N/m}, \qquad \eta = v/v_s, \qquad k_o = k\,L^2/N, \qquad P_o = P\,L/N. \tag{7}$$

The quantity v_s represents velocity of the transverse wave in the system of double-string. On the other hand the boundary conditions for both Eq. (5) and Eq. (6) take the form:

$$w_j(0,T) = 0, \qquad w_j(1,T) = 0, \qquad j = \{1,\ 2\} \tag{8}$$

whereas the initial conditions are the following:

$$w_j(\xi,0) = 0, \qquad \left.\frac{\partial w_j(\xi,T)}{\partial T}\right|_{T=0} = 0, \qquad j = \{1,\ 2\}. \tag{9}$$

It is easy to see that if you add together the equations (5) and (6) and introduce a new function as $w_I(\xi,T)$ we get:

$$-\frac{\partial^2 w_I(\xi,T)}{\partial^2 \xi} + \eta^2 \frac{\partial^2 w_I(\xi,T)}{\partial^2 T} = P_o\,\delta(\xi - T), \tag{10}$$

which describes vibrations of a single string. But then again, when we take the difference of these equations and differences of deflection functions take as a new function $w_{II}(\xi,T)$, that can be saved:

$$-\frac{\partial^2 w_{II}(\xi,T)}{\partial^2 \xi} + \eta^2 \frac{\partial^2 w_{II}(\xi,T)}{\partial^2 T} + 2k_o\,w_{II}(\xi,T) = P_o\,\delta(\xi - T). \tag{11}$$

In turn, this one describes vibrations of a single string resting on an elastic Winkler support with double parameter k ($2k_o$). So the solution (10) and (11) is also a solution of expressions (5) and (6), after appropriate transformation function $w_I(\xi,T)$ and $w_{II}(\xi,T)$ into $w_1(\xi,T)$ and $w_2(\xi,T)$. In addition, the solutions of equations (5), (6), (10) and (11) for boundary conditions (8) and initial conditions (9) are assumed to be in the form of sine series:

$$w_k(\xi,T) = \sum_{n=1}^{\infty} y_{kn} \sin n\pi\xi, \qquad k = \{1,\ 2, I, II\}. \tag{12}$$

By substituting expression (10) into equations (5), (6), (10) or (11) and using the orthogonalization method one obtains set of uncoupled ordinary differential equations. Eventually, the solution of the above differential equations are sums of the particular integrals $w_k^A(\xi,T)$ and general integrals $w_k^S(\xi,T)$. We know that the angle of inclination of the tangent to the deflection function $w_k(\xi,T)$ can be presented:

$$\varphi_k(\xi,T)=\frac{\partial w_k(x,t)}{\partial x}=\frac{1}{L}\frac{\partial w_k(\xi,T)}{\partial \xi}, \tag{13}$$

additionally the dynamic component of the tension in the strings is given by:

$$N_k(\xi,T)=EA\frac{\partial w_k(x,t)}{\partial x}=\frac{EA}{L}\frac{\partial w_k(\xi,T)}{\partial \xi}. \tag{14}$$

3 THE CLASSICAL SOLUTIONS

The classical solution has a form of an infinite series, so classical part of the particular and general solution of the first string presents itself as:

$$w_1(\xi,T)=w_1^A(\xi,T)+w_1^S(\xi,T)=\frac{P_o}{1-\eta^2}\left\{\sum_{n=1}^{\infty}\frac{\left[2\,(n\pi)^2\,(1-\eta^2)+k_o\right]\,\sin n\pi T}{(n\pi)^4\,(1-\eta^2)+(n\pi)^2 k_o}\sin n\pi\xi+\right.$$
$$\left.-\sum_{n=1}^{\infty}\frac{\left[\frac{(n\pi)^3}{(1-\eta^2)^{-1}}\sin\left[\frac{\sqrt{(n\pi)^2+k_o}}{\eta}T\right]+\sqrt{(n\pi)^2+k_o}\left[\frac{(n\pi)^2}{(1-\eta^2)^{-1}}+k_o\right]\sin\frac{n\pi}{\eta}T\right]}{\eta^{-1}\,(n\pi)^2\sqrt{(n\pi)^2+k_o}\left[(n\pi)^2(1-\eta^2)+k_o\right]}\sin n\pi\xi\right\}, \tag{15}$$

and the second string:

$$w_2(\xi,T)=w_2^A(\xi,T)+w_2^S(\xi,T)=\frac{P_o}{1-\eta^2}\left\{\sum_{n=1}^{\infty}\frac{k_o\,\sin n\pi T}{(n\pi)^4\,(1-\eta^2)+(n\pi)^2 k_o}\sin n\pi\xi+\right.$$
$$\left.-\sum_{n=1}^{\infty}\frac{\left[\frac{(n\pi)^3}{(1-\eta^2)^{-1}}\sin\left[\frac{\sqrt{(n\pi)^2+k_o}}{\eta}T\right]-\sqrt{(n\pi)^2+k_o}\left[\frac{(n\pi)^2}{(1-\eta^2)^{-1}}+k_o\right]\sin\frac{n\pi}{\eta}T\right]}{\eta^{-1}\,(n\pi)^2\sqrt{(n\pi)^2+k_o}\left[(n\pi)^2(1-\eta^2)+k_o\right]}\sin n\pi\xi\right\}. \tag{16}$$

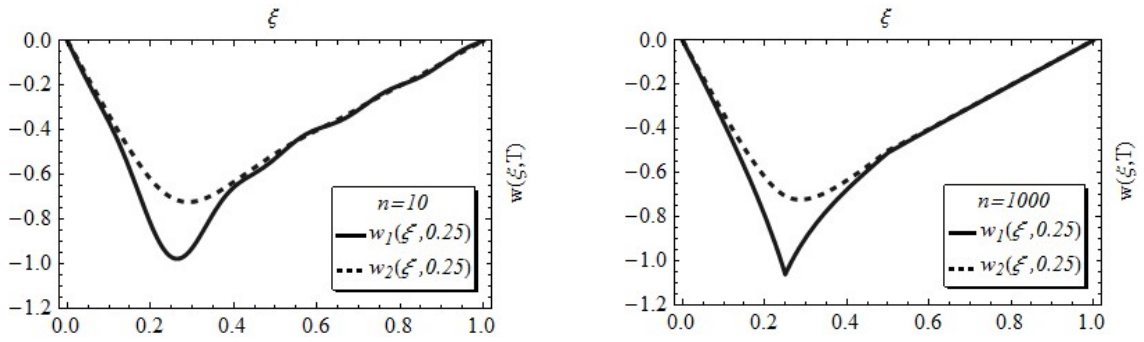

Figure 3: Deflection of the strings system depending on the number of approximation functions.

Analysis of functions (15) and (16) at the critical speed is difficult, even impossible, for example when $v = v_s$ ($\eta = 1$). On the one hand, the accuracy of the solution depends on respectively large number of approximation functions.

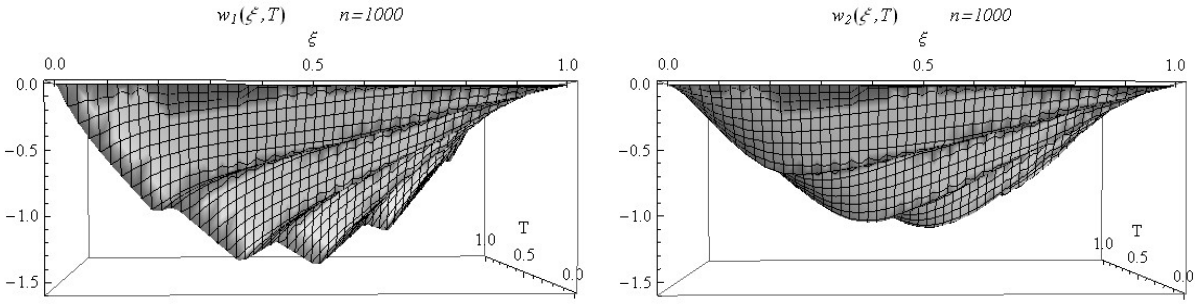

Figure 4: Overlap transverse waves in time of the double-string system under a moving force.

4 THE CLOSED-FORM SOLUTIONS

The classical solution of the response of complex systems subjected to forces moving with a constant velocity has a form of an infinite series, expressions (15) and (16). But also it is possible to show that in the considered case part of the solution can be presented in a closed, analytical form instead of an infinite series. The presented method to search for a solution in a closed, analytical form is based on the observation that the solution of the system of partial differential equations in the form of an infinite series is also a solution of an appropriate system of ordinary differential equations. For instance, let's take into consideration the particular solution Eq. (10) in the form of a series that is:

$$w_I^A(\xi,T)=\frac{2P_o}{1-\eta^2}\sum_{n=1}^{\infty}\frac{\sin n\pi T\sin n\pi\xi}{(n\pi)^2}. \tag{17}$$

It can be proved that the expression (17) is also integral ordinary differential equation:

$$-\frac{d^2w_I^A(\xi,T)}{d\xi^2}=\frac{2P_o}{1-\eta^2}\delta(\xi-T), \tag{18}$$

where T is only a parameter of time. Solving formula (18), by a finite Fourier sine transform, we get:

$$(n\pi)^2\,\overline{w}_I^A(n,T)=\frac{P_o}{1-\eta^2}\sin n\pi T, \tag{19}$$

where

$$\overline{w}_I^A(n,T)=\int_0^1 w_I^A(\xi,T)\sin n\pi\xi\;d\xi, \tag{20}$$

and thus we return to the expression (17), which proves our assumption. Therefore if the function (17) satisfies the equation (18), it can be represented as closed-solution:

$$w_I^A(\xi,T)=\frac{P_o}{1-\eta^2}\left[(1-T)\xi-(\xi-T)H(\xi-T)\right], \tag{21}$$

where $H(.)$ denotes the Heaviside step function, or the unit step function.

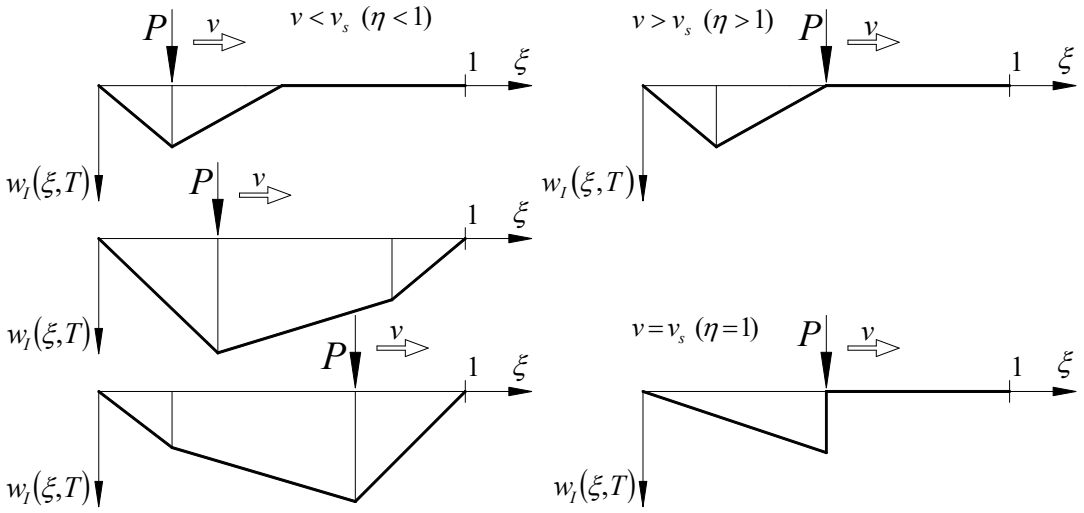

Figure 5: Deflection of string depending on velocity of moving force v and velocity of propagation transverse wave in string v_s.

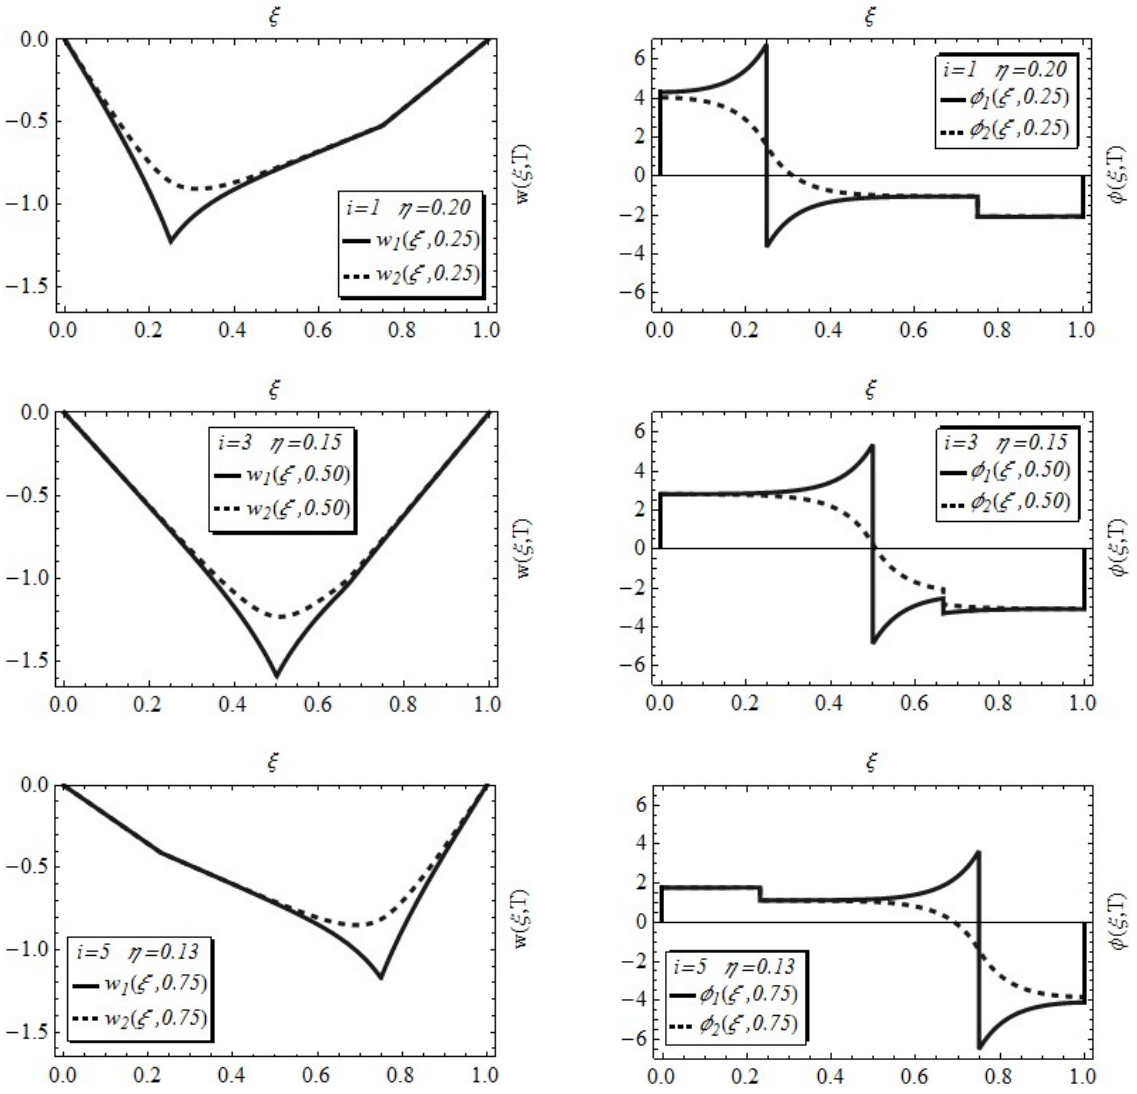

Figure 6: Deflection $w_i(\xi,T)$ and rotation $\varphi_i(\xi,T)$ of double-string system under a moving force.

The general integral $w_I^S(\xi,T)$ can be represented as closed-form solution, too. In a period of time $i\,\eta \le T \le (i+1)\,\eta \le 1$, where $i = 0, 2, 4,\ldots, 2n$, it satisfies the differential relationship:

$$\frac{d^2 w_I^S(\xi,T)}{d\xi^2} = \frac{P_o\,\eta}{1-\eta^2}\,\delta\left[\xi - \left(\frac{T}{\eta} - i\right)\right], \tag{22}$$

with the closed-form solution:

$$w_I^S(\xi,T) = \begin{cases} -\dfrac{P_o}{1-\eta^2}\,\xi\,\left[(i+1)\eta - T\right] & \text{for} \quad \xi \le \dfrac{T}{\eta} - i, \\ -\dfrac{P_o}{1-\eta^2}\,(1-\xi)(i\,\eta - T) & \text{for} \quad \xi \ge \dfrac{T}{\eta} - i. \end{cases} \tag{23}$$

For example, assuming $i = 0$ and consider the cases when the velocity of a moving force is smaller, equal or larger than the shear wave velocity of the strings. In a situation where $\eta < 1$ ($v < v_s$) and $\eta > 1$ ($v > v_s$) we get the formulas:

$$\eta < 1 \qquad w_I^S(\xi,T) = \begin{cases} \dfrac{P_o}{1+\eta}\,\xi & \text{for } \xi \le T, \\ \dfrac{P_o}{1-\eta^2}\,(T - \eta\,\xi) & \text{for } T \le \xi \le \dfrac{T}{\eta}, \\ 0 & \text{for } \dfrac{T}{\eta} \le \xi \le 1, \end{cases} \qquad \eta > 1 \qquad w_I^S(\xi,T) = \begin{cases} \dfrac{P_o}{1+\eta}\,\xi & \text{for } \xi \le \dfrac{T}{\eta}, \\ \dfrac{P_o}{1-\eta^2}\,(\xi - T) & \text{for } \dfrac{T}{\eta} \le \xi \le T, \\ 0 & \text{for } \xi \ge T. \end{cases} \tag{24}$$

Whereas when $\eta = 1$ ($v = v_s$):

$$w_I^S(\xi,T) = \begin{cases} \dfrac{P_o}{2}\,\xi & \text{for} \quad \xi < T, \\ 0 & \text{for} \quad \xi \ge T. \end{cases} \tag{25}$$

The closed-form solutions take different forms depending on the velocity of a moving force in relation to shear wave velocity of the strings. The graphic interpretation of this relationship is shown in Figure 5. And Figure 6 shows graphs in a period of time $i\,\eta \le T \le (i+1)\,\eta \le 1$, where $i = 1, 3, 5,\ldots, 2n-1$. More examples of closed-form solutions can be found [8,18-21].

5 SOME NUMERICAL RESULTS

In Figures 3-6, we presented deflections $w_k(\xi,T)$ and rotations $\varphi_k(\xi,T)$ of double-string complex system under the concentrated moving force. And the following dimensionless values of the parameters are used in the numerical calculations: $n = \{10, 1000\}$, $P_o = 10$, $k_o = 200$, $i = \{1, 3, 5\}$, $\eta = \{0.10, 0.13, 0.15, 0.20, 1.00\}$ and $T = \{0.25, 0.50, 0.75\}$. The results for different location of the moving force are presented in graphical form in Figs. 3-6. The continuous line represents the functions of the loaded string. The dashed line shows the functions of the second string for which the load is transferred with the coupling.

6 CONCLUSIONS

- The solution of the response of string-string complex systems subjected to forces moving with a constant velocity has a form of an infinite series, but also it is possible to show that in the considered case part of the solution can be presented in a closed, analytical form.

- A system of partial differential equations with solution in the form of an infinite series can be also a solution of an appropriate system of ordinary differential equations where a variable of time becomes only a parameter of time.
- The closed solutions take different forms depending if the velocity of a moving force is smaller, equal or larger than the shear wave velocity of the strings.
- The wave phenomena may occur in a complex system of double-string under moving forces.
- It is predicted a nonlinear solution in solid under load moving at a speed of transverse wave propagating in a solid.
- It is easier to observe the wave effect in a string, contrary to many more complex systems where it might be either not present or not clearly visible.
- The accuracy of solution gives the locate position of a transverse wave's front and a soliton which is a self-reinforcing solitary wave that maintains its shape while it propagates at a constant velocity.
- The double string connected in parallel by linear elastic elements can be studied as a theoretical model of composite system or prestressed structure in which coupling effects and transverse wave effects are taken into account.

Keywords: Self damping, cable dynamics, hysteretic bending, friction.

Abstract. *A new formulation is presented to model the hysteretic bending behaviour of metallic strands. The interaction between the wires of the strand is modeled through a frictional contact model based on the Amontons-Coulomb law and accounts for the effects of the tangential compliance mechanism. The new model is presented with reference to a single-layered mono-metallic strand and is applied to the study of the energy dissipation in cyclic bending.*

1 INTRODUCTION

Overhead electrical lines and, more in general, suspended cable structures subjected to wind forces are typically subjected to aeolian vibration, due to the alternate shedding of Von Karman's vortices. These vibrations can strongly affect the service life of cable structures, by inducing alternate bending stresses leading to wear damage and fretting fatigue of the strands and of the connected support equipment [3]. The assessment of the aeolian vibration level, therefore, is a crucial issue in the design and maintenance of cable supported structural systems.

During aeolian vibration, a relevant fraction of the power transmitted by the wind to the structure is dissipated through frictional dissipation phenomena, which occur within the vibrating cable (also referred to as *cable self-damping*) [3]. Stranded cables, in fact, are made of wires, which tend to slip relatively one to each other during the bending of the element.

An upper bound of the aeolian vibration amplitude can be found by imposing the balance between the input power, provided by the wind, and the total dissipation in the cable structure (Energy Balance Principle, see e.g. [1, 3]). Within this context, the most common approach to estimate the self-damping of the cables is based on experimental measurements on indoor laboratory test spans [4] and empirical or semi-empirical (e.g. [13]) expressions.

Focusing on overhead electrical lines, the following power law is commonly adopted to evaluate the power per unit-length, P_d, dissipated when the conductor vibrates according to a flexural natural mode with amplitude A [m] (single-peak antinode vibration amplitude) and frequency f [Hz]:

$$P_d = k \frac{A^l f^m}{T^n} \tag{1}$$

where: T [kN] is the axial load of the cable (assumed constant over the span) and k is a proportionality factor, depending in general on the mechanical and geometrical properties of the strand (see e.g. [2, 3]). The exponents (l, m, n) of the power law are determined by fitting the experimental data from laboratory forced vibration tests.

The approach based on the empirical power law (1) for the definition of the cable self-damping has two major drawbacks: (a) firstly, it relies on expensive and time consuming laboratory tests, and (b) secondly, it is subjected to quite relevant uncertainties since even small variations in the values of the exponents (l, m, n) can lead to a large scatter in the results of equation (1) (see e.g. [1]).

On the other hand, mechanical models starting from a description of the cable internal structure and of the interaction between wires to determine cable self-damping, up to date are still at the research stage (see e.g. the recent review by Spak et al. [14]).

Recently, the authors proposed a new approach to define the self damping of metallic cables [11], starting from the description of the hysteretic bending behaviour of metallic strands provided in [5, 8, 9]. The relative sliding between wires of a strand is first studied, by modeling each wire as a curved thin rod, according to the classic Kirchhoff-Clebsh-Love structural theory. A kinematic model is defined to relate the generalized strains of the wires to those of the strand and the internal contact conditions are analyzed by neglecting the deformation of the contact surfaces and assuming the classic Amontons-Coulomb friction law. The cross sectional response of the strand under cyclic bending is then studied, to obtain a closed-form expression for the dissipated energy per cycle. The latter turns out to be a non-linear function of the maximum bending curvature reached during the cycle. Furthermore, the dissipated energy depends also on the axial load of the strand and on the friction coefficient of the internal contact surfaces. Finally, once the cross sectional hysteretic bending behaviour is fully character-

ized, the cable self-damping can be easily evaluated through a straightforward analytical procedure.

The application of this new approach to overhead electrical lines has shown (see [11] for details) that it allows to recover the same structure of the empirical power law introduced in equation (1), while providing a full mechanical interpretation of the exponents (l, m, n) and of the proportionality factor k. The proposed approach has been successfully compared with experimental data from vibration tests on 20-60 m length laboratory test spans. Within this context, it has been shown that the proposed model delivers an upper-bound estimate of the cable self-damping. The latter finding has been recognized as a consequence of the assumption of non-deformable contact surfaces adopted to describe the hysteretic cross sectional behaviour of the strand. Neglecting the tangential compliance of the internal contact surfaces, indeed, can lead to an overestimate both of the dissipated energy per cycle as well as of the maximum bending stiffness of the strand cross section.

The aim of the present paper is to investigate the effect of the tangential compliance mechanism of the internal contact surfaces on the hysteretic bending behaviour of metallic strands. Accordingly, the mechanical model of the strand originally proposed in [5] is extended to account for the effects of the internal relative displacements due to the tangential contact compliance (see also [6]) and applied to evaluate the energy dissipated under cyclic bending loading.

The new mechanical model is presented in this paper with reference to the special case of a single-layered mono-metallic strand, in order to avoid cumbersome calculations stemming from a more complex internal geometry.

2 INTERNAL STRUCTURE OF THE STRAND

A typical structural steel strand is considered in this work. The strand is made of six circular round wires (diameter d_1) wrapped around a straight round core wire (diameter d_0), as it is sketched in Figure 1.

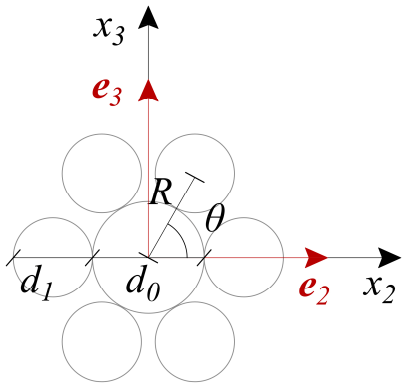

Figure 1: Cross section of the strand.

The external wires are in contact with the core, but not among them. Their centerline can be described as a circular helix in a reference system attached to the strand centerline, with axes $\{x_i\}$ (i=1, 2, 3). The axes x_2 and x_3 are defined on the cross section of the strand, as it is shown in Figure 1, while x_1 identifies the strand centerline. By denoting $\{\mathbf{e}_i\}$ the unit vectors of the axes $\{x_i\}$, the position vector of generic wire centerline can be defined as:

$$\mathbf{x}(\theta) = \frac{R}{\tan(\alpha)}(\theta - \theta_0)\mathbf{e}_1 + R\cos(\theta)\mathbf{e}_2 + R\sin(\theta)\mathbf{e}_3 \tag{2}$$

where: R is the *helix radius*, which can be simply evaluated as R=0.5(d_0+d_1), α is the lay angle, i.e. the constant angle which the tangent vector to the helix defines with the strand centerline (axis x_1), θ is the *swept angle* defined in Figure 1, and θ_0 denotes the value of the swept angle on the strand cross section identified by the coordinate: x_1=0.

3 MODELING OF THE HYSTERETIC BENDING BEHAVIOUR OF THE STRAND

The cross-sectional behaviour of a strand subjected to a combination of axial load F_s and bending moment M_s (herein assumed acting in the plane (x_1, x_3), without loss of generality) can be described through the following constitutive equations (see [5, 6, 8, 9] for details):

$$\begin{cases} F_s = EA_s\varepsilon_s \\ M_s = EI_{\min}\chi_s + M_s^{add}(\varepsilon_s, \chi_s) \end{cases} \tag{3a, b}$$

where ε_s and χ_s are the axial strain and bending curvature of the strand, respectively.

The axial behaviour of the strand (equation (3a)) is linear and independent of the bending curvature. By denoting as EA_0 and EA_1 the axial stiffness of the core and of the external wires, the axial stiffness EA_s can be evaluated (see also [6]) as:

$$EA_s = EA_0 + 6EA_1\cos^3(\alpha) \tag{4}$$

On the other hand, two contributions can be recognized in the expression of the bending moment M_s (equation (3b)). The first one is linear, independent on the axial strain of the strand and accounts for the individual bending of the wires with respect to a diameter parallel to the axis x_2 (see e.g. [8] for details). This term can be evaluated by assuming that the strand behaves as a bundle of individually bent elastic curved thin rods, i.e. by neglecting interaction between the wires of the strand. Under this limit kinematic assumption, the cross sectional bending stiffness attains its minimum value [8]:

$$EI_{\min} = EI_0 + 6\cos^3(\alpha)EI_1 \tag{5}$$

where EI_0 and EI_1 are the bending stiffness of the core and of the external wires, respectively.

The additional term M_s^{add} in equation (3b), instead, is non-linear and accounts for the contribution to the total bending moment of the cross section due to the axial force acting in the individual wires: F_{w1}. The latter, can be decomposed (see also [6]) into a first contribution, $F_{w1,a}$, due to the axial load F_s, and a second one, $F_{w1,b}$, due to the bending of the strand, i.e.: $F_{w1} = F_{w1,a} + F_{w1,b}$. Due to the axial symmetry of the strand, the term $F_{w1,a}$ doesn't depend on the swept angle θ and the additional bending moment in (3b) can be expressed as a function of the components $F_{w1,b}$. The following expression can be easily obtained through equilibrium:

$$M_s^{add} = \sum_{i=1}^{6} R\cos(\alpha)F_{w1,b}(\theta_i)\sin(\theta_i) \tag{6}$$

As long as the friction forces on the internal contact surfaces are large enough to prevent relative displacements (*gross-sliding*) between the wires and the core, i.e. in the *no-sliding* regime, the force $F_{w1,b}$ can be evaluated as:

$$F_{w1,b}^{no-sliding}(\theta) = \frac{\cos^2(\alpha) R\, EA_1\, \chi_s}{1 + \dfrac{C_{Ti}(P)\, EA_1 \sin^2(\alpha)}{R^2}} \sin(\theta) \tag{7}$$

The above expression accounts for the effect of the internal relative displacements due to the tangential contact compliance mechanism and has been first derived by one of the authors in [6] by extending the mechanical model previously developed in [5] under the assumption of non-deformable contact surfaces.

The variable C_{Ti} in equation (7) is the initial value of the tangential compliance between the external wires and the core, evaluated in the straight configuration of the strand (i.e. for χ_s=0), which depends on the normal force per unit length P exerted from the external wires on the core. The latter, in turn, depends on the axial force acting on the strand and introduces a coupling between the axial problem and the bending of the strand, as already highlighted in equation (3b). Closed-form expressions for the normal contact force P and for the tangential compliance C_{Ti}, here omitted for the sake of conciseness, can be found in [6].

The gradient of the wire axial force $F_{w1,b}$, which can be easily derived from (7), gives the wires the trend to slip with respect to the underlying core. The gross-sliding of the wires, however, is contrasted by the tangential contact forces which act on the internal contact surfaces and are bounded by the Amontons-Coulomb friction law. To study the non-linear transition between the no-sliding and gross-sliding regime, a numerical strategy has been developed by the authors (see e.g.: [5, 9]) and is adopted also in this work. The numerical procedure is based on a classic *Return-Map algorithm*, based on a *no-sliding* prediction and a *gross-sliding* correction. The algorithm delivers the value of the gradient of the wire axial force which satisfies the Amontons-Coulomb friction law, over a discrete set of control points defined along the pitch of the wire. Then, the wire axial force $F_{w1,b}$ is obtained through numerical integration along the wire length.

Once the axial force $F_{w1,b}$ is known, the additional bending moment M_s^{add} can be evaluated from equation (6). Finally, by assuming that the strand is subjected to a bending curvature χ_s cyclically variable in the range $\pm \chi_{\max}$, the dissipated energy per cycle can be simply evaluated as the area A_c enclosed in the hysteretic moment-curvature diagrams, i.e.:

$$A_c = \oint_{\pm\chi_{\max}} M_s(\chi_s)\, d\chi_s \tag{7}$$

A more detailed discussion on the cross sectional model can be found e.g. in [6] where the results of the implementation into a corotational beam finite element [7, 10] are also presented. The relation between A_c and the dissipated power P_d per unit length of the cable (self-damping), instead, is extensively discussed in [11].

4 NUMERICAL APPLICATION

The proposed model is applied to study the cross sectional hysteretic behaviour of a well-documented steel strand (see e.g. [12, 15]), already studied by the authors under the action of axial load and planar bending in [6, 9]. The geometric and material properties of the element are listed in Table 1.

d_0 (mm)	d_1 (mm)	α (deg)	E (GPa)	ν (-)
3.94	3.73	11.8	188	0.3

Table 1: Geometric and material parameters from [12].

The results obtained with the new formulation proposed in this paper are systematically compared with the predictions of the previous authors' model [5], which neglects the effect of the tangential compliance mechanism (i.e. C_{Ti}=0 in equation (7)). The initial behaviour of the latter model, will be referred to, in the following, as the *full-stick initial behaviour*, to emphasize the fact that in this case the cross section of the strand is initially considered to behave as an ideal rigid body.

Figures 2(a, b, c) show the cross sectional hysteresis loops evaluated for several values of the maximum curvature χ_{max}. The results have been evaluated for different values of the interwire friction coefficient μ and of the non-dimensional axial load parameter η, defined as the ratio between the axial force F_s and the Rated Tensile Strength of the strand (here 137 kN – see [15]).

From Figures 2(a) and 2(b), it can be easily appreciated that by increasing the strand axial load, the area of the hysteresis loop can be remarkably enlarged. A similar effect is obtained by increasing the value of the friction coefficient (see Figures 2(a) and 2(c)).

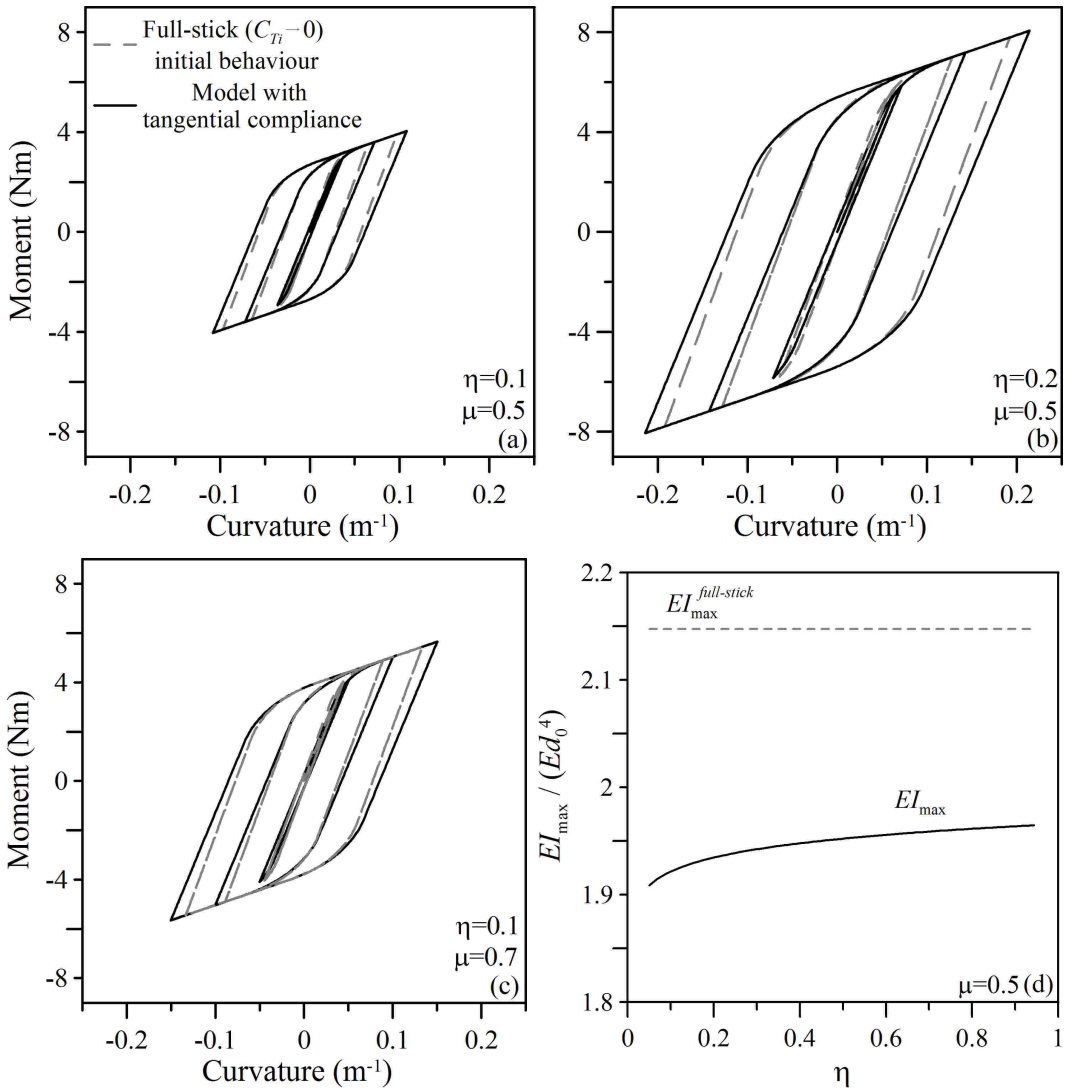

Figure 2: Cross sectional hysteretic behaviour. Hysteresis loops evaluated for: (a) η=0.1 and μ=0.5, (b) η=0.2 and μ=0.5, (c) η=0.1 and μ=0.7. Figure 2(d) shows the non-dimensional initial bending stiffness vs. the axial loading parameter η.

The results of the two models are very similar, for the special case considered in this application. As a matter of fact, the main effect of the tangential compliance mechanism can be recognized in a reduction of about 10% of the value of the initial stiffness of the moment-curvature relation (i.e. the maximum bending stiffness of the strand section: $EI_{\max}$). This effect can be clearly appreciated from Figure 2(d), where the non-dimensional initial bending stiffness $EI_{\max}/(Ed_0^4)$ is plotted against the loading parameter η. As a reference, the corresponding constant value evaluated under the full-stick assumption is also plotted with a grey dashed line.

On the other hand, both the area as well as the shape of the hysteresis loops are very slightly affected by the presence of the tangential compliance mechanism. The latter findings can be further appreciated from Figures (3) and (4), where the secant stiffness of the hysteresis loops and the dissipated energy per cycle (see equation (7)), respectively, are plotted against the maximum curvature of the cycles. It's worth noting that, as expected, the dissipated energy per cycle predicted by the new model is always slightly lower than the one evaluated by neglecting the tangential compliance between the external wires and the core.

5 CONCLUSIONS

A new formulation to model the hysteretic bending behaviour of metallic strands has been developed and presented for the special case of single-layered mono-metallic elements. Each wire of the strand is individually modeled as an elastic curved thin rod, in linear contact with the underlying core. A contact model is then introduced to describe the interaction among the external wires and the core. Friction is modeled through the Amontons-Coulomb law and the effects of the tangential contact compliance are accounted for, aiming at extending a previous authors' model taking into account the gross sliding only.

The proposed model, then, has been applied to study the energy dissipation of a steel strand subjected to cyclic bending loading. For the particular strand considered in this work, it is found that the tangential contact compliance mainly influence the initial bending stiffness of the strand, while it has only a small effect on the secant stiffness and area of the hysteresis loops. Ongoing research is devoted to the extension of the proposed formulation to other strand geometries, including the case of multi-layer elements, for which the effects of the tangential compliance are expected to be more pronounced.

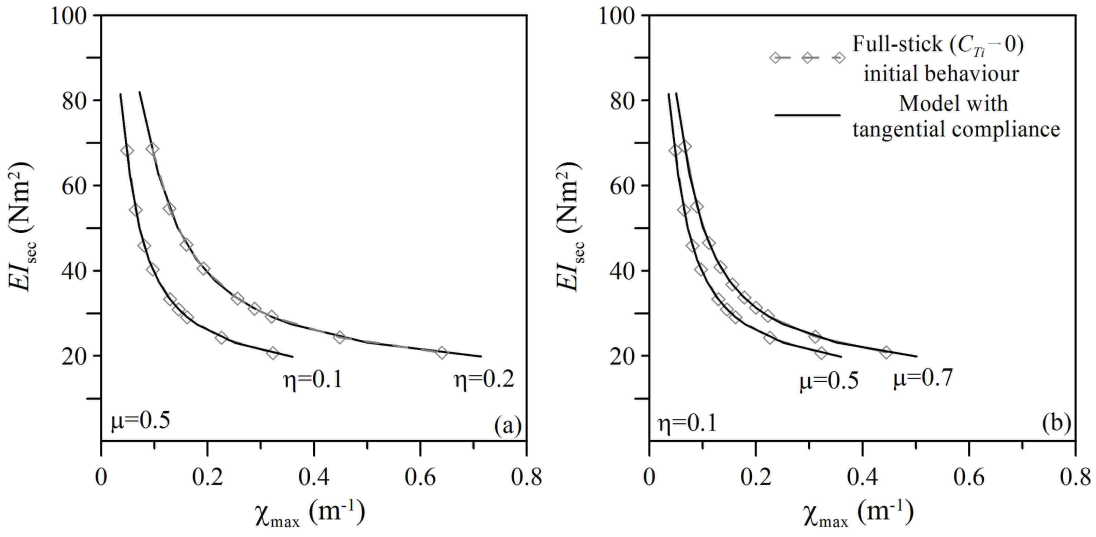

Figure 3: Secant stiffness EI_{sec} of the hysteresis loops vs. the maximum curvature of the cycles χ_{max}. (a) Friction coefficient μ=0.5, different values of η. (b) Axial loading parameter η=0.1, different values of μ.

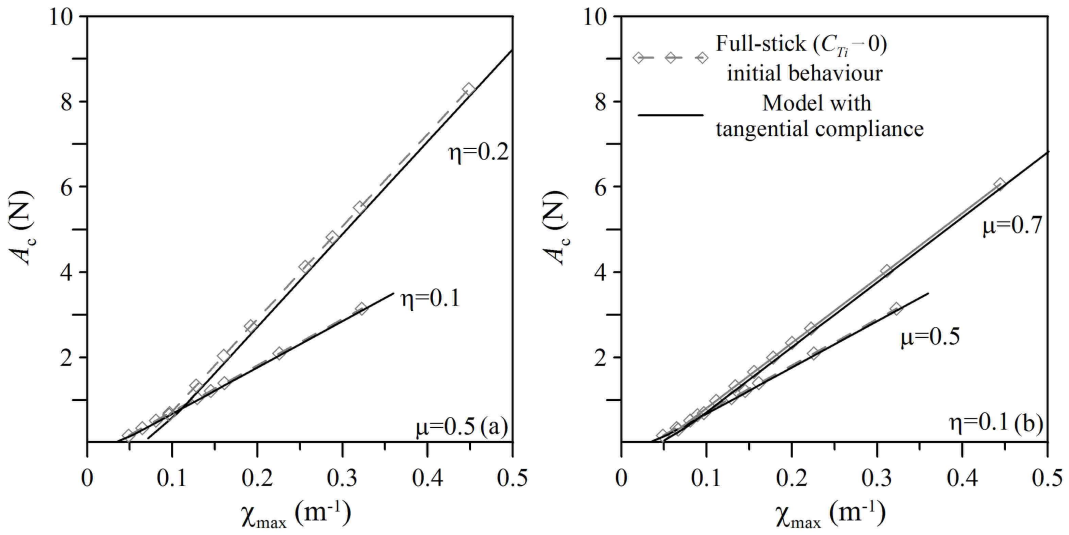

Figure 4: Dissipated energy per cycle A_c vs. the maximum curvature of the cycles χ_{max}. (a) Friction coefficient μ=0.5, different values of η. (b) Axial loading parameter η=0.1, different values of μ.

Abstract. *Distributed control systems for vibration control of large structures involve a large number of actuation devices and sensors that work coordinately to produce the desired control actions. Design strategies based on linear matrix inequality (LMI) formulations allow obtaining controllers for these complex control problems, which are characterized by large dimensionality, high computational cost and severe information constraints. In this paper, we conduct a comparative study of the computational effectiveness of three different LMI-based controller design strategies: H_∞, energy-to-peak and energy-to-componentwise-peak. The H_∞ approach is a well-known design methodology and has been widely used in the literature. The energy-to-peak approach is a particular case of generalized H_2 design that is gaining a growing relevance in structural vibration control. Finally, the energy-to-componentwise-peak approach is a less common case of generalized H_2 design that produces promising results among the three considered approaches. These controller design strategies are applied to synthesize active state-feedback controllers for the seismic protection of a five-story building and a twenty-story building both equipped with complete systems of interstory actuation devices. To evaluate the computational effectiveness of the proposed LMI design methodologies, the corresponding computation times are compared and a suitable set of numerical simulations is carried out to assess the performance of the obtained controllers. As positive results, two main facts can be highlighted: the computational effectiveness of the energy-to-peak control design strategy and the particularly well-balanced behavior exhibited by the energy-to-componentwise-peak controllers. On the negative side, it has to be mentioned the computational inefficiency of the considered LMI design methodologies to properly deal with very-large-scale control problems.*

1 INTRODUCTION

Over the last years, controller design strategies based on linear matrix inequality (LMI) formulations have been attracting increasing interest [1]. In the field of vibration control of large structures, these design strategies allow obtaining optimal controllers for complex control problems that involve a large number of actuation devices and sensors, and are typically characterized by large dimensionality, high computational cost and severe information constraints [2–7].

An important family of controller design methodologies for linear systems is based on the idea of minimizing the worst-case gain from the disturbance-input $w(t)$ to the closed-loop controlled-output $z(t)$, which can be modeled as the value

$$\sup_{\|w\|_{\mathrm{w}}\neq 0} \frac{\|z\|_{\mathrm{z}}}{\|w\|_{\mathrm{w}}}, \tag{1}$$

where $\|\cdot\|_{\mathrm{z}}$ and $\|\cdot\|_{\mathrm{w}}$ denote particular signal norms defined on the controlled-output and disturbance-input sets, respectively. Broadly speaking, an optimal controller is computed by minimizing the worst-case gain and, simultaneously, demanding asymptotic stability of the closed-loop system. From a computational point of view, an important fact is that some of these optimization problems can be formulated in terms of LMIs and solved using the existing LMI solvers [8]. Following this approach, different control design strategies can be obtained by selecting different signal norms in the controlled-output and disturbance-input spaces. In the present work, three different signal norms are considered: (i) the continuous 2-norm

$$\|f\|_2 = \left[\int_0^\infty f^T(t) f(t) dt\right]^{1/2}, \tag{2}$$

which is commonly understood as the signal energy content, (ii) the usual continuous peak-norm

$$\|f\|_\infty = \sup_{0\leq t<+\infty} \left[f^T(t) f(t)\right]^{1/2} \tag{3}$$

and (iii) the componentwise-peak-norm

$$\|f\|_{\infty,\mathrm{cw}} = \sup_{0\leq t<+\infty} \max_i |f_i(t)| = \max_i \sup_{0\leq t<+\infty} |f_i(t)|, \tag{4}$$

where $f(t) = [f_1(t), \ldots, f_n(t)]^T$ is a real vector of dimension n. The objective of the paper is to conduct a comparative study of the computational effectiveness of three different LMI-based controller design strategies: H_∞, energy-to-peak and energy-to-componentwise-peak. The H_∞ approach is a well-known design methodology that uses the 2-norm to measure both the controlled-output and the disturbance-input [9–15]. The energy-to-peak approach is a particular case of generalized H_2 design [16] that is gaining a growing relevance in structural vibration control [17–20]. This second case uses the 2-norm for the disturbance-input and the peak-norm for the controlled-output. Finally, the energy-to-componentwise-peak approach is a less common case of generalized H_2 design, which uses the 2-norm for the disturbance input and the componentwise-peak-norm for the controlled-output [21]. These three controller design strategies are applied to synthesize active state-feedback controllers for the seismic protection of a five-story building and a twenty-story building equipped with complete systems of inter-story actuation devices. To assess the performance of the obtained controllers, a proper set of numerical simulations is conducted and the computational effectiveness of the proposed LMI design methodologies is evaluated by comparing the corresponding computation times.

The rest of the paper is organized as follows: In Section 2, a brief summary of the LMI formulations corresponding to the H_∞, energy-to-peak and energy-to-componentwise-peak controller design strategies is presented. In Section 3, a mathematical model for a n-story building is provided. In Section 4, the controllers corresponding to the three proposed design strategies are computed, the computation times are compared and the results of the numerical simulations are discussed. Finally, some conclusions are presented in Section 5.

2 LMI CONTROLLER DESIGN STRATEGIES

Let us consider the system

$$\begin{cases} \dot{x}(t) = Ax(t) + Bu(t) + Ew(t) \\ z(t) = Cx(t) + Du(t) \end{cases} \tag{5}$$

where $x(t) \in \mathbb{R}^{n_x}$ is the state, $u(t) \in \mathbb{R}^{n_u}$ is the control input, $w(t) \in \mathbb{R}^{n_w}$ is the disturbance input, $z(t) \in \mathbb{R}^{n_z}$ is the controlled output and A, B, E, C, D are constant real matrices with appropriate dimensions. Given a state-feedback controller

$$u(t) = Gx(t), \tag{6}$$

with state gain matrix $G \in \mathbb{R}^{n_u \times n_x}$, we obtain the closed-loop system

$$\begin{cases} \dot{x}(t) = A_G x(t) + Ew(t) \\ z(t) = C_G x(t) \end{cases} \tag{7}$$

where

$$A_G = A + BG, \quad C_G = C + DG. \tag{8}$$

The worst-case gain from the disturbance-input to the closed-loop controlled-output associated to the control gain matrix G can be modeled by the system norm

$$\gamma(G) = \sup_{\|w\|_{\mathrm{w}} \neq 0} \frac{\|z\|_{\mathrm{z}}}{\|w\|_{\mathrm{w}}}, \tag{9}$$

where $\|\cdot\|_{\mathrm{z}}$ and $\|\cdot\|_{\mathrm{w}}$ denote particular signal norms defined on the controlled-output and disturbance-input spaces, respectively. An optimal state-feedback controller

$$u(t) = \widetilde{G}x(t) \tag{10}$$

can then be obtained by solving the following optimization problem:

$$\min_G \{\gamma(G) : A_G \text{ asymptotically stable}\}. \tag{11}$$

The H_∞ controller design considers the system norm

$$\gamma_\infty(G) = \sup_{\|w\|_2 \neq 0} \frac{\|z\|_2}{\|w\|_2}, \tag{12}$$

where $\|\cdot\|_2$ is the continuous 2-norm in (2). The optimization problem (11) corresponding to this case can be formulated as the following LMI optimization problem [1]:

$$\mathcal{P}_\infty : \begin{cases} \text{maximize } \eta \\ \text{subject to } X > 0,\ \eta > 0 \text{ and the LMI in (14)} \end{cases} \tag{13}$$

$$\begin{bmatrix} AX + XA^T + BY + Y^T B^T + \eta EE^T & (CX + DY)^T \\ CX + DY & -I_{n_z} \end{bmatrix} < 0, \tag{14}$$

where $X = X^T \in \mathbb{R}^{n_x \times n_x}$ and $Y \in \mathbb{R}^{n_u \times n_x}$ are the optimization variables and I_n is the identity matrix of order n . If an optimal value $\widetilde{\eta}_\infty$ is attained in $\mathcal{P}_\infty$ for the pair $\big(\widetilde{X}_\infty, \widetilde{Y}_\infty\big)$, then the state gain matrix

$$\widetilde{G}_\infty = \widetilde{Y}_\infty \widetilde{X}_\infty^{-1} \tag{15}$$

is an optimal solution to the H_∞ controller synthesis problem and the corresponding γ-value can be computed as

$$\widetilde{\gamma}_\infty = \gamma_\infty\big(\widetilde{G}_\infty\big) = \big(\widetilde{\eta}_\infty\big)^{-1/2}. \tag{16}$$

The energy-to-peak controller design uses the system norm

$$\gamma_{\mathrm{p}}(G) = \sup_{\|w\|_2 \neq 0} \frac{\|z\|_\infty}{\|w\|_2}, \tag{17}$$

where $\|\cdot\|_2$ is the 2-norm in (2) and $\|\cdot\|_\infty$ is the peak-norm given in (3). The optimization problem (11) associated to this second case admits the following LMI formulation [16]:

$$\mathcal{P}_{\mathrm{p}} : \begin{cases} \text{minimize } \eta \\ \text{subject to the LMIs in } (19) \text{ and } (20) \end{cases} \tag{18}$$

$$AX + XA^T + BY + Y^T B^T + EE^T < 0, \tag{19}$$

$$\begin{bmatrix} X & (CX + DY)^T \\ CX + DY & \eta I_{n_z} \end{bmatrix} > 0, \tag{20}$$

with LMI variables $X = X^T \in \mathbb{R}^{n_x \times n_x}$, $Y \in \mathbb{R}^{n_u \times n_x}$. If an optimal value $\widetilde{\eta}_{\mathrm{p}}$ is attained in $\mathcal{P}_{\mathrm{p}}$ for the pair $\big(\widetilde{X}_{\mathrm{p}}, \widetilde{Y}_{\mathrm{p}}\big)$, then the state gain matrix

$$\widetilde{G}_{\mathrm{p}} = \widetilde{Y}_{\mathrm{p}} \widetilde{X}_{\mathrm{p}}^{-1} \tag{21}$$

is an optimal solution to the energy-to-peak controller synthesis problem with an associated γ-value

$$\widetilde{\gamma}_{\mathrm{p}} = \gamma_{\mathrm{p}}\big(\widetilde{G}_{\mathrm{p}}\big) = \big(\widetilde{\eta}_{\mathrm{p}}\big)^{1/2}. \tag{22}$$

Finally, the energy-to-componentwise-peak controller design considers the system norm

$$\gamma_{\mathrm{cwp}}(G) = \sup_{\|w\|_2 \neq 0} \frac{\|z\|_{\infty,\mathrm{cw}}}{\|w\|_2}, \tag{23}$$

where $\|\cdot\|_2$ is the usual 2-norm and $\|\cdot\|_{\infty,\mathrm{cw}}$ is the componentwise-peak-norm defined in (4). The optimization problem corresponding to this third case

$$\min_G \{\gamma_{\mathrm{cwp}}(G) : A_G \text{ asymptotically stable}\} \tag{24}$$

can be formulated as follows [16]:

$$\mathcal{P}_{\mathrm{cwp}} : \begin{cases} \text{minimize } \ \eta \\ \text{subject to the LMIs in } (26) \text{ and } (27) \end{cases} \tag{25}$$

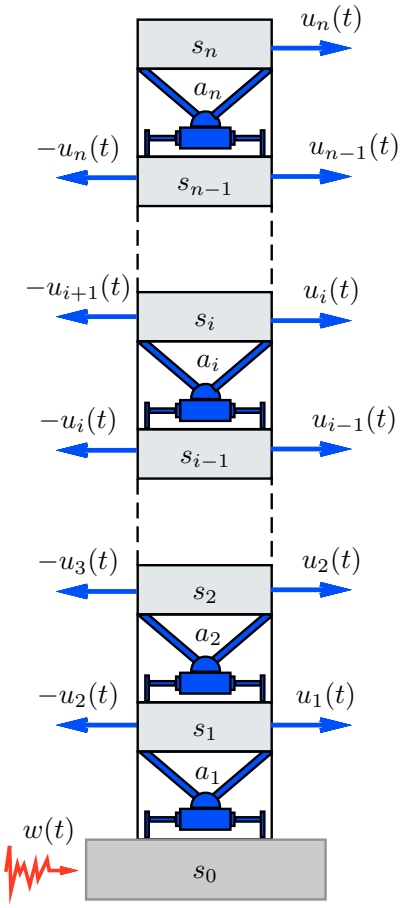

Figure 1: Building structure equipped with interstory actuation devices.

$$AX + XA^T + BY + Y^T B^T + EE^T < 0, \tag{26}$$

$$\begin{bmatrix} X & (C_i X + D_i Y)^T \\ C_i X + D_i Y & \eta \end{bmatrix} > 0, \quad \text{for } 1 \leq i \leq n_z, \tag{27}$$

where C_i and D_i denote the ith row of the matrices C and D, respectively, and $X = X^T \in \mathbb{R}^{n_x \times n_x}$, $Y \in \mathbb{R}^{n_u \times n_x}$ are the LMI variables. As it happened in the previous designs, if an optimal value $\widetilde{\eta}_{\text{cwp}}$ is attained in $\mathcal{P}_{\text{cwp}}$ for the pair $\left(\widetilde{X}_{\text{cwp}}, \widetilde{Y}_{\text{cwp}}\right)$, then the state gain matrix

$$\widetilde{G}_{\text{cwp}} = \widetilde{Y}_{\text{cwp}} \widetilde{X}_{\text{cwp}}^{-1} \tag{28}$$

is an optimal solution to the energy-to-componentwise-peak controller synthesis problem with an associated γ-value

$$\widetilde{\gamma}_{\text{cwp}} = \left(\widetilde{\eta}_{\text{cwp}}\right)^{1/2}. \tag{29}$$

3 BUILDING MODEL

Let us consider the n-story building structure schematically depicted in Figure 1, where a_i, $i = 1, \ldots, n$, represents an interstory actuation device implemented between the stories s_{i-1} and s_i, $w(t)$ denotes the seismic ground acceleration and $u_i(t)$ is the control action exerted by

the actuator a_i, which produces a pair of opposite structural forces as indicated in the figure. By considering the vector of displacements

$$q(t) = \left[q_1(t), \ldots, q_n(t)\right]^T, \tag{30}$$

where $q_i(t)$ is the lateral displacement of the story s_i with respect to the ground level s_0, the lateral motion of the structure can be described by the differential equation

$$M\,\ddot{q}(t) + C_d\,\dot{q}(t) + K\,q(t) = T_u u(t) + T_w w(t), \tag{31}$$

where

$$u(t) = \left[u_1(t), \ldots, u_n(t)\right]^T \tag{32}$$

is the vector of control actions, M, C_d and K are the mass, damping and stiffness matrices, respectively, T_u is the control location matrix and T_w is the excitation input matrix. The mass matrix is a diagonal matrix

$$M = \begin{bmatrix} m_1 & & & \\ & \cdots & & \\ & & \cdots & \\ & & & m_n \end{bmatrix} \tag{33}$$

and the stiffness matrix has the following tridiagonal structure:

$$K = \begin{bmatrix} k_1 + k_2 & -k_2 & & & & & \\ -k_2 & k_2 + k_3 & -k_3 & & & & \\ & \cdots & \cdots & \cdots & & & \\ & & \cdots & \cdots & \cdots & & \\ & & & -k_{n-1} & k_{n-1} + k_n & -k_n & \\ & & & & -k_n & k_n \end{bmatrix}, \tag{34}$$

where m_i and k_i, $i = 1, \ldots, n$ denote the mass and stiffness coefficients of the i-th story, respectively. The damping matrix C_d can be computed from M and K by setting a proper damping ratio on the building modes [22], the control location matrix is a square matrix of size n with the following upper-diagonal band form:

$$T_u = \begin{bmatrix} 1 & -1 & & & & \\ & 1 & -1 & & & \\ & & \cdots & \cdots & & \\ & & & \cdots & \cdots & \\ & & & & 1 & -1 \\ & & & & & 1 \end{bmatrix}, \tag{35}$$

and the excitation input matrix has the form

$$T_w = -M[1]_{n\times 1}, \tag{36}$$

where $[1]_{n\times 1}$ denotes a vector of dimension n with all its entries equal to 1. By introducing the interstory drifts

$$\begin{cases} r_1(t) = q_1(t) \\ r_i(t) = q_i(t) - q_{i-1}(t) \quad \text{for } \; i = 2, \ldots, n, \end{cases} \tag{37}$$

story	1	2	3	4	5
mass ($\times 10^5$ Kg)	2.152	2.092	2.070	2.048	2.661
stiffness ($\times 10^8$ N/m)	1.470	1.130	0.990	0.890	0.840
relative damping	5%				

Table 1: Parameter values corresponding to the five-story building model.

and the augmented state vector

$$x(t) = \begin{bmatrix} r(t) \\ \dot{r}(t) \end{bmatrix}, \tag{38}$$

we obtain the following first-order state-space model:

$$\dot{x}(t) = A\,x(t) + B\,u(t) + E\,w(t), \tag{39}$$

with

$$A = P\,\widehat{A}\,P^{-1}, \quad B = P\,\widehat{B}, \quad E = P\,\widehat{E}, \tag{40}$$

$$\widehat{A} = \begin{bmatrix} [0]_{n\times n} & I_n \\ -M^{-1}K & -M^{-1}C_d \end{bmatrix}, \quad \widehat{B} = \begin{bmatrix} [0]_{n\times n} \\ M^{-1}T_u \end{bmatrix}, \quad \widehat{E} = \begin{bmatrix} [0]_{n\times 1} \\ -[1]_{n\times 1} \end{bmatrix}, \tag{41}$$

where $[0]_{n\times m}$ represents a zero-matrix of the indicated dimensions and P is the change-of-basis matrix corresponding to the state transformation

$$\begin{bmatrix} r(t) \\ \dot{r}(t) \end{bmatrix} = P \begin{bmatrix} q(t) \\ \dot{q}(t) \end{bmatrix}. \tag{42}$$

Assuming that the control objective is to reduce the interstory drift values in the seismically excited building by means of moderate control actions, we also consider the controlled-output vector

$$z(t) = Cx(t) + Du(t), \tag{43}$$

defined by the matrices

$$C = \begin{bmatrix} I_n & [0]_{n\times n} \\ [0]_{n\times n} & [0]_{n\times n} \end{bmatrix}, \quad D = \alpha \begin{bmatrix} [0]_{n\times n} \\ I_n \end{bmatrix}, \tag{44}$$

where α is a scaling factor that compensates the different magnitude of interstory drifts and control forces.

4 NUMERICAL RESULTS

Let us consider the particular five-story building model [23] corresponding to the mass, stiffness and damping parameters presented in Table 1. For this small-building problem, we first solve the LMI optimization problem $\mathcal{P}_\infty$ in (13) with the matrices A, B and E in (40) and the controlled-output matrices in (44) with $n = 5$ and the scaling factor $\alpha = 10^{-7.3}$, obtaining the H_∞ control gain matrix

$$\widetilde{G}_\infty = 10^6 \times \begin{bmatrix} -1.7423 & 0.8569 & -0.2631 & -0.1886 & -0.1406 & -1.6424 & -1.4244 & -1.1155 & -0.7819 & -0.4437 \\ -0.2858 & -2.3937 & 1.0316 & -0.2427 & -0.1045 & -1.8366 & -1.7286 & -1.4129 & -1.0100 & -0.5778 \\ 0.9696 & -0.7657 & -2.7917 & 0.9250 & -0.1450 & -1.6440 & -1.6154 & -1.4853 & -1.1130 & -0.6484 \\ 0.6555 & 0.7633 & -0.7879 & -3.2342 & 0.5932 & -1.2969 & -1.2853 & -1.2396 & -1.0883 & -0.6678 \\ 0.4777 & 0.3678 & 0.4047 & -0.6065 & -3.5459 & -0.7887 & -0.7835 & -0.7630 & -0.7086 & -0.5564 \end{bmatrix}. \tag{45}$$

controller	H_∞	ETP	ETCWP
computation time (s)	0.6724	0.2105	0.3209

Table 2: Computation time (in seconds) corresponding to the H_∞, energy-to-peak (ETP) and energy-to-componentwise-peak (ETCWP) control gain matrices obtained for the five-story building.

Next, we solve the optimization problem $\mathcal{P}_{\rm p}$ in (18) with the same matrices A, B, E , and C used in the previous design, and the matrix D corresponding to the values $n=5$ and $\alpha=10^{-7.55}$. As a result, we obtain the following energy-to-peak control gain matrix:

$$\widetilde{G}_{\rm p}=10^7\times\begin{bmatrix} 2.0601 & -0.0664 & -0.6853 & -0.9248 & -0.6478 & -0.2957 & -0.1719 & -0.1008 & -0.0544 & -0.0253\\ 1.5023 & -0.1639 & -0.4423 & -0.6833 & -0.4994 & -0.1944 & -0.2417 & -0.1429 & -0.0877 & -0.0453\\ -0.5285 & 0.2894 & -0.2447 & 0.2835 & 0.1484 & -0.1126 & -0.1279 & -0.1886 & -0.0995 & -0.0532\\ -1.8625 & 0.0735 & 0.8007 & 0.3661 & 0.6780 & -0.0563 & -0.0626 & -0.0846 & -0.1506 & -0.0606\\ -1.7561 & -0.0616 & 0.7355 & 0.9459 & 0.0174 & -0.0237 & -0.0239 & -0.0341 & -0.0533 & -0.1178 \end{bmatrix}. \tag{46}$$

Finally, by solving the optimization problem $\mathcal{P}_{\rm cwp}$ in (25) with the same matrices A, B, E , C and D used in the energy-to-peak design, we obtain the energy-to-componentwise-peak control gain matrix

$$\widetilde{G}_{\rm cwp}=10^6\times\begin{bmatrix} -3.2275 & 4.1177 & -0.9820 & -0.7206 & -0.6506 & -2.2112 & -1.3045 & -0.9855 & -0.7097 & -0.3988\\ -6.1129 & -9.5642 & -2.3243 & -1.1240 & -0.3647 & -1.1163 & -1.5038 & -0.9947 & -0.6253 & -0.3360\\ 1.7722 & 0.1933 & -7.6837 & -5.2039 & -0.9188 & -1.3303 & -1.3716 & -1.5983 & -1.0710 & -0.5912\\ 1.7341 & 2.9811 & 5.6210 & -4.0119 & -6.3957 & -1.3482 & -1.2888 & -1.3998 & -1.5583 & -0.9837\\ 2.0888 & 1.3659 & 1.4997 & 8.0527 & 1.5823 & -0.9926 & -1.0051 & -1.0788 & -1.2018 & -1.0811 \end{bmatrix}. \tag{47}$$

All the controllers in this section have been computed with the LMI solver included in the MATLAB Robust Control Toolbox [8] and using a personal computer with a two-core Intel i5 processor. The computation times corresponding to the control gain matrices $\widetilde{G}_\infty$, $\widetilde{G}_{\rm p}$ and $\widetilde{G}_{\rm cwp}$ are collected in Table 2.

To demonstrate the performance of the proposed controllers, a suitable set of numerical simulations has been carried out using the scaled North-South El Centro 1940 seismic record as a ground acceleration input (see Figure 2). The obtained absolute interstory-drift peak-values are displayed in Figure 3(a), where the black line with squares represents the uncontrolled response, the blue line with circles corresponds to the H_∞ controller $u(t)=\widetilde{G}_\infty\,x(t)$, the green line with triangles presents the response of the energy-to-peak controller $u(t)=\widetilde{G}_{\rm p}\,x(t)$ and the red line with asterisks describes the energy-to-componentwise-peak controller $u(t)=\widetilde{G}_{\rm cwp}\,x(t)$. The corresponding absolute control-effort peak-values are displayed in Figure 3(b) using the

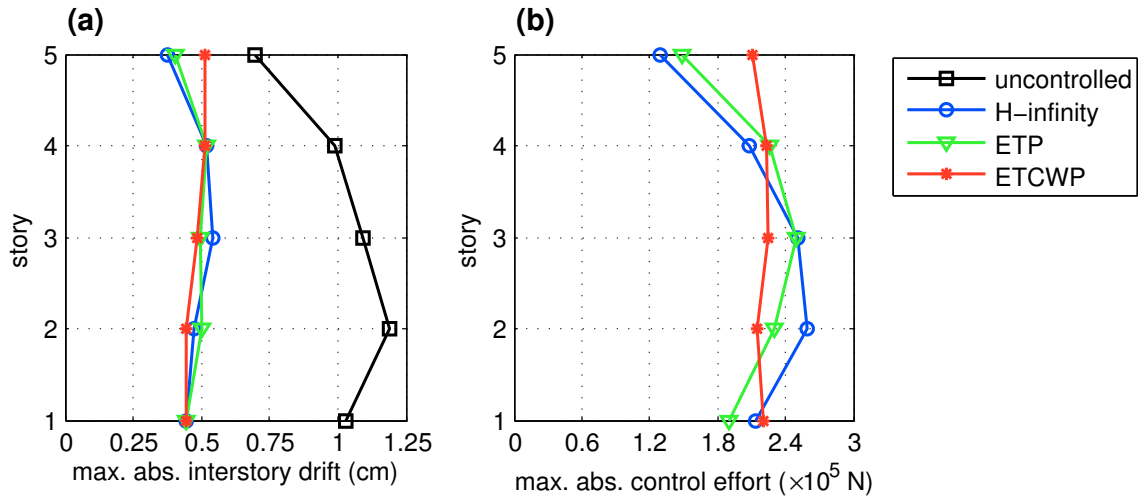

Figure 3: Response of the five-story building model corresponding to the scaled North-South El Centro 1940 seismic record for the uncontrolled configuration (black line with squares), the H_∞ controller (blue line with circles), the energy-to-peak controller (green line with triangles) and the energy-to-componentwise-peak controller (red line with asterisks). (a) Maximum absolute interstory drifts. (b) Maximum absolute control efforts.

relative damping	5%					

Table 3: Parameter values corresponding to the twenty-story building model.

same colors and symbols.

Looking at the matrices in (45), (46) and (47) it can be appreciated that the proposed design methods certainly produce different results. A quick inspection of the plots in Figure 3 reveals two clear facts: (i) the three controllers provide a good level of seismic protection with similar levels of control effort and (ii) the energy-to-componentwise-peak controller exhibits a particularly well-balanced behavior. The computation times in Table 2 also indicate two facts: (i) all the proposed design strategies demand very small computation times and, consequently, are suitable for control problems involving small-size building models and (ii) the shortest computation time is attained by the energy-to-peak controller.

Now we consider the twenty-story building model [10] corresponding to the mass, stiffness and damping parameters presented in Table 3. For this large-building problem, we compute an H_∞ controller by solving the LMI optimization problem $\mathcal{P}_\infty$ in (13) with the matrices A, B and E corresponding to the values in Table 3 and the controlled-output matrices in (44) with $n=20$ and the scaling factor $\alpha=10^{-8.0}$. We also design an energy-to-peak controller and an energy-to-componentwise-peak controller by solving the optimization problems $\mathcal{P}_{\rm p}$ in (18) and $\mathcal{P}_{\rm cwp}$ in (25), respectively, with the same matrices A, B, E and C used in the H_∞ design and the matrix D defined by $n=20$ and the scaling factor $\alpha=10^{-8.2}$. The computation times corresponding to this second set of controllers are collected in Table 4. To illustrate the seismic performance of the proposed design strategies in this harder control problem, the twenty-story building vibration response has been numerically simulated using also the scaled North-South El Centro 1940

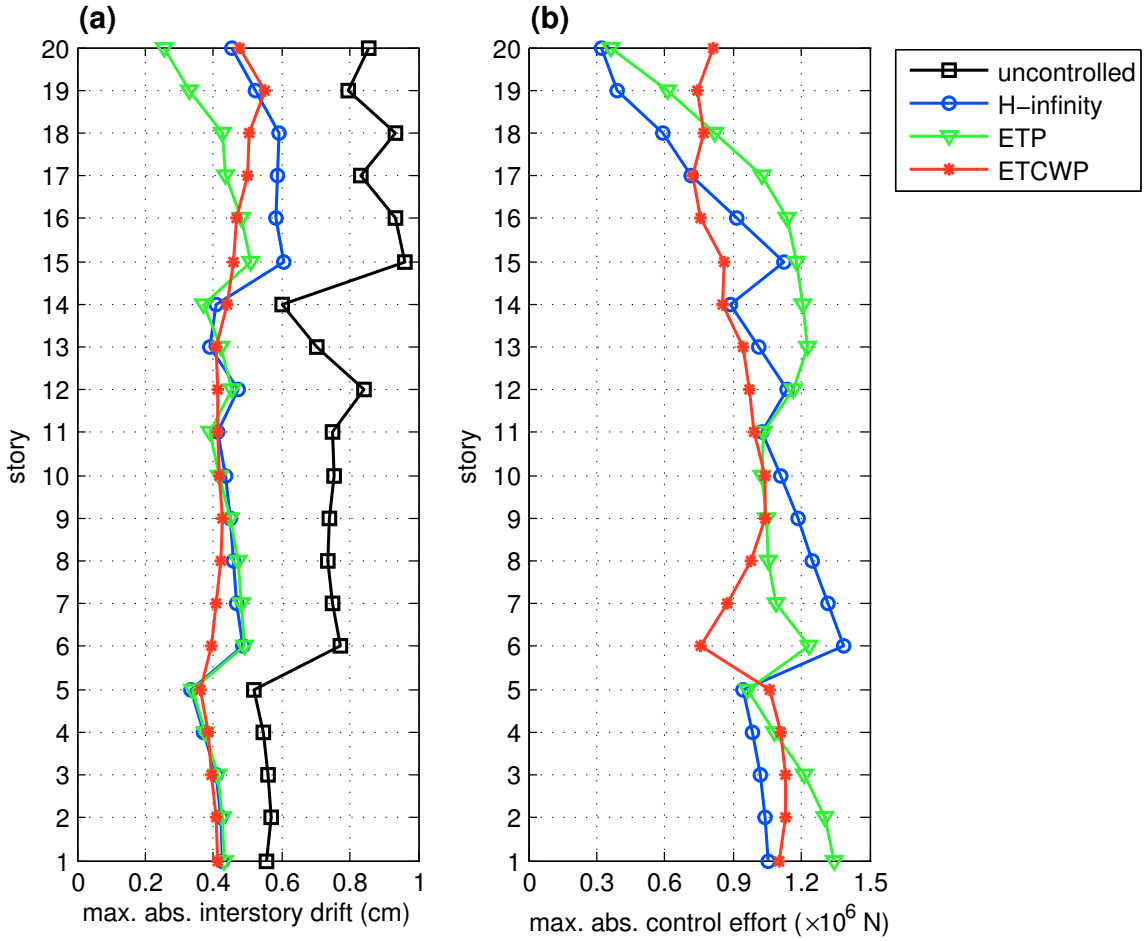

Figure 4: Response of the twenty-story building model corresponding to the scaled North-South El Centro 1940 seismic record for the uncontrolled configuration (black line with squares), the H_∞ controller (blue line with circles), the energy-to-peak controller (green line with triangles) and the energy-to-componentwise-peak controller (red line with asterisks). (a) Maximum absolute interstory drifts. (b) Maximum absolute control efforts.

controller	H_∞	ETP	ETCWP
computation time (s)	169.25	60.63	458.24

Table 4: Computation time (in seconds) corresponding to the H_∞, energy-to-peak (ETP) and energy-to-componentwise-peak (ETCWP) controllers designed for the twenty-story building model.

seismic record as ground acceleration input. The corresponding absolute interstory-drift and absolute control-effort peak-values are displayed in Figure 4(a) and Figure 4(b), respectively, using the same colors and symbols: black line with squares for the uncontrolled response, blue line with circles for the H_∞ controller, green line with triangles for the energy-to-peak controller and red line with asterisks for the energy-to-componentwise-peak controller.

The inspection of the plots in Figure 4 indicates that the same two facts observed in the five-story building problem still hold in the present case: (i) the three controllers provide a good level of seismic protection with similar levels of control effort and (ii) a particularly well-balanced behavior is exhibited by the energy-to-componentwise-peak controller. Looking at the

computation times in Table 4 and comparing with the data in Table 2, three main facts can be appreciated: (i) the best results are still attained by the energy-to-peak controller, (ii) all computation times are significantly larger and, (iii) a particularly larger computation time is required by the energy-to-componentwise-peak controller. The good computational performance of the energy-to-peak design strategy is a remarkable fact that converts this design methodology in an interesting option for vibration control of large structures. The observed increment of the computation times can be partially explained by the increase in the number of LMI variables. It should be observed that, in the general case of a n-story building with n actuation devices, the dimensions of the LMI variable matrices X and Y are $2n \times 2n$ and $n \times 2n$, respectively, and the total number of variables in the considered LMI optimization problems is $4n^2 + n$. This means that a controller design for a five-story building involves 105 LMI variables while a twenty-story building design requires 1620 LMI variables. Additionally, the larger computation time required by the energy-to-componentwise-peak design in the twenty-story building problem is consistent with the higher complexity of the corresponding LMI formulation.

5 CONCLUSIONS

In this paper, we have conducted a comparative study of three LMI-based controller design strategies for structural vibration control, paying special attention to the computational effectiveness in large-dimension problems. Together with the well-known H_∞ approach, the study includes the energy-to-peak and energy-to-componentwise-peak methodologies, which are particular cases of generalized H_2 designs. These three controller design strategies have been applied to synthesize active state-feedback controllers for the seismic protection of a five-story building and a twenty-story building, both equipped with a complete system of interstory actuation devices. The corresponding computation times have been considered to evaluate the computational effectiveness of the proposed design strategies and a proper set of numerical simulations has been carried out to assess the performance of the obtained controllers. In the five-story building problem, all the proposed design strategies have demanded computation times inferior to one second and the obtained controllers provide a good level of seismic protection with similar levels of control effort. In the twenty-story building problem, a good level of performance is also attained by all the controllers but an important increment of the computation times has been observed and significant differences can be appreciated in the computational effectiveness of the different design strategies. Overall, the following three main facts can be highlighted: (i) significantly shorter computation times are required by the synthesis of energy-to-peak controllers, (ii) a particularly well-balanced behavior is exhibited by the energy-to-componentwise-peak controllers and (iii) important computational difficulties should be expected when applying the considered controller design strategies to very-large-scale control problems.

Keywords: Semi-Active Control, Wind Turbine, Magnetorheological Damper.

Abstract. *Concerns in the last decades of the negative impact of the use of fossil fuels on the environment has lead to a boom in the production of wind turbines. To take advantage of the smoother stronger winds at height, wind turbine heights are progressively increasing. This has led to an increased demand to control tower forces. The application of a semi-active (SA) control system is herein proposed and discussed. Its aim is to limit bending moment demand at the base of a wind turbine by relaxing the base restraint of the turbine's tower, without increasing the top displacement. This is done thanks to the sharp increase of the dissipated energy in selected intervals of time and an adaptive change in tower dynamic properties. This SA control system reproduces a variable restraint at the base that changes in real time its mechanical properties according to the instantaneous response of the turbine's tower. This smart restraint is made of a central smooth hinge, elastic springs and SA magnetorheological dampers driven by a control algorithm properly designed for the specific application. A commercial 105 m tall wind turbine has been assumed as a case study. Several numerical simulations have been performed with reference to an extreme load, aimed at establishing a procedure for the optimal calibration of the control algorithm according to the specific case, finally proving the actual potential of the proposed control technique in reducing the structural demand with respect to the "fixed base" structure.*

1 INTRODUCTION

Wind turbine manufacturers have become ever more interested in methods for reducing or limiting tower base moments for turbines of increasing height. There are two main reasons for this. First, the tower diameters at the base are increasing beyond the point where they can be fabricated off-site and shipped to the location of installation. This significantly increases construction costs and complexity. Second, the tower diameters and associated base moments of newer wind turbines far exceed those of existing wind turbines that the newer ones hope to replace. Therefore, existing foundations cannot be utilized and new or strengthened foundations need to be constructed.

The maximum base moments of a wind-turbine are generated by few very specific, and in some cases improbable, load cases. These include the load cases which involve extreme gusts of wind combined with emergency shut-down procedures and extreme wind loading in a parked configuration. All of the extreme load cases generate maximum expected tower base moments via short duration impulse loading – something which cannot be combated using traditional damping devices. Damping is generally considered ineffective for impact type loading. Instead, a variable tower stiffness and damping approach needs to be followed. Therefore, in this paper, the concept of an adaptive wind turbine tower is examined, where the adaptation is realized through the implementation of a semi-active (SA) control system.

Chen and Georgakis [1] performed an experimental analysis of a 1/20-scale wind tower model equipped with a passive rolling-ball damper to reduce vibrations. Such damper consists of a glass container placed at the top of the model and having one or more steel balls inside. Different configurations have been tested, changing the geometry of the container (one or two layers) and the number of balls (one to six) placed inside, showing a significant reduction of the peak value and standard deviation of top displacement and base bending moment. The same authors [2] tested the same model using water rather than steel balls inside the glass container, i.e. realizing a spherical tuned liquid damper. The optimal degree of filling with water (1-2% of the total generalized mass of the system) has been found as leading to the maximum reduction of structural demand.

About active/semi-active control strategies from literature related to wind turbines, Karimi et al. [3] and Luo et al. [4] propose a SA control technique for floating wind turbines with TLCD. This device, generally used as a passive damper, turns into a SA device using a controllable valve. The orifice opening is real time adapted according to the structure response and loading conditions, with a control logic based on a H_∞ feedback methodology. Lackner and Rotea [5] investigate the effectiveness of an optimal passive TMD and of a hybrid mass damper (HMD, i.e. a TMD improved with the addition of a controlled force actuator) in reducing fatigue loads due to bending moment at the base of the tower, showing a percentage reduction of about 10% and 30% respectively due to each of the two proposed systems. Kirkegaard et al. [6] have been the first to explore the use of magnetorheological (MR) dampers to control a wind turbine, assuming such type of smart device to be installed, in a vertical position, between the base and the top of the tower. Even hard to be implemented in a real case, the numerical simulations show good results. Experimental results are also made available by the authors, unfortunately referred to the passive use (constant voltage fed to the MR damper) of the device only.

The authors recently proposed a SA control system based on the application of MR devices to realize a time-variant base restraint whose 'stiffness' can be driven in real time by a properly written control logic [7]. The high promptness of response of the SA control chain based on the use of MR dampers and of an appropriate electronic and power equipment has been experimentally demonstrated [8], showing that unavoidable delays however are always less than 10

ms, thus negligible compared to the long period of the flexible structures under examination. This is one of the aspects strongly encourage the use of such technology for the application in question. The controller has to be programmed to instantaneously calibrate the MR devices installed at the base of the tower in order to reduce the base bending moment, relaxing in selected intervals of time the base restraint. Again, the control logic has to hold the top displacement within acceptable values so as to avoid significant, detrimental second order effects. At the laboratory of the Denmark Technical University (DTU) in Copenaghen, some shaking table tests of a wind turbine tower model semi-actively controlled as above has been recently performed by the authors. After the formulation of the above idea, a finite element model of the structure has been calibrated so as to develop several numerical simulations addressed to optimally calibrate the control logic properly designed for such kind of applications.

2 A VARIABLE BASE RESTRAINT FOR WIND TURBINE TOWERS: CONTROL ALGORITHM

A smart restraint at the base of high-rise wind turbine towers is proposed with the aim of reducing wind induced structural demand by exploiting magnetorheological devices. This is schematically shown in Figure 1, where the uncontrolled wind turbine, fully restrained at the base, is modeled as a single degree of freedom dynamic system (Figure 1(a)), having top mass m, stiffness k_T and inherent damping c_T. In order to control the structural demand, the authors proposed to replace the perfectly rigid base restraint with a controllable one that is able to instantaneously become more or less "stiff", during the motion. Figure 1(b) just sketches the materialization of this idea by a smooth hinge, with a rotational spring (of stiffness k_ϕ) and a rotational variable damper whose damping constant c_ϕ can be driven in real time by a control algorithm. The same result can be obtained in practice by mounting two vertical linear springs (k_s) placed at a certain distance (l_s) from the hinge and two vertical SA dampers (c_d) at a distance l_d from the central hinge (Figure 1(c)).

SA MR dampers were considered as smart devices within the proposed control system: when a low value is imposed to the base damping, the base restraint is less 'stiff', so that the structure's restraint is able to relax by converting its potential energy into kinetic energy, and the bending moment at the base is reduced. A direct consequence of controlling the demand of base bending stress could be an increase of top displacement demand; therefore, the SA base control system was thought to reduce base stress, by restraining the increase of top displacements within certain limits to control second order effects. A specific bang-bang control algorithm has been formulated by the authors [7] to instantaneously decide the system's base configuration: it switches back and forth from an "OFF" state (intensity of current $i = i_{\min}$, i.e. the minimum current set to be given to the dampers) to an "ON" state ($i = i_{\max}$, i.e. the maximum assumed value for the current) according to a logic aiming to control both the base stress and the top displacement. Therefore, the control algorithm was so formulated:

$$\begin{aligned}
&1)\ \text{if } |\pm(t)| < \pm_{\lim} && && && \rightarrow i(t) = i_{\max}\\
&2)\ \text{if } |\pm(t)| \geq \pm_{\lim} && \text{and } |x(t)| < x_{\lim} && && \rightarrow i(t) = 0\\
&3)\ \text{if } |\pm(t)| \geq \pm_{\lim} && \text{and } |x(t)| \geq x_{\lim} && \text{and } x(t)\cdot\dot{x}(t) > 0 && \rightarrow i(t) = i_{\max}\\
&4)\ \text{if } |\pm(t)| \geq \pm_{\lim} && \text{and } |x(t)| \geq x_{\lim} && \text{and } x(t)\cdot\dot{x}(t) \leq 0 && \rightarrow i(t) = 0
\end{aligned} \tag{1}$$

where $\sigma(t)$, $x(t)$ and $\dot{x}(t)$ are respectively the value of stress at the base, top displacement and top velocity at the instant of time t. In other words, the controller keeps 'stiffer' the base restraint until the stress exceeds the limit value σ_{lim} (expression 1) of Eq. (1)), whereas 'relaxes' it ("OFF" state of the dampers) when this limit is overpassed and the displacement falls within

the limit of acceptability x_{lim} (expression 2) of Eq. (1)). When both stress and displacement are beyond the respective threshold values, the controller switches "ON" the dampers if the displacement is going towards a larger value (so trying to damp or invert the displacement's trend; expression 3) of Eq. (1)), otherwise it switches "OFF" the MR devices to make them collaborating to both stress and displacement reduction. Figure 2 schematically describes the above defined logic: the decision of the controller (switch "ON" or switch "OFF") depends on the occurrence of each of the four possible combinations regarding the value of base stress and top displacement. The application of the proposed control algorithm requires the definition of rational criteria to optimally calibrate the parameters involved in ($i_{\min}$, $i_{\max}$, σ_{lim} and x_{lim}). A large numerical campaign has been performed with reference to a case study structure, aiming to investigate the role each parameter has regarding the structural response, and to learn a possible procedure to calibrate them aiming at achieving the maximum reduction of stresses and displacements.

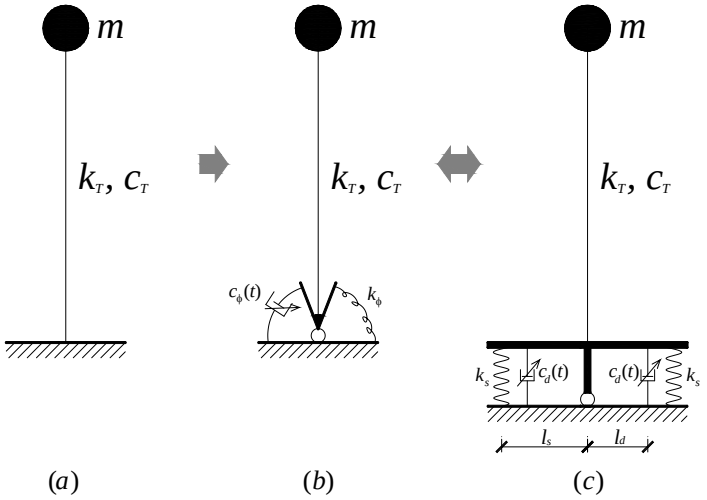

Figure 1: Basic idea of SA control of a wind turbine via MR dampers.

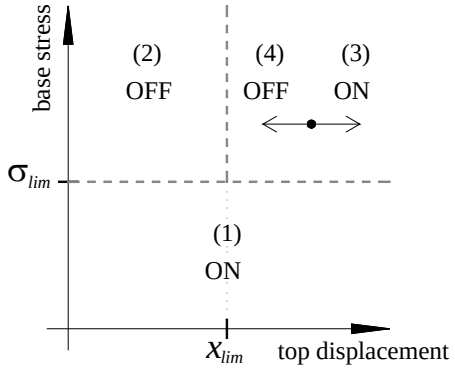

Figure 2: The logic behind the controller (symbols refer to Eq. (1)).

3 CALIBRATION OF THE SA CONTROLLER: A CASE STUDY

A possible calibration procedure is herein proposed to provide the optimal choice of values to be assigned to the parameters involved in the control algorithm. The first step is generating a finite element model of the structure to be examined, able to reproduce both fixed base (FB) and SA controlled configurations. With reference to a given wind load, the structural response in the FB case has to be determined. Then a wide number of SA numerical simulations has to

be designed and performed. Analyzing the results using a constrained optimization approach allows to single out the optimal configuration of the controller able to achieve the maximum reduction of base stress while not causing increasing of top displacement in respect to the FB case. This procedure is practically applied in the following with reference to a specific case study.

3.1 Case Study

The case study structure is a 1/20-scale structural model of a prototype real wind turbine. The reference real structure is a 3 MW wind turbine with horizontal power transmission axle, 102.4 m tall, with a variable hollow circular cross section whose external diameter is variable from 2.30 m (top) to 4.15 m (bottom). Chen and Georgakis [1] demonstrated its dynamic equivalence (in terms of equivalent flexural stiffness) with a single degree of freedom (SDOF) structural system made up of a tapered tubular cantilever beam with a concentrated mass at the top. The scaled mock-up structure is characterized by a 5.12 m high vertical tube with uniform cross section Φ133/4 (133 mm is the external diameter, 4 mm the thickness), and a lumped mass of 280 kg placed at the top (Figure 3).

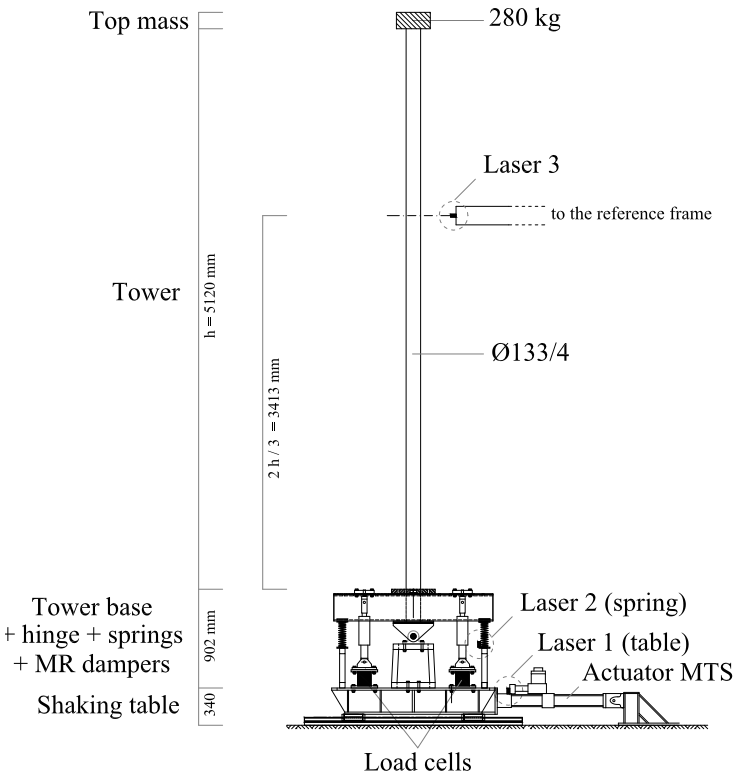

Figure 3: Case study model and experimental setup at the DTU laboratory.

The base of the model is highly stiff and is supported in the middle by a cylindrical steel hinge. On both sides of the base, one cylindrical spring (89 kN/m stiff) and one MR damper are installed. The assembly “elastic springs + SA MR dampers”, placed in parallel at the base of the tower, just represents the smart base restraint herein proposed to control the dynamic behavior of the structure. An extreme operating gust loading has been considered in the following as reference wind action: a sharp increase, then decrease in wind speed within a short period of time. Chen and Georgakis [1] defined an equivalent base acceleration time history

(Figure 4), that is the base input that would provide the same top mass response of the real fixed base structure subjected to the wind action.

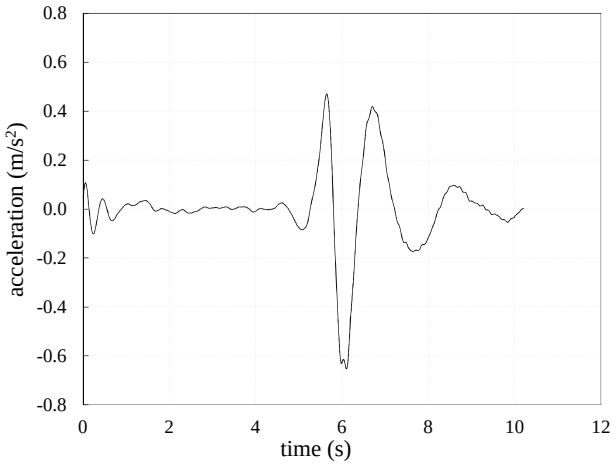

Figure 4: Equivalent base acceleration time history for the wind load case.

3.2 Numerical model

A finite element model has been generated in Matlab environment to simulate the dynamic behavior of the case study structure. It consists in 37 elements: 36 elements simulate the tower with uniform diameter (133 mm) and thickness (4 mm) along the height, while the last element (37^{th}) is more rigid and represents the connection of the top of the tower to the barycenter of the nacelle. The rotor and the aerodynamics have not been included in the model due to its complexity, and the nacelle and its internal components are represented by a concentrated mass at the top of the structure, with no dynamic interaction considered. Such mass is added in the global mass matrix at the translational degree of freedom at the top of the tower.

The base support has been modeled as in Figure 5, that is by a rotational spring k_{spring} and a Maxwell element (representing the MR dampers) working in parallel. The value for k_{spring} (7.5e4 Nm/rad) has been easily derived known the stiffness of the two linear springs and their distance from the center of rotation (hinge).

The Maxwell element, as known, consists of a spring $k_{Maxwell}$ and a linear viscous damper $c_{Maxwell}$ in series. The controllable part of this device is represented by the constant $c_{Maxwell}$, while $k_{Maxwell}$ has been simply assumed high enough (1.5e6 Nm/rad) so as to behave like a rigid link. Two different values of $c_{Maxwell}$ (c_{on}, c_{off}) have been determined so as to reproduce the dissipative capability of MR dampers respectively in the "ON" and "OFF" states. These two opposite configurations of the MR dampers are assumed to be those of the experimental campaign cited above, respectively corresponding to $i=i_{min}=0$ A and $i=i_{max}=1$ A. The MR dampers considered to calibrate the Maxwell device properties are those adopted for the test at DTU also [9]. Suitable numerical models for such devices are described in [10]. The values of c_{on}, c_{off} have been experimentally calibrated and resulted to be c_{on}=1e7 Nms/rad and c_{off}=2e3 Nms/rad.

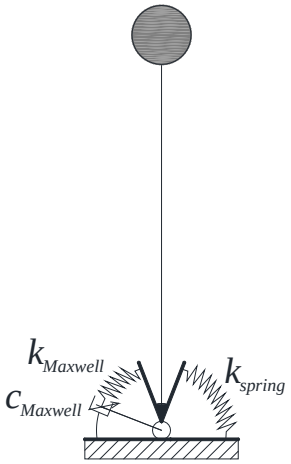

Figure 5: Representation of the base restraint within the FE model of the SA controlled structure.

3.3 Numerical simulations

A number of 100 numerical tests have been performed with reference to the above FEM model in SA configuration. This is the total number of different combinations of stress (σ_{lim}) and displacement (x_{lim}) limits that have been tested, chosen within the ranges [5, 50] MPa and [5, 50] mm with a step of 5 MPa and 5 mm, respectively. Performance indices have been assumed to quantitatively summarize the structural response in the examined cases.

These allow to compare the effectiveness of the SA control strategy for each of the above settings for the controller, then to select the optimal calibration of the latter. They are:

- ratio of maximum bending stress σ_{max} to limit value σ_{lim} assumed to calibrate the controller (σ_{max} / σ_{lim});
- ratio of maximum bending stress in SA to fixed base (FB) conditions (σ_{max} / $\sigma_{max,FB}$);
- ratio of maximum top displacement in SA to FB conditions (x_{max} / $x_{max,FB}$).

Moreover, to better interpret the results, the following two additional information have been gathered from each simulation performed:

- total amount of time in which the MR damper has been switched off by the controller (t_{off});
- total number of switches (on→off and vice versa) commanded to the variable device (n_{sw}).

The ratio σ_{max} / σ_{lim} is assumed so as to check if and how the controller has been able to limit the bending stress to the desired value σ_{lim}, while the ratio x_{max} / x_{lim} has not been assumed as parameter for comparison because it is not significant to the same extent given that x_{lim} has a reduced impact on the controller operation. The indices σ_{max} / $\sigma_{max,FB}$ and x_{max} / $x_{max,FB}$ express the effectiveness of the controller in reducing the structural response with respect to the FB conditions. Values less than one are desired, in fact they reflect the main purpose of the control strategy. The indices t_{off} and n_{sw} give a quantitative idea about the activity of the MR damper during each test. When the smart device is set to "ON", it is not very far from acting as a rigid link. Therefore, the above t_{off} gives also a measure of the overall duration of the dissipation phase.

4 DISCUSSION ABOUT RESULTS AND CONCLUSIONS

The constrained optimization of the controller is performed according to the condition:

$$\min\left(\sigma_{max} / \sigma_{max,FB}\right) \quad \text{subject to} \quad x_{max} / x_{max,FB} \leq 1 \tag{2}$$

that is, aiming to achieve the greatest reduction of the base stress (objective function) and, at the same time, a top displacement (constraint function) no higher than that in uncontrolled FB conditions.

Analyzing diagrams (a) in Figure 6, it emerges that the SA control of the case study wind turbine is always beneficial in terms of reduction of base stress with respect to the fixed base scheme. Considered the whole set of examined cases, the maximum base stress reduction results to be around 80%, and corresponds to the case (σ_{lim}, x_{lim})=(5 MPa, 25 mm). The maximum top displacement reduction is about 35%, for (σ_{lim}, x_{lim})=(10 MPa, 15 mm). The worst case, i.e. that corresponding to the maximum amplification of x (+40%) with respect to the FB case is (σ_{lim}, x_{lim})=(35 MPa, 50 mm).

Higher operation of the SA controller for smaller value of σ_{lim}, as expected, can be deduced from Figure 6(d). Figure 6(c) instead highlights that response values in terms of maximum base stress σ_{max} are practically always included in the interval [σ_{lim}, $2\sigma_{lim}$], with the exception of those cases where both very small values are fixed both for σ_{lim} and x_{lim}.

Actually, about half (53%) of the examined configurations of the controller leaded to undesired response in top displacement, i.e. values of x_{max} larger than $x_{max,FB}$. Figure 7 helps to understand better which are the combinations of limit values σ_{lim} and x_{lim} that give undesired response in displacement. It results that, when values of σ_{lim} greater than 30 MPa are adopted (i.e. roughly greater than half of the $\sigma_{max,FB}$ value), there is no chance to reduce displacements in respect to the FB case. The reason is related to the fact that in such cases the SA operations are really limited, as from Figure 6(d) clearly emerges. Therefore, the dissipation phases are concentrated in much small intervals of time, not effective in reducing significantly the response in displacement. Vice versa, when smaller values of σ_{lim} are used (i.e. less than 30 MPa), the reduction or amplification of x_{max} in respect to $x_{max,FB}$ also depends on the assumed value for x_{lim}. Also in this case, it seems that selecting values for x_{lim} less than $0.5x_{max,FB}$ leads always to good results in terms of displacement response.

According to the criterion defined in the condition above, the optimal configuration of the control algorithm corresponds to the case (σ_{lim}, x_{lim})=(5 MPa, 25 mm) since it leads to the maximum response reduction (about 80%) in base stress, and also to a reduction (about 30%) of displacement in respect to the FB case.

Therefore, preliminary conclusions about a possible way to optimally calibrate the controller could be drawn suggesting to assume, for σ_{lim} and x_{lim}, values respectively around $0.1\sigma_{max,FB}$ and $0.5x_{max,FB}$. Moderately low values of σ_{lim} (25-50% of $\sigma_{max,FB}$) leaded to increased top displacements, even higher than the reference value $x_{max,FB}$. A trend reversal for values of σ_{lim} even more smaller (10-20% of $\sigma_{max,FB}$) has been registered, leading them to significant reduction of both base stress and top displacement, as said above, due to the higher operation of the controller and, consequently, to the sharp increase of dissipated energy due to the larger rocking of the base.

The above results cannot be directly generalized, since clearly dependent on the specific wind load case and turbine model assumed for the analyses. On the contrary, the conceptual findings they allowed to gather are always valid and will be exploited by the authors to program further investigations aimed at consolidating those outcomes and to finally determine the practical implications they could have. Future further research about this topic will have to consider a larger set of wind load cases, different for magnitude, duration and frequency content, to understand if and how the optimal calibration of the control algorithm depends on the characteristics of the external action.

Abstract. *In spite of the fact that avant-garde sliding bearings have been proposed, the application of the single friction pendulum (FP) bearing is increasing due to its conceptual simplicity; yet there are still important aspects of its behaviour that need further attention. More specifically, the FP system presents spatial variation of friction coefficient, depending on the sliding velocity of the FP bearings. Moreover, the frictional force and restoring stiffness during the sliding phase are proportional to the axial load. Long duration intense velocity pulses in the horizontal direction and high values of the ratio between vertical and horizontal peak ground acceleration are expected for near-fault earthquakes. Torsion with residual displacement and uplift of the FP system need to be better understood for base-isolated structures located in near-fault areas. To this end, a numerical investigation is carried out with reference to a six-storey reinforced concrete (r.c.) framed building, characterized by an L-shaped plan with wings of different length and setbacks at different heights along the main in-plan directions. Twelve base-isolated test structures are designed in line with the Italian seismic code, considering (besides the gravity loads) the horizontal seismic loads acting alone or in combination with the vertical ones. Three design values of the radius of curvature for the FP system and two in-plan distributions of dynamic-fast friction coefficient for the FP bearings, ranging from a constant value for all isolators to a different value for each, are assumed. A nonlinear force-displacement law of the FP bearings in the horizontal direction, depending on sliding velocity and axial load, is considered, while a gap model takes into account the vertical uplift of the FP bearings. The nonlinear seismic analysis is performed on two sets of seven near-fault earthquakes, both sets with significant horizontal or vertical components selected and normalized on the basis of the design hypotheses adopted for the test structure.*

1 INTRODUCTION

The friction pendulum (FP) system is one of the most in-demand techniques for the seismic isolation of buildings [1], where the geometry and gravity allow a minimization of torsion and a self-centring of the base-isolation FP system for a wide range of frequency inputs [2]. However, the (low) constant isolation frequency, proportional to the curvature of the sliding surface, may induce resonance of base-isolated structures if it is close to the predominant vibration period of near-fault ground motions [3]. Specifically, fling-step and forward-directivity in near-fault areas can produce long duration pulses of intense velocity in the horizontal direction [4, 5], amplifying the displacement and inducing torsional and re-centring problems [6, 7]. On the other hand, since the response of the FP system during the sliding phase is strongly influenced by the axial load, amplification of torsional demand and residual displacement and uplift of the FP bearings may also be induced by the high frequency vertical component of near-fault earthquakes [8-10]. This vertical motion is characterized by peak ground acceleration higher than the horizontal one and closer in time for decreasing values of distance from the fault [11, 12].

In order to verify the occurrence of torsion with residual displacement and uplift of the FP system for base-isolation of structures located in near-fault areas, this study aims to investigate the following two effects in FP bearings: friction variability, as a function sliding velocity; friction force and restoring stiffness during the sliding phase, proportional to the axial load variation. To this end, a six-storey reinforced concrete (r.c.) framed building, characterized by an L-shaped plan with wings of different length and setbacks at different heights along the in-plan X (i.e. one setback, at the third-storey) and Y (i.e. two setbacks, at the second- and fourth-storey) principal directions is considered. In detail, twelve base-isolated structures are designed in line with the Italian seismic code (NTC08, [13]), with the horizontal seismic loads acting alone or in combination with the vertical ones. Furthermore, two in-plan distributions of low-type friction properties, ranging from a constant value for all isolators to a different value for each, are designed for three low-to-medium design values of the radius of curvature of the FP bearings. Two sets of seven near-fault earthquakes, each with significant components in the horizontal or vertical direction, are selected from the *Pacific Earthquake Engineering Research center database* (PEER, [14]) and normalized with the design hypotheses adopted for the test structure (i.e. medium-risk seismic region and stiff site).

2 LAYOUT AND DESIGN OF THE BASE-ISOLATED BUILDINGS

A six-storey r.c. office building base-isolated with the FP system, characterized by an L-shaped plan with wings of different length (Figure 1a) and setbacks at different heights (Figure 1b), is considered as test structure. It is designed in line with NTC08 [13] and besides the gravity loads, the horizontal seismic loads are assumed to act alone or in combination with the vertical ones. The following design assumptions are considered: elastic response of the superstructure (i.e. behaviour factor for the horizontal seismic loads, q_H=1; behaviour factor for the vertical seismic loads, q_V=1); stiff site (i.e. subsoil class B); medium-risk seismic region (i.e. peak ground accelerations: $PGA_{H,LS}$=0.16gx1.2=0.19g and $PGA_{V,LS}$= 0.08g, at the life-safety limit state for the superstructure; $PGA_{H,CP}$=0.21gx1.2=0.25g and $PGA_{V,CP}$=0.13g, at the collapse prevention limit state for the base-isolation system). The gravity loads used in the design are represented by a dead load of 6.7 kN/m^2 and a live load of 2.0 kN/m^2, on all floors, and a perimeter masonry-infills of 2.7 kN/m^2, on the first five floors. A cylindrical compressive strength of 25 N/mm^2 for the concrete and a yield strength of 450 N/mm^2 for the steel are assumed for the r.c. frame members, whose cross sections are reported in Tables 1 and 2.

Table 2: Cross-sections of r.c. columns (units in cm).

The FP system is designed at the CP limit state, requiring the fulfilment of the provisions imposed by NTC08: i.e. maximum compression axial load of the FP bearing less than its capacity; maximum horizontal displacements less than the spectral value; absence of tensile axial loads at the level of the FP system.

Three values of the effective fundamental vibration period of the isolation system

$$T_{e,I} = 2\pi \sqrt{\frac{1}{g\left(\frac{1}{R} + \frac{\mu_{fast}}{u_{H,d}}\right)}} \tag{1}$$

are considered (i.e.=2s, 2.5s and 3s), corresponding to the effective stiffness

$$K_e = N_{Sd}\left(\frac{1}{R} + \frac{\mu_{fast}}{u_{H,d}}\right) \tag{2}$$

and a value equal to 20% for the effective equivalent viscous damping

$$\xi_{e,I} = \frac{2}{\pi}\frac{1}{1+\frac{u_{H,d}}{\mu_{fast}R}} \tag{3}$$

The nonlinear system based on Equations (1) and (3) returns the values of the radius of curvature (R) and dynamic-fast friction coefficient (μ_{fast}) of the FP bearings, which correspond to the spectral displacement ($u_{H,d}$). Then, the maximum axial load capacity of the FP bearings (N_{Ed}) is evaluated by Equations (4a) and (4b), as function of the assigned value of the quasi-permanent gravity loads (N_{Sd}) transmitted from the superstructure [15]

$$\mu_{fast}(\%) = 17, \quad \left(\frac{N_{Sd}}{N_{Ed}}\right) \le 0.1 \tag{4a}$$

$$\mu_{fast}(\%) = 2.5\left(\frac{N_{Sd}}{N_{Ed}}\right)^{-0.834}, \quad \left(\frac{N_{Sd}}{N_{Ed}}\right) > 0.1 \tag{4b}$$

Moreover, two in-plan distributions of N_{Ed} are assumed for the FP bearings: case A in Figure 2a, with fifteen types of FP bearings (i.e. μ_{fast} equal for all isolators); case B in Figure 2b, with only three types of FP bearings (i.e. μ_{fast} different for each isolator), which are selected with reference to the maximum value of N_{Ed} from those of the isolators corresponding to three ranges of $\beta=N_{Sd}/N_{Sd,max}$ (i.e. $\beta\le0.4$; $0.4<\beta\le0.7$; $\beta>0.7$). It is worth noting that the final values of μ_{fast} take into account the fact that the FP bearings need the fulfilment of the CP limit state imposed by NTC08. For all the examined cases, design parameters of the FP systems are reported in Tables 3 and 4 where horizontal seismic loads act alone (i.e. H) or in combination with the vertical ones (i.e. HV), respectively.

3 NONLINEAR MODELLING OF THE FP BEARINGS

The single FP bearing consists of a spherical concave sliding surface of polished stainless steel, with a radius of curvature R and a centre of curvature C, and an articulated slider coated with a layer of low friction composite material. The frictional force and stiffness during the sliding phase are proportional to the axial load. Moreover, an exponential analytical law can describe the velocity dependence of the dynamic friction coefficient [16]

$$\mu = \mu_{fast} - \left(\mu_{fast} - \mu_{slow}\right) e^{-\alpha \dot{u}_H} \tag{5}$$

where μ_{fast} and μ_{slow} are the friction coefficients at fast and slow sliding velocities $\dot{u}_H$, respectively, and α is a rate parameter which depends on the contact pressure and condition of the interface. The experimental results indicate that μ_{slow} can be assumed to be 2.5 times lower than μ_{fast} [17], while α can be considered approximately equal to 0.0055 s/mm [18].

The friction force for horizontal (bidirectional) motion is equal to [19]

$$\boldsymbol{F}_f = \begin{Bmatrix} F_{f,x} \\ F_{f,y} \end{Bmatrix} \cong \mu N \frac{1}{\|\dot{\boldsymbol{u}}_H\|} \begin{Bmatrix} \dot{u}_{H,x} \\ \dot{u}_{H,y} \end{Bmatrix} \tag{6}$$

where N is the axial load on the FP bearing. Finally, the restoring force can be evaluated as [20]

$$\boldsymbol{F}_H = \begin{Bmatrix} F_{H,x} \\ F_{H,y} \end{Bmatrix} \cong \frac{N}{R} \begin{Bmatrix} u_{H,x} \\ u_{H,y} \end{Bmatrix} + \begin{Bmatrix} F_{f,x} \\ F_{f,y} \end{Bmatrix} \tag{7}$$

containing a pendular component, directed toward the centre of the bearing, and a friction component, acting in the opposite direction to the velocity. For constant values of axial load and friction coefficient, the force-displacement behaviour of the FP bearing in the horizontal

direction (F_H-u_H) can be idealized by a bilinear law with lateral restoring stiffness

$$K_r = \frac{N}{R} \tag{8}$$

However, due to high values of vertical ground acceleration and global overturning moment produced by the horizontal seismic loads, the axial load variation on the FP bearing leads to changes in μ, F_f and K_r. In particular, at any given moment during an earthquake, the weight (W) of the superstructure acting on a FP bearing can be modified in accordance with the following expression [9]

$$N = W\left(1 - \frac{\ddot{u}_{g,V}}{g} + \frac{N_{OM}}{W}\right) \tag{9}$$

where $\ddot{u}_{g,V}$ is the vertical ground acceleration (positive when the direction is downwards) and N_{OM} is the additional axial load due to overturning (positive when compressive). It is worth noting that the fluctuation in the bearing axial load can be large enough to produce reversal of the axial load from compression to tension. A gap element is considered in the vertical direction, to take into account the fact that the FP bearing does not resist tensile axial loads and thus is free to uplift, assuming infinite rigidity in compression.

Maximum floor rotation at the level of the FP system, during the total duration (t_{tot}) of each ground motion, is evaluated as

$$\tan\vartheta_{max} = \max\left\{\left|u_{X,1}(t) - u_{X,22}(t)/L_Y\right| = \left|u_{Y,1}(t) - u_{Y,19}(t)/L_X\right|\right\},\ t\text{=0-}t_{tot} \tag{10}$$

referring to the horizontal displacement of three FP bearings at the corners of the building plan (i.e. FP_i, i=1, 19 and 22 in Figure 1a), being L_X=20m and L_Y=25m the maximum length along the X and Y directions. Moreover, the maximum residual displacement of the FP bearings is obtained as the vector sum of the residual displacement along the local axes

$$u_{res,max} = \max\left\{\sqrt{(u_{resx,i})^2 + (u_{resy,i})^2 + (u_{resz,i})^2}\right\},\ \text{i=1-24} \tag{11}$$

while the maximum vertical uplift

$$u_{up,max} = \max\left\{\left|u_{V,i}(t) - R\left[1 - cos\left(arcsin\frac{u_{H,i}(t)}{R}\right)\right]\right|\right\},\ \text{i=1-24} \tag{12}$$

is obtained as function of vertical and horizontal displacements on their spherical surface.

4 UNSCALED AND SCALED NEAR-FAULT GROUND MOTIONS

Ground motions recorded at near-fault sites may be characterized by strong long-duration velocity pulses in the horizontal direction, which may affect the friction coefficient of the FP bearings and their axial load variation due to overturning. To study torsional and re-centring problems of base-isolated structures with the FP system subjected to near-fault ground motions, seven recordings with significant horizontal components are selected from the *Pacific Earthquake Engineering Research center database* [14] on the basis of the design hypotheses adopted for the test structures. In Table 5a their main data are shown: i.e. year; recording station; closest distance from the fault (Δ); magnitude (M_w); peak ground acceleration for the two horizontal (i.e. PGA_{H1} and PGA_{H2}) and the vertical component (i.e. PGA_V); orientation of the strongest observed pulse (α_{sp}), clockwise from North [21].

Table 5a: Characteristics of the selected near-fault ground motions with significant horizontal components.

On the other hand, near-fault ground motions may be characterized by high values of the acceleration ratio $\alpha_{PGA}(=PGA_V/PGA_H)$, which may influence the friction force and lateral stiffness of the FP bearings during the sliding phase and produce uplift of the FP bearings. To study the nonlinear response of base-isolated structures with the FP system subjected to near-fault ground motions with significant vertical component, seven recordings are selected from the *PEER database*. Table 5b shows their main data: i.e. year; recording station; closest distance from the fault (Δ); magnitude (M_w); peak ground accelerations (i.e. PGA_{H1}, PGA_{H2} and PGA_V); maximum value of the acceleration ratio (i.e. $\alpha_{PGA,max}$).

Table 5b: Characteristics of the selected near-fault ground motions with significant vertical component.

To account for the potential structural damage of near-fault earthquakes, maximum value of spectral acceleration is assumed as a seismic intensity measure. In detail, horizontal components corresponding to the effective fundamental vibration period (i.e. T_{eI}) and equivalent viscous damping (i.e. ξ_{eI}) of the base-isolated structures reported in Tables 3 and 4 (i.e. $S^{(NF)}{}_{aH,1}$ and $S^{(NF)}{}_{aH,2}$) are considered. Then, the scale factor (*SF*), whereby the selected accelerograms are normalized with respect to the NTC08 spectrum, is evaluated as

$$SF = \frac{S_{aH}^{NTC08}\left(T_{eI},\xi_{eI}\right)}{\max\left\{S_{aH,1}^{NF}\left(T_{eI},\xi_{eI}\right),S_{aH,2}^{NF}\left(T_{eI},\xi_{eI}\right)\right\}} \tag{13}$$

Finally, normalization of the selected near-fault ground motions is carried out by scaling their *PGA* values with reference to *SF* values reported in Tables 6a and 6b.

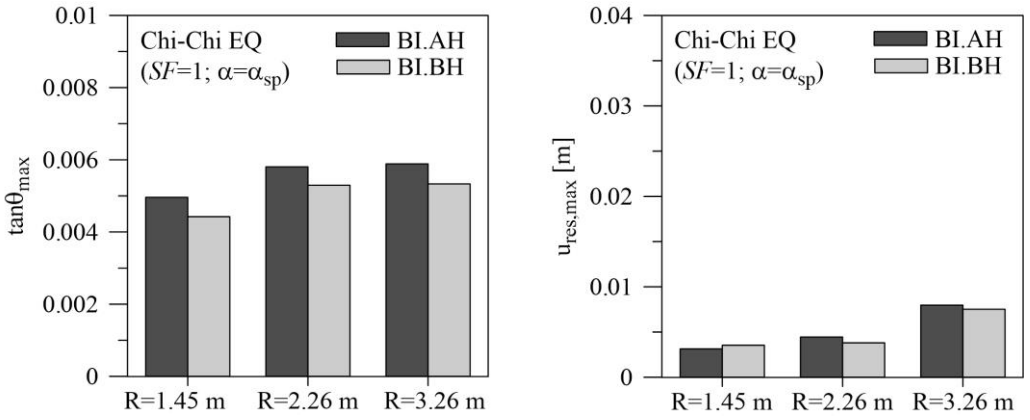
5 NUMERICAL RESULTS

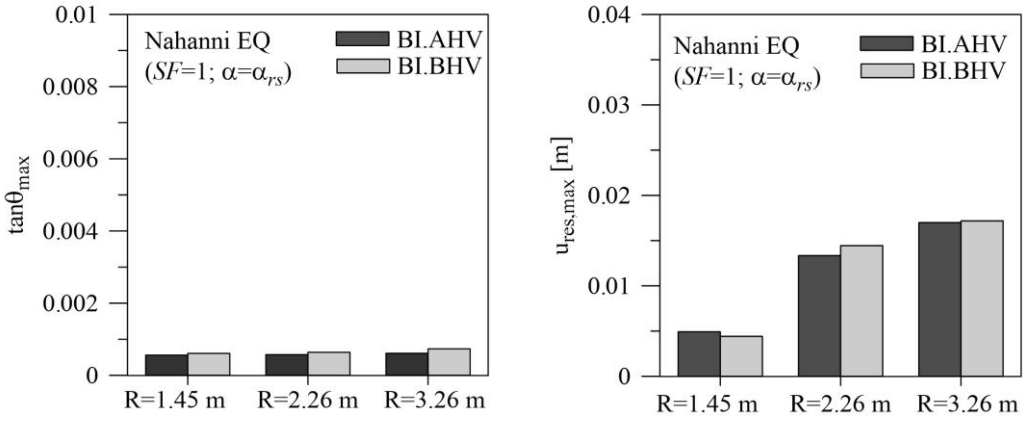
A numerical study is carried out to analyze torsional response, re-centring capability and uplift of base-isolated structures subjected to near-fault ground motions. In detail, maximum effects are evaluated for the orientation of the strongest pulse (i.e. $\alpha=\alpha_{sp}$) in the case of earthquakes with significant horizontal components, while accelerograms applied in line with the direction of the recording station (i.e. $\alpha=\alpha_{rs}$) are considered for earthquakes with significant vertical component. A computer code is adopted for the nonlinear dynamic analysis of the test structures [22-25], considering an elastic-linear behaviour of the superstructure and a nonlinear force-displacement law of the FP bearings in the horizontal direction depending on sliding velocity and axial load. A gap model is also assumed to capture the uplift of the FP bearings in the vertical direction. Moreover, a stiffness-proportional damping matrix of the superstructure is considered, by applying a viscous damping ratio ξ_S=1% to the fundamental vibration period of the base-isolated structures [26]. To take into account the uncertainty in the selection of the seismic intensity measure [27] and code-mandated damping modification factor [28] to be adopted for base-isolated structures subjected to near-fault earthquakes, two series of analyses are carried out on the selected ground motions applied with and without the scaling factor described in Section 4.

Firstly, maximum values of floor rotation ($tan\theta_{max}$) and residual displacement ($u_{res,max}$) at the level of the FP system are reported in Figures 3a-4a and 3b-4b, respectively, for base-isolated structures subjected to the unscaled Chi-Chi and Nahanni near-fault earthquakes (EQs). Two in-plan distributions of dynamic-fast friction coefficient for the FP system (i.e. BI.A and BI.B structures) are compared for three low-to-medium values of the radius of curvature for the FP bearings (i.e. R=1.45m, 2.26m and 3.26m).



(a) Floor rotation. (b) Residual displacement.

Figure 3: Effects of the radius of curvature of the FP bearings on the nonlinear response of base-isolated structures subjected to the unscaled Chi-Chi EQ.

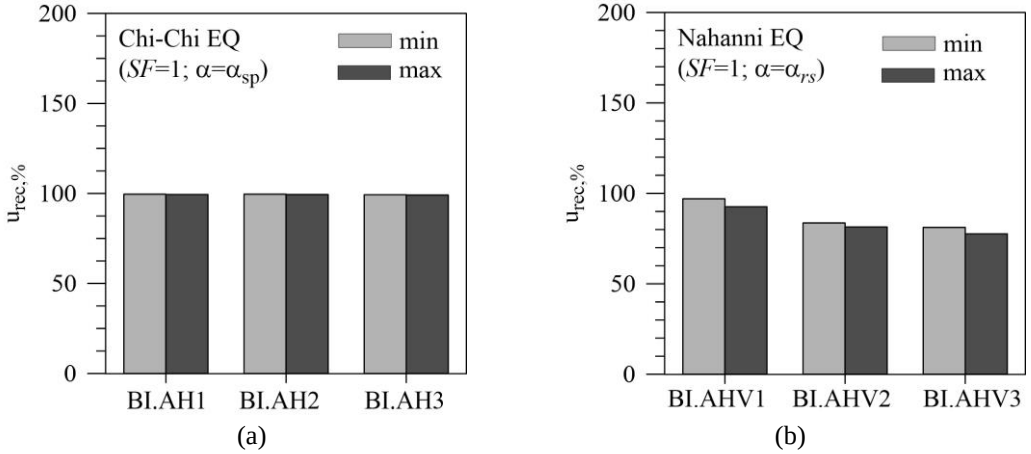


(a) Floor rotation. (b) Residual displacement.

Figure 4: Effects of the radius of curvature of the FP bearings on the nonlinear response of base-isolated structures subjected to the unscaled Nahanni EQ.

The BI.AH and BI.BH structures are designed considering the horizontal seismic loads acting alone and thus they are subjected to the Chi-Chi EQ (Figure 3), in which significant horizontal components are dominant; on the other hand, the Nahanni EQ (Figure 4), with a significant vertical component, is considered for the BI.AHV and BI.BHV structures designed also considering the vertical seismic loads. As can be noted, torsional effects are found to be important for the Chi-Chi EQ (Figure 3a), while in the case of the Nahanni EQ the effect is minor (Figure 4a). On the other hand, the residual displacement is generally more marked for the base-isolated structures subjected to the Nahanni EQ (Figure 4b) than the Chi-Chi EQ (Figure 3b). This behaviour can be interpreted by observing that higher spectral values of acceleration in the vertical direction are obtained for the Nahanni EQ, at least for rather low values of the vibration periods, thereby increasing the friction threshold of the FP bearings. As expected, the concave spherical surface of the FP bearing ensures a reduction of the residual displacement for decreasing values of the radius of curvature (Figures 3b and 4b). The BI.BH and BI.BHV structures respond in a similar way to the corresponding BI.AH and BI.AHV structures, but the former are less expensive because they require only three typologies of isolators in accordance with the maximum axial load capacity of the FP bearings.

Similar graphs in Figure 5 refer to minimum and maximum percentage of re-centring displacement ($u_{rec,\%}$) compared to maximum horizontal displacement.



(a) (b)

Figure 5: Percentage of re-centring displacement for base-isolated structures subjected to the unscaled Chi-Chi and Nahanni EQs.

The BI.AHV structures subjected to the unscaled Nahanni EQ (Figure 5b) highlight values of $u_{rec,\%}$ lower than those obtained for the BI.AH structures under the Chi-Chi EQ (Figure 5a). Moreover, it is worth noting that the BI.AHV structures subjected to the Nahanni EQ exhibit different minimum and maximum values of $u_{rec,\%}$, highlighting the possibility of residual floor rotation at the level of the FP system.

Next, maximum values of uplift ($u_{up,max}$) for the BI.AHV and BI.BHV structures subjected to the unscaled Nahanni EQ are compared in Figure 6. More specifically, uplift of the six FP bearings at the corners of the building plan (i.e. FP_i, i=1, 11, 19, 21, 22 and 24 shown in Figure 1a) are reported. Note that uplift takes place in all the examined cases although the presence of tensile axial loads at the level of the FP system was prevented when designed for the horizontal seismic loads acting in combination with the vertical seismic ones. As can be observed, the variability of the in-plan distribution of friction coefficient and the choice of different radii of curvature for the FP bearings are not able to prevent uplift. Further results, omitted for brevity, confirm the absence of uplift due to overturning produced by the horizontal components of the unscaled Chi-Chi EQ.

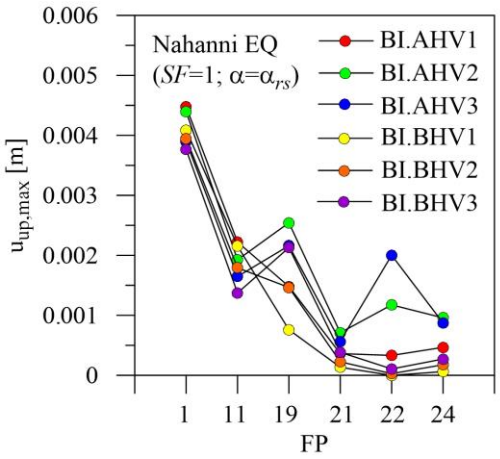


Figure 6: Effects of the radius of curvature of the FP bearings on the uplift of base-isolated structures subjected to the unscaled Nahanni EQ.

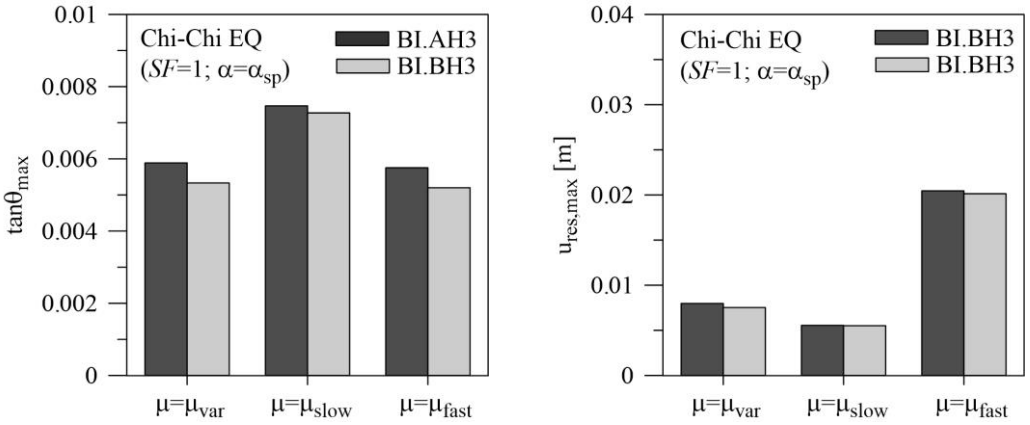
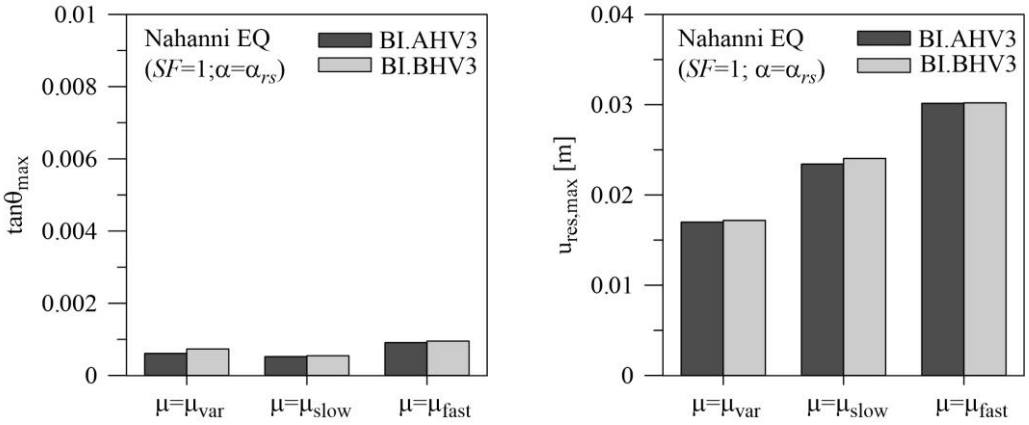
Afterwards, in order to evaluate the effects of the modelling assumptions related to velocity dependence of the friction coefficient of the FP bearings, maximum values of the floor rotation and residual displacement are reported in Figures 7 and 8.



(a) Floor rotation. (b) Residual displacement.

Figure 7: Effects of modelling of the friction coefficient on the nonlinear response of base-isolated structures subjected to the unscaled Chi-Chi EQ.

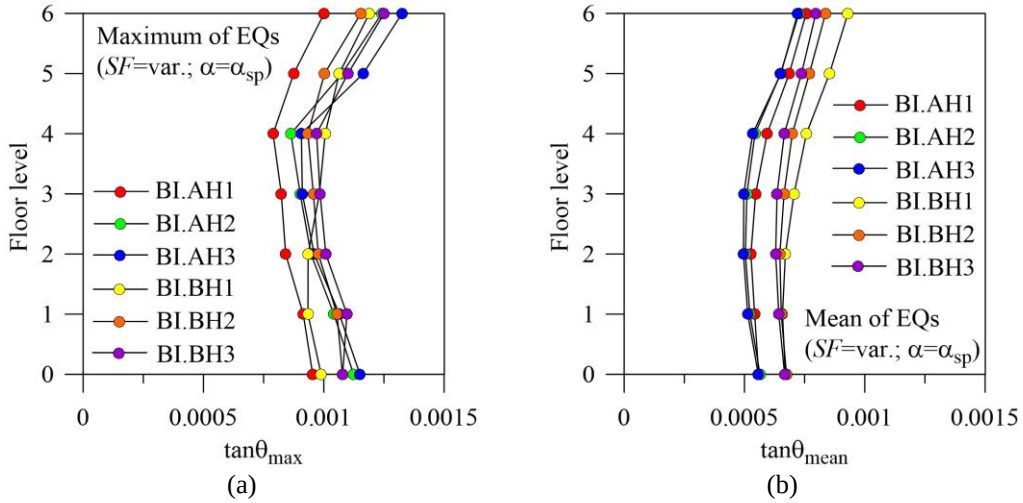


(a) Floor rotation. (b) Residual displacement.

Figure 8: Effects of modelling of the friction coefficient on the nonlinear response of base-isolated structures subjected to the unscaled Nahanni EQ.

Only results for base-isolated structures exhibiting maximum effects are examined for the unscaled Chi-Chi (i.e. BI.AH3 and BI.BH3 structures) and Nahanni (i.e. BI.AHV3 and BI.BHV3 structures) EQs. Three cases are compared: (a) friction coefficient variability as a function of the sliding velocity (i.e. $\mu=\mu_{var}$); (b) constant friction coefficient, at fast sliding velocity (i.e. $\mu=\mu_{fast}$); (c) constant friction coefficient, at slow sliding velocity (i.e. $\mu=\mu_{slow}$). As can be observed, maximum floor rotation is obtained for the BI.AH3 and BI.BH3 structures subjected to the Chi-Chi EQ (Figure 7a). This is evident when the minimum friction coefficient is assumed (i.e. μ_{slow}), while comparable results are found for the maximum (i.e. μ_{fast}) and variable (i.e. μ_{var}) friction coefficients. On the other hand, maximum values of residual displacement are obtained for the BI.AHV3 and BI.BHV3 structures under the Nahanni EQ (Figure 8b) and correspond to maximum friction coefficient (μ_{fast}); lower values are obtained for the minimum (μ_{slow}) and variable (μ_{var}) friction coefficients. In all the examined cases, comparable results are obtained for the base-isolated structures designed to consider the two in-plan distributions of the FP bearings (i.e. cases A and B shown in Figure 2).

Finally, maximum ($tan\theta_{max}$) and mean ($tan\theta_{mean}$) floor rotations along the building height are plotted for base-isolated structures subjected to two sets of seven scaled near-fault ground motions with significant horizontal (Figure 9) and vertical (Figure 10) components.



(a) (b)

Figure 9: Maximum and mean floor rotations of the superstructure for scaled near-fault EQs with significant horizontal components.

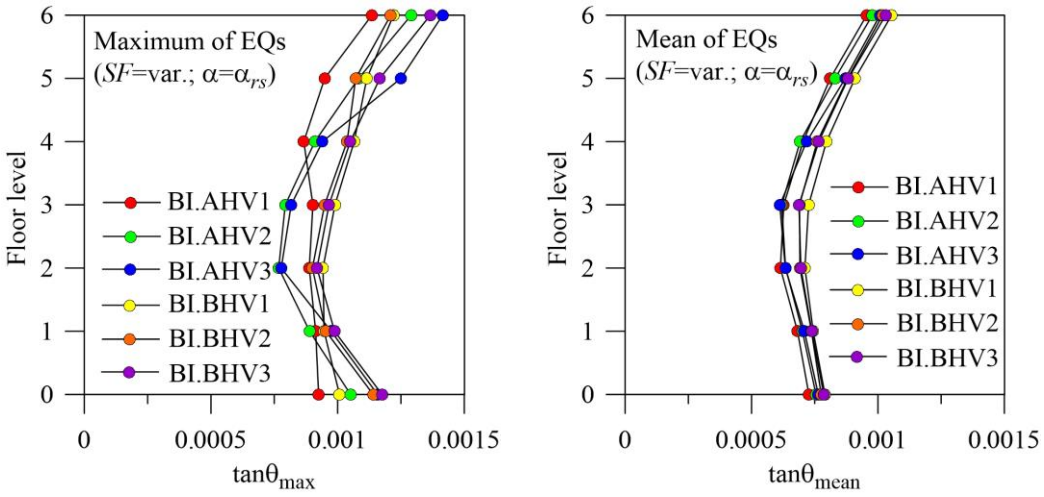


Figure 10: Maximum and mean floor rotations of the superstructure for scaled near-fault EQs with significant vertical component.

Note the highest values of floor rotation at the top level, with variability of torsional effects at the floor levels of the superstructure which are more evident in terms of $tan\theta_{max}$ (Figures 9a and 10a) than $tan\theta_{mean}$ (Figures 9b and 10b). However, limited torsional effects are highlighted for all the examined structures subjected to scaled near-fault EQs, which are normalized in accordance with a medium risk seismic region. Further results, omitted for the sake of brevity, highlight low values of maximum and mean residual displacement and uplift of the FP system.

6 CONCLUSIONS

The nonlinear seismic analysis of base-isolated structures with the FP system is carried out under near-fault ground motions, considering three low-to-medium design values of the radius of curvature of the FP bearings and two in-plan distributions of their dynamic-fast friction coefficient. Torsional effects are found to be more evident for unscaled earthquakes with significant horizontal components (e.g. the Chi-Chi EQ). On the other hand, residual displacement are generally more marked for base-isolated structures subjected to unscaled earthquakes with significant vertical component (e.g. the Nahanni EQ). Torsional and residual effects of the BI.BH and BI.BHV structures are similar to those of the corresponding BI.AH and BI.AHV structures, but the former are less expensive because they require only three typologies of isolators. As expected, a reduction of the residual displacement is obtained for decreasing values of the radius of curvature of the FP bearings. It is interesting to note that the BI.AHV structures subjected to the Nahanni EQ exhibit different minimum and maximum values of the percentage of re-centring displacement, highlighting the possibility of residual floor rotation at the level of the FP system. Moreover, the BI.AHV and BI.BHV structures exhibit uplift when subjected to the Nahanni EQ. The modelling of the friction coefficient highlights maximum floor rotation under the Chi-Chi EQ, when the minimum (constant) friction coefficient is assumed, while comparable results are found for maximum (constant) and variable friction coefficients. Maximum values of residual displacement are obtained under the Nahanni EQ, corresponding to maximum (constant) friction coefficient, while lower values are obtained for the minimum (constant) and variable friction coefficients. Finally, the highest values of mean floor rotation are found at the top level of the superstructure. However, torsional effect and residual displacement and uplift are less evident for scaled near-fault earthquakes, confirming the crucial importance of selecting suitable seismic intensity measure and code-mandated damping modification factor.

Keywords: Multibody Systems, Dynamics, Finite Elements, Absolute Coordinates, Seismic Excitations, Flexible Structures.

Abstract. *In the paper a novel method of finite elements in absolute coordinates is presented. The flexible elements and their node coordinate systems are considered free objects in space which motion is restricted by the elastic forces of the adjacent flexible elements. So, no kinematic restrictions, respectively algebraic equations, are imposed to the dynamic equations and the dynamic model is presented as Ordinary Differential Equations. Incremental approach for definition of system configuration during its global motion is applied, which avoids singularity of the large rotations. The proposed numerical procedure defines the element nodes as moving coordinate systems that makes possible their motion coordinates to be compared to rigid bodies and the large rotations to be taken into account. External excitations as wave propagation and earthquakes are subjects of the investigations.*

Generalized Newton – Euler dynamic equations for rigid and flexible bodies are applied for precise definition of the velocity dependent inertia forces in the dynamic equations. The seismic excitations are presented as reonomic constraints. Examples of large spatial flexible deflections of complex flexible structure verify the effectiveness of the method proposed.

1 INTRODUCTION

Multibody system methodology is a recently developing field in the theoretical and applied mechanics. Multibody dynamics as independent branch of mechanics was agreed to and established in 1977 at an IUTAM Symposium held in Munich, Germany and chaired by Magnus [1]. The first steps of the new discipline started with the dynamic analysis of rigid and flexible body systems striving to solve complicated nonlinear problems that the analytical methods cannon cover. In particular, elastic or flexible multibody systems, respectively, contact and impact problems where key issues for researchers worldwide. Multibody dynamics depends on computational dynamics and is closely related to control design and vibration theory.

Recently the multibody system methodology experienced huge progress including real time simulation, contact and impact problems, extension to electronics and mechatronics, dynamic strength analysis, optimization of design and control devices, integration codes in particular for differential algebraic systems, challenging applications in biomechanics, robotics and vehicle dynamics, manufacturing science and molecular dynamics and etc. Multibody dynamics is an excellent foundation for multivariable vibration analysis and sophisticated control design. The natural relations between the motion behavior of the mechanical systems with the sensors and the control devices make the mechatronic systems a basic subject for the Multibody system methodology. The precise analysis, simulation and planning of the system motion and design could be done deriving the dynamic equations including the control inputs and the information coming from the sensors. Obviously, the higher level of the mechatronic devices is the intelligent multibody systems which include all the characteristics of the mechatronics, as well as, the precise dynamics simulation and motion planning and control [2, 3].

Example of such mechatronic (intelligent) multibody systems are autonomous vehicles, space structures, structures imposed on external and seismic excitations, large flexible structures and wind generators. Solution of these tasks requires up-to-date methods for dynamics analysis and simulation, novel methods for numerical solution of ODE and DAE, real time simulation, passive, semi-passive and active control algorithms taking into account the control system and the feedback information.

The methods of the finite element theory (FET) [4] have been constantly developing to successfully solve the up-to-date tasks in structural statics. The problem of deriving the dynamics equations of flexible bodies using finite element discretization is really topical. Many books and papers [5, 6] discuss the problems that could arise using the finite element methodology and commercially available software (NASTRAN, ANSYS, ABAQUS) for simulation of nonlinear phenomena. It was pointed out that the FET approach cannot effectively simulate nonlinear effects of high velocity global motion in space and large flexible deformations.

The finite element theory proposed the theoretical basis for profound numerical analysis of complex flexible structures. The methodology for discretization of the continuum and the theory for polynomial approximation of the form of the deformations and on this basis computation and distribution of the mass and stiffness properties of the materials of flexible elements to discrete objects (nodes), actually, have been used afterward for development of various methods for static and dynamic analysis, even in the multibody system dynamics (MDS) simulation of rigid and flexible bodies. Attempts had been made for direct application of FET for dynamics simulation of systems that undergo global motion in space superimposed by large flexible deflections. In the recent decades the scientists successfully developed up-to-date methods for dynamics analysis of rigid and flexible mechanical systems setting the basis of multibody system methodology. Actually, the scientists use the theoretical rules of the FET for deriving the basic properties of the discretized elastic bodies but, on the other hand, they

strive to escape from the motion parameters of the FET in order to catch the nonlinear effects of the large displacements and deformations. It was proven [7 – 9] that using the FET approach the dynamic equations are free of centrifugal and Coriolis accelerations and the corresponding inertia forces.

Khan and Anderson [10] proposed the most recent classification of the methods for MBS dynamics. Tthey applied the Floating Frame of Reference (FFR) and Absolute Nodal Coordinate Formulation (ANCF) approaches for realization of their numerical procedure.

The FFR approach was developed [7, 11, 12] and has been successfully applied for dynamics simulation of large spatial motion and rotation of flexible multibody systems. This approach is also used for application of the modal coordinates and significant decreasing of the flexible coordinates.

Recently a novel method of ANCF has been developed [13, 14]. It is based on the theory of the curvilinear coordinates. The slopes of the nodes in the tangential line or plane of the space curve or shell are applied as coordinates. The method proposes important advantages mainly in large rotation simulation and mass matrices formulation. Review on the ANCF method for large deformation dynamics simulation of flexible multibody systems was presented by Gerstmayr et al. [15]. The paper provided a comprehensive review of the advantages and further developments of the ANCF method.

As it was said above the dynamic equations derived on basis of the FET do not include the Coriolis and the centrifugal accelerations. Shabana [16] and Meijard [17] derived generalized Newton – Euler dynamic equations for the case of FFR formulation. The equations represent the inertia forces as function of the velocities and accelerations of the global and flexible coordinates. Zahariev [18] derived generalized Newto-Euler dynamics equations for the rigid and flexible bodies for which the kinetic energy is quadratic form of the velocities. The equations are applicable for the flexible elements of the FET. The inertia forces are with respect to the quasi velocities and accelerations and are invariant to the kind of the coordinates.

In [19] a method of Finite Elements in Relative Coordinates (FERC) based on the FET was proposed for dynamic simulation of large flexible structures. Using the generalized Newton-Euler dynamic equations nonlinear effects and velocity dependent terms are successfully simulated. But using this approach for complex structures with many mutually connected adjacent flexible bodies one could experience a lot of difficulties that mainly consists in its program system realization and complex pre-processor procedures.

A method of Finite Elements in Absolute Coordinates (FEAC) is discussed in the paper. It was recently presented in [18] and further developed for different applications. FEAC are proposed here for simulation of structures subject to seismic excitations. Acceleration and force methods are used in practice for dynamics simulation of the earthquake structure response. Acceleration approach consists in registration of the motion of a structure foundation by accelerographs and normally consists in three orthogonal components of the ground acceleration. The velocity and displacement of the ground are obtained integrating the data of the accelerograms. The statistical data for the specific regions are than applied as input data for the dynamic simulation. In [20] the accelerations of the foundation are reonomic constraints for the dynamic equations which are transformed with respect to the parameters that consists of structure displacement and the forces, applied to the foundation.

Investigation of the forces loading the basement is a natural way for simulation of the structure response because of earthquakes [21]. This task is implemented analyzing the soil-structure interaction. Computation of the forces loading the foundation as a function of the relative motion ground – basement is the first stage for the numerical simulation process using the multibody system methodology.

The problems related to the subjects of the large scale flexible structures are discussed in [22]. Problem oriented articles devoted to the structures subject to seismic excitation were collected in [23]. The up-to-date methods and devices for prevention of structure damages and collapse are based manly of passive, semi-active and active structure basement suspension. Mainly spring, dampers and rubber isolators are used for passive suppression of the structure deflections. Shock absorbers or dampers are added to the structure to dissipate the seismic shocks. Active Tuned Mass Dampers use a computer controlled counter moving weight to actively move against the building sway. Active large scale springs and dampers together with computer controlled motion of large masses ensure calculated action against the building deflections. The article of Yao [24] seems to be the cornerstone in the structural control in civil engineering. An early review article of active control in structural engineering was published by Soong [25]. Latest surveys in 2003 [26] and another recent one in 2012 [27] emphasize on the semi-active and active control of structures subject to earthquake excitations and discuss theoretical backgrounds of different control schemes.

Dynamics simulation is extremely important for the design process of slender and large scale flexible systems as skyscrapers, bridges, wind power generators and many others. The devices for deviation suppression including passive, semi-active or active, although being designed on the basis of the eigenvalue analysis, should be simulated and analyzed for long time operational time and different kind of external excitations. This process includes development of reliable dynamic model and deriving precise dynamic equations. For efficient dynamic and motion simulation of complex structures that implement spatial motion and experience external excitations an important thing is to provide numerical procedure that ensures long lasting operational time of simulation and convergence of the numerical integration. Keeping in mind that such structures are with tremendously high nodes and degree of freedom with many complicated relations and geometrical constraints the following requirements to the program systems for dynamic simulation are stated:

a) Simple and straight forward algorithm for pre-processor development of the input data compliant with the dynamic model.

b) An approach to presentation of the rotational parameters keeping in mind that the systems could implement large rotations and translations.

c) Efficient dynamic model for simulation of rigid and flexible systems taking into account nonlinear effects as geometrical stiffening, velocity dependent terms and external excitations;

d) Reliable methods for node, respectively, degree of freedom reduction.

e) Efficient program procedures for numerical integration of Ordinary Differential Equations (ODE) and Differential Algebraic Equations with proven convergence.

The efficient simulation procedure based on a precise dynamic model and efficient numerical solution significantly improves the design process making him more reliable and inexpensive. In the paper the main attention is paid to first three items (a, b, c). The numerical procedure proposed here defines the element nodes as moving coordinate systems that makes possible their motion coordinates to be compared to rigid bodies, respectively, the large rotations to be taken into account. In the paper a novel method of finite elements in absolute coordinates of modified finite elements is presented. External excitations as wave propagation and earthquakes are subjects of the investigations. The flexible elements and their node coordinate systems are considered free objects in space which motion is restricted by the elastic forces of the adjacent flexible elements. So, no kinematic restrictions, respectively algebraic equations, are imposed to the dynamic equations and the dynamic model is presented as ODE. Incremental approach for definition of system configuration during its global motion is applied, which avoids singularity of the large rotations.

Generalized Newton – Euler dynamic equations for rigid and flexible bodies are applied for precise definition of the velocity dependent inertia forces. Wave propagations and seismic excitation are presented as reonomic constraints. Examples of large spatial and flexible deflections of complex rigid and flexible body structure verify the effectiveness of the method proposed.

2 KINEMATICS OF LARGE SPATIAL ROTATIONS OF FLEXIBLE ELEMENTS

2.1 Relative node position of a flexible element

To understand the difference between the classical FET and the method of the finite elements in absolute nodal coordinates using multibody system methodology some explanations about the kinematics of flexible nodes will be presented here. Since the basic relations and deductions as discretization of the flexible elements, the forms of the deformations, as well as, the methods for computation of the mass and stiffness matrices are well known for the readers [4, 28] no special attention will be paid to that procedures.

In Figure 1 a non-isoparametric space beam element (with index i) is presented. This finite element is relatively simple for explanation but, at the same time, presents the most common six degree of freedom (dof) space deflections of the nodes. In the figure the beam and small translations and rotations, respectively $\boldsymbol{\Delta}_{i,k} = \left[\Delta x_{i,k} \;\; \Delta y_{i,k} \;\; \Delta z_{i,k}\right]^{\backslash}$, $\boldsymbol{\theta}_{i,k} = \left[\theta x_{i,k} \;\; \theta y_{i,k} \;\; \theta z_{i,k}\right]^{\backslash}$, $i = 1,2$ of its nodes (indices i,1 and i,2 – the first and second nodes of element i) with respect to the initial not deformable element coordinate system $\underline{X}_i\underline{Y}_i\underline{Z}_i$ are depicted [4].

With the superscript "\" a matrix transpose is denoted. The underlined notations denote initial configurations. With bold characters matrices are pointed out. For scalars and objects, for example points, bodies, coordinate systems, italic notations are used.

It should be said that in FET these deflections are with respect to the element reference frame in its initial position (not deformed position) and no rotation of the element coordinate system is taken into account. Of course, coordinate system transformation with respect to the absolute reference frame $X_0Y_0Z_0$ of mass and stiffness matrices is considered but for the structure initial configuration only. As a result of the node deflections the element coordinate system $X_iY_iZ_i$, respectively the node i,1 coordinate system $X_{i,1}Y_{i,1}Z_{i,1}$, moves to a new position defined by the radius – vector $\boldsymbol{\rho}_{i,1}$ that could be easily estimated adding the initial

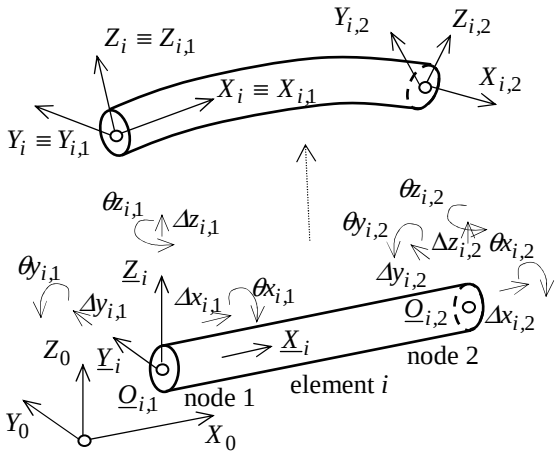

Figure 1: Small flexible node deflections of space non-isoparametric beam finite element

position of element coordinate system origin, radius – vector $\underline{\boldsymbol{\rho}}_i \equiv \underline{\boldsymbol{\rho}}_{i,1}$, and the node *i*,1 deflections $\boldsymbol{\Delta}_{i,1}$. The same holds for the radius –vector $\boldsymbol{\rho}_{i,2}$, taking into account the initial position of node *i*,2 coordinate system origin - radius – vector $\underline{\boldsymbol{\rho}}_{i,2}$, and the node *i*,2 deflections $\boldsymbol{\Delta}_{i,2}$. The node deflections of the i-*th* beam element are set in a 12×1 matrix – column $\boldsymbol{\Theta}_i = \left[\boldsymbol{\Theta}_{i,1}^{\backslash} \;\; \boldsymbol{\Theta}_{i,2}^{\backslash}\right]^{\backslash} = \left[\boldsymbol{\Delta}_{i,1}^{\backslash} \;\; \boldsymbol{\theta}_{i,1}^{\backslash} \;\; \boldsymbol{\Delta}_{i,2}^{\backslash} \;\; \boldsymbol{\theta}_{i,2}^{\backslash}\right]^{\backslash}$.

In Figure 2 the element *i* is not drawn but only the coordinate systems *i*,1 and *i*,2 of its nodes are shown in their initial and final configurations. The nodes are actually free objects, respectively coordinate systems that implement free motion in space restricted by the elastic forces only. Six possible deflections of the nodes are assumed (translations and rotations). The elastic forces $\mathbf{F}_{i,1}$ and torques $\mathbf{L}_{i,1}$ in the first node, as well as, $\mathbf{F}_{i,2}$, $\mathbf{L}_{i,2}$ in the second node, which are 3×1 matrix – vectors, are set in a 12×1 matrix – column $\boldsymbol{\Xi}_i = \left[\mathbf{F}_{i,1}^{\backslash} \;\; \mathbf{L}_{i,1}^{\backslash} \;\; \mathbf{F}_{i,2}^{\backslash} \;\; \mathbf{L}_{i,2}^{\backslash}\right]^{\backslash}$ arranged in the same order as the corresponding elements of $\boldsymbol{\Theta}_i$.

Actually, the position of the element coordinate system $X_i Y_i Z_i$ in the deformed configuration coincides with the coordinate system $X_{i,1} Y_{i,1} Z_{i,1}$ of node *i*,1. So, the deflections of the flexible element could be considered as free motion of the element coordinate system and the flexible deflections of the second node with respect to it. These are the flexible deflections relative to the element coordinate system.

In Figure 3 the beam element in the configuration as this of Figure 1 is depicted including the length L_i of the beam (along axis *X*) and the small deflections $\boldsymbol{\Delta}_{i,2\rangle i}$ of node *i*,2 relative to the beam coordinate system *i*. In the right subscript $\boldsymbol{\Delta}_{i,2\rangle i}$ the symbol "$\rangle$" serves as an arrow pointing out that the coordinate system with index *i*,2 is with respect to coordinate system *i*.

The right symbol of the subscript could be omitted if it points the absolute reference frame with index "0" – zero. Obviously, the beam configuration is quite the same and the fact that the flexible deflections are read relative to the moving element coordinate system does not change the regulations for FET discretization and for computation of the mass and stiffness matrices. The position of node *i*,2 coordinate system relative to the coordinate system of the moving beam is presented by 4×4 homogeneous transformation matrix $\mathbf{T}_{i,2\rangle i}$, i.e.:

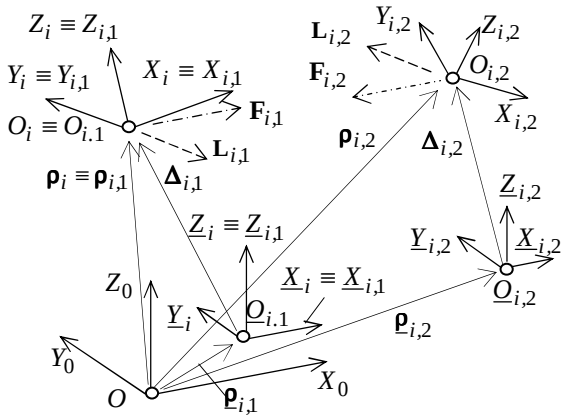

Figure 2: Presentation of the nodes as moving coordinate systems

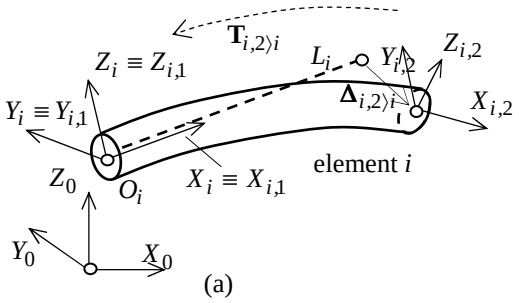

Figure 3: Finite beam element in relative coordinates

$$\mathbf{T}_{i,2\rangle i} = \begin{bmatrix} {}^{3.3}\boldsymbol{\tau}_{i,2\rangle i} & {}^{3,1}\boldsymbol{\rho}_{i,2\rangle i} \\ {}^{1,3}\mathbf{0} & 1 \end{bmatrix} =$$

$$= \begin{bmatrix} 0 & -\theta z_{i,2\rangle i} & \theta y_{i,2\rangle i} & L_i + \Delta x_{i,2\rangle i} \\ \theta z_{i,2\rangle i} & 0 & -\theta x_{i,2\rangle i} & \Delta y_{i,2\rangle i} \\ -\theta y_{i,2\rangle i} & \theta x_{i,2\rangle i} & 0 & z y_{i,2\rangle i} \\ 0 & 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} 0 & -q_{i_6} & q_{i_5} & L + q_{i_1} \\ q_{i_6} & 0 & -q_{i_4} & q_{i_2} \\ -q_{i_5} & q_{i_4} & 0 & q_{i_3} \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{1}$$

which for small rotational deflections does not include trigonometric functions. With this assumption that the homogeneous transformation matrix is linear for the relative coordinates $q_{i_j}, j = 1,2,...6$ of element i that include the small translational and rotational flexible deflections. ${}^{3,3}\boldsymbol{\tau}_{i,2\rangle i}$ is 3×3 rotational matrix; the left superscripts point out (used if needed) the matrix dimensions (rows, columns).

Since the beam coordinate system is moving the flexible deflections of node i,1 relative to the element coordinate system are zero and the matrix vector of the beam relative coordinates $\mathbf{q}_i$ is $\boldsymbol{\Theta}_{i\rangle i} = \begin{bmatrix} \boldsymbol{\Delta}_{i,2\rangle i}^{\backslash} & \boldsymbol{\theta}_{i,2\rangle i}^{\backslash} \end{bmatrix}^{\backslash} = \mathbf{q}_i = \begin{bmatrix} q_{i_1} & q_{i_2} & \dots & q_{i_6} \end{bmatrix}^{\backslash}$ (see Equation 1), as well as, the beam mass and stiffness matrices are constant.

2.2 Finite elements in absolute coordinates

In Figure 4 the coordinate systems of the beam element and its nodes are depicted without the beam shape and configuration. As we said above the beam coordinate system and that of node i,1 coincide and their relative position does not change during the beam motion. That is why we shall regard the motion of node coordinate systems taking into account which one is of the beam. Loading the nodes with the inertia, elastic and external forces, just like free rigid bodies they will implement, for a small increment of time, small increments of the motion parameters. Six are the minimal number of the coordinates that define the position as of a rigid body, so of a node. When a flexible element implements global motion in space overlapped by flexible deflections even small increments of the node coordinates with respect to their initial position do not present the real deformation of the flexible element.

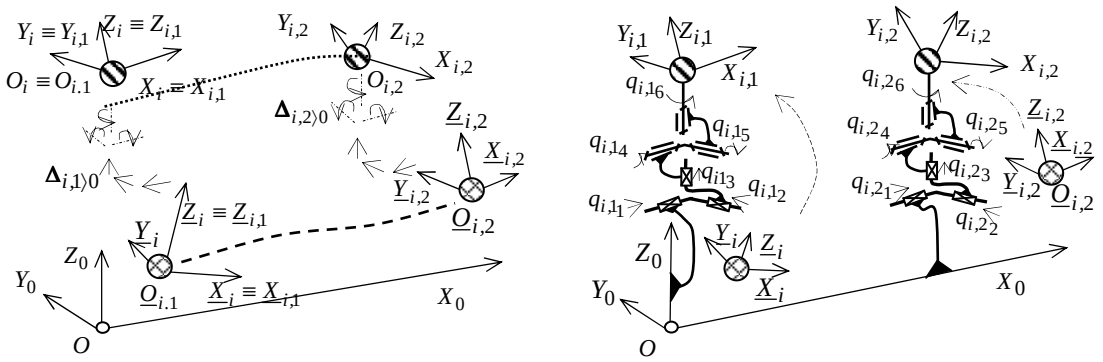
The solution of the problem how to use the FET in case of global motion and large flexible deflections consists in:

a) definition of proper node reference frame coordinates for the case of small increments of time, respectively, for small increments of that coordinates;

b) estimation of the magnitudes of the elastic deformations.

The solution of problem (a) consists in selection of node reference frame coordinates compatible with the coordinates used in FET. The solution of problem (b) consists in separation of the flexible deflections from the global motion of the node coordinate systems.

In Figure 4, similar to Figure 2, the coordinate systems of nodes *i*,1 and *i*,2, $X_{i,k}Y_{i,k}Z_{i,k}$; $i=1,2$, are located in their final configuration. The initial positions of the node coordinate systems are presented by the same but underlined notations. FET claims for the small deflections to be read with respect to the system initial configuration.



(a) possible small global deflections

(b) virtual joint presentation of the deflections

Figure 4: Nodes as free coordinate systems and corresponding motion coordinates

In Figure 4 (a) these deflections are presented by arrows and in Figure 4 (b) they are presented by virtual translational and rotational joints. These presentations are one and the same but give proper comparison to the free moving objects, constraint kinematics, joint coordinates, as well as, reveal the generality of the methodology proposed in the paper.

The homogeneous transformation matrices $\mathbf{T}_{i,1\rangle 0}$, $\mathbf{T}_{i,2\rangle 0}$ of the absolute position of the node coordinate systems *i*,1 and *i*,2, respectively, are expressed by the matrices $\underline{\mathbf{T}}_{i,1\rangle 0}$ and $\underline{\mathbf{T}}_{i,2\rangle 0}$ of their initial configuration and the transformation matrix because of the small node deflections.

$$\mathbf{T}_{i,k\rangle 0}=\left[\begin{array}{c|c}\boldsymbol{\tau\Delta}_{i,k\rangle 0}\cdot\underline{\boldsymbol{\tau}}_{i,k} & \underline{\boldsymbol{\rho}}_{i,k}+\boldsymbol{\Delta}_{i,k}\\ \hline \mathbf{0}_{1,3} & 1\end{array}\right]=\left[\begin{array}{ccc|c} & & & \underline{\rho x}_{i,k}+q_{i,k_1}\\ & \boldsymbol{\tau\Delta}_{i,k\rangle 0}\cdot\underline{\boldsymbol{\tau}}_{i,k} & & \underline{\rho y}_{i,k}+q_{i,k_2}\\ & & & \underline{\rho z}_{i,k}+q_{i,k_3}\\ \hline 0 & 0 & 0 & 1\end{array}\right];$$

$$\boldsymbol{\Delta}_{i,k\rangle 0}^{\backslash}=\left[q_{i,k_1}\;\; q_{i,k_{21}}\;\; q_{i,k_3}\right]^{\backslash}; \tag{2}$$

$$\boldsymbol{\tau\Delta}_{i,k\rangle 0}=\begin{bmatrix}0 & -\theta z_{i,k\rangle 0} & \theta y_{i,k\rangle 0}\\ \theta z_{i,k\rangle 0} & 0 & -\theta x_{i,k\rangle 0}\\ -\theta y_{i,k\rangle 0} & \theta x_{i,k\rangle 0} & 0\end{bmatrix}=\begin{bmatrix}0 & -q_{i,k_6} & q_{i,k_5}\\ q_{i,k_6} & 0 & -q_{i,k_4}\\ -q_{i,k_5} & q_{i,k_4} & 0\end{bmatrix}\quad k=1,2,$$

where $\mathbf{q}_{i,k}=\left[\boldsymbol{\Delta}_{i,k\rangle 0}^{\backslash}\quad \boldsymbol{\theta}_{i,k\rangle 0}^{\backslash}\right]^{\backslash}=\left[q_{i,k_1}\quad q_{i,k_2}\quad \ldots\quad q_{i,k_6}\right]^{\backslash}$, $k=1,2$ are the deflections of node *k* from element *i* with respect to the absolute reference frame (index 0), which are also the coordinates of the free moving nodes. To apply Equation (2) the deflections are to be small al-

though they do not present the flexible deformations only. The deflections q_{i,k_n}, $k=1,2; n=1,6$ include also the global motion of the nodes. To define the flexible deformations of the element i the relative position of node $i,2$ with respect to node $i,1$ that coincides with the element coordinate system i, should be defined, i.e.:

$$\begin{aligned}\mathbf{T}_{i,2\rangle i,1} = \mathbf{T}_{i,1\rangle 0}^{-1} \cdot \mathbf{T}_{i,2\rangle 0} = \left[\underline{\mathbf{T}}_{i,1\rangle 0} \cdot \mathbf{T}\boldsymbol{\Delta}_{i,1}\right]^{-1} \cdot \underline{\mathbf{T}}_{i,2\rangle 0} \cdot \mathbf{T}\boldsymbol{\Delta}_{i,2} = \\ = \mathbf{T}\boldsymbol{\Delta}_{i,1}^{-1} \underline{\mathbf{T}}_{i,1\rangle 0}^{-1} \cdot \underline{\mathbf{T}}_{i,2\rangle 0} \cdot \mathbf{T}\boldsymbol{\Delta}_{i,2}\end{aligned} \tag{3}$$

The matrix elements $\mathbf{T}_{i,2\rangle i,1} = \mathbf{T}_{i,2\rangle i}$ are actually the flexible deformations (rotations and translations) and, since they are to be small, the rotations could be presented without trigonometric functions, i.e.:

$$\mathbf{T}_{i,2\rangle i} = \begin{bmatrix} 0 & -\theta z_{i,2\rangle i} & \theta y_{i,2\rangle i} & L_i + \Delta x_{i,2\rangle i} \\ \theta z_{i,2\rangle i} & 0 & -\theta x_{i,2\rangle i} & \Delta y_{i,2\rangle i} \\ -\theta y_{i,2\rangle i} & \theta x_{i,2\rangle i} & 0 & z y_{i,2\rangle i} \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{4}$$

Taking into account that the relative deformations of node 1 are zero, the flexible deformations of the element i relative to its own reference frame are as follows $\boldsymbol{\Theta}_{i\rangle i} = \left[\boldsymbol{\Delta}_{i,2\rangle i}^{\backslash} \;\; \boldsymbol{\theta}_{i,2\rangle i}^{\backslash}\right]^{\backslash}$ and appear explicitly in matrix $\mathbf{T}_{i,2\rangle i}$ without trigonometric functions.

To realize the numerical algorithm with the proposed coordinates the integration process should be realized with small increments of time, respectively, with small increments of the nodal coordinates. For this purpose on every step of the time increment the new configuration of the system is the initial configuration for the next iteration and the absolute nodal coordinates start again with zero values. That process is not disadvantage since during the numerical integration of the dynamic equations the new positions of the coordinate systems are to be recalculated and the new mass and stiffness properties of the bodies are to be computed. Detailed statements of the procedures are presented in [29].

3 FORCES LOADING THE NODES OF FLEXIBLE ELEMENTS

The forces loading the nodes are internal elastic forces, external forces and, during the global motion, the inertia forces. Regarding static structures the internal elastic and external forces are in equilibrium. The external forces could be included in the dynamic equations using the principle of the virtual work and here we will not discuss this matter. The main subjects related to the dynamics in FET these are the internal elastic and inertia forces. The stiffness matrices play the major role in computation of the elastic forces, while the mass matrices are used for computation of the inertia force. Since the nodes of the flexible elements are considered coordinate systems implementing free motion in space they are kinematical independent, which means that the coordinates of a node do not depend on the coordinates of the adjacent ones. Unfortunately the static and dynamic equations cannot be solved separately for the nodes since deflections of a node give rise of elastic forces added to the adjacent nodes. The same holds for the velocities and accelerations and the resulting inertia forces.

3.1 Elastic and inertia forces of flexible elements

In the paper special attention is paid to the elastic and inertia forces loading the nodes of flexible elements. As it could be seen above the relative flexible deformations of nodes with respect to the element coordinate system, $\mathbf{\Theta}_{i\rangle i}$ play significant role for FEAC. The relative flexible deformations for the first node, in which the moving coordinate system of the element is located, are equal zero. The matrix-vector $\mathbf{\Theta}_{i\rangle i}$ is compiled without the deformations in the first node and is used for computation of the elastic forces loading both element nodes, i.e.:

$$\mathbf{\Xi}_{i\rangle i} = -\mathbf{K}_{i\rangle i} \cdot \mathbf{\Theta}_{i\rangle i}\,, \tag{5}$$

where for a beam element $\mathbf{K}_{i\rangle i}$ is 12×6 matrix compiled from the last six columns of the conventional FET stiff matrix of element *i* relative to its own beam coordinate system. The first six elements of $\mathbf{\Xi}_{i\rangle i}$ are the forces and torques loading the coordinate system of node *i*,1 and the last six elements are the forces and torques loading node *i*,2.

Taking into account that the nodes are coordinate systems and summarizing the results for FEAC methodologies one concludes that the dynamics analysis of multibody systems of rigid and flexible bodies could be analyzed by a common methodology. As it was discussed above one of the major problems for application of the FET in dynamics of rigid and flexible mutibody systems it is definition of the node accelerations, respectively, the inertia forces. In [18] generalized Newton-Euler dynamic equations for rigid and flexible bodies discretized using the FET are derived. The inertia forces in the nodes of the flexible elements are expressed with respect to the quasi velocities and accelerations and are independent of the kind of coordinates. The notations for the quasi-velocities and accelerations of node *i,k* are $\dot{\mathbf{\Theta}}_{i,k} = \left[\mathbf{v}_{i,k}^{\backslash} \;\; \boldsymbol{\omega}_{i,k}^{\backslash}\right]^{\backslash}$, $\ddot{\mathbf{\Theta}}_{i,k} = \left[\mathbf{a}_{i,k}^{\backslash} \;\; \boldsymbol{\varepsilon}_{i,k}^{\backslash}\right]^{\backslash}$ where $\mathbf{v}_{i,k}^{\backslash}$ and $\mathbf{a}_{i,k}^{\backslash}$, respectively, $\boldsymbol{\omega}_{i,k}^{\backslash}$ and $\boldsymbol{\varepsilon}_{i,k}^{\backslash}$, are the node linear and angular velocities. For a flexible element *i* with two nodes (indices 1 and 2), and 12×12 mass matrix **M** the inertia forces and torques, 12×1 matrix vector $\mathbf{F}_i = \left[\mathbf{P}_{i,1}^{\backslash} \;\; \mathbf{\Phi}_{i,1}^{\backslash} \;\; \mathbf{P}_{i,2}^{\backslash} \;\; \mathbf{\Phi}_{i,2}^{\backslash}\right]^{\backslash}$, is as follows:

$$\mathbf{F}_i = \mathbf{M}_i \cdot \begin{bmatrix} \ddot{\mathbf{\Theta}}_{i,1} \\ \ddot{\mathbf{\Theta}}_{i,2} \end{bmatrix} + \begin{bmatrix} \boldsymbol{\omega}_{i,1}^{\times} & {}^{3,3}\mathbf{0} & {}^{3,3}\mathbf{0} & {}^{3,3}\mathbf{0} \\ \mathbf{v}_{i,1}^{\times} & \boldsymbol{\omega}_{1}^{\times} & {}^{3,3}\mathbf{0} & {}^{3,3}\mathbf{0} \\ {}^{3,3}\mathbf{0} & {}^{3,3}\mathbf{0} & \boldsymbol{\omega}_{i,2}^{\times} & {}^{3,3}\mathbf{0} \\ {}^{3,3}\mathbf{0} & {}^{3,3}\mathbf{0} & \mathbf{v}_{i,2}^{\times} & \boldsymbol{\omega}_{i,2}^{\times} \end{bmatrix} \cdot \mathbf{M}_i \cdot \begin{bmatrix} \dot{\mathbf{\Theta}}_{i,1} \\ \dot{\mathbf{\Theta}}_{i,2} \end{bmatrix} - \mathbf{M}_i \cdot \begin{bmatrix} \boldsymbol{\omega}_{i,1}^{\times} \cdot \mathbf{v}_{i,1} \\ {}^{3,1}\mathbf{0} \\ \boldsymbol{\omega}_{i,2}^{\times} \cdot \mathbf{v}_{i,2} \\ {}^{3,1}\mathbf{0} \end{bmatrix}, \tag{6}$$

where the notation "×" means skew-symmetric matrix. In Equations (8) all vectors and matrices are to be with respect to one and the same coordinate system. For elements with more than two nodes, for examples plates and shells, their elements are to be arranged in a similar order. The forces of elements in the common nodes are to be summarized.

The general Newton – Euler dynamic equations are applicable as for rigid, so for flexible systems and provide the basis for effective general recursive algorithms and program systems for multibody system dynamics analysis. The elements of the homogeneous transformation matrices are explicitly defined with respect to the deflections and computational expenses are low. The numerical procedure uses constant relative mass and stiffness matrices for definition of the elastic and inertia forces. Here we do not discuss the methodology for application of the principle of virtual work for reduction of forces to the system coordinates and deriving the

dynamic equations since that is well known procedure. Possible kinematic constraints are to be expressed in the same way as in the case of rigid bodies.

4 DYNAMICS OF STRUCTURES SUBJECT TO SEISMIC EXCITATIONS

The methodology based on the FEAC has been successfully applied for large structures with many flexible elements and nodes that compose closed chains with many dependent coordinates. The approach is successfully applied for simulation of complex structures subject to external disturbances like seismic excitations.

Two methods are used for simulation of seismic excitation, ground – structure force interaction method and the basement acceleration method. The first one uses data from simulation of ground structure interaction and the output data so obtained, the forces loading the basement, are input data for the dynamics analysis of the structure. This approach is the easiest for dynamics simulation of the structures and is fully compatible with the methods discussed above.

The acceleration based approach uses statistical data for the accelerograms for specific regions and the motion characteristics of the basement are input data for the dynamics simulation process. Actually, the basement acceleration and the integrated velocities and displacements are reonomic constraints for the dynamic equations. Further down an approach for solution of the dynamic equations subject to reonomic constraints and on application of FEAC is presented.

Using the principle of the virtual work the forces are reduced to the system coordinates to derive the dynamic equations

$$\mathbf{M}\cdot\ddot{\mathbf{q}}+\mathbf{B}(\mathbf{q},\dot{\mathbf{q}})=\mathbf{S} \tag{7}$$

where $\mathbf{S}$ is $n\times 1$ matrix-vector of the generalized forces, $\mathbf{B}(\mathbf{q},\dot{\mathbf{q}})$ is velocity depend term.

Earthquake shaking affects forced motion of the structure basement. For a region using statistical data the accelerograms for the space displacements are as follows:

$$\ddot{q}_i=\ddot{q}_i(t), i=1,2,3 \tag{8}$$

These are reonomic constraints that depend on time. For a multibody system with dof n which motion is described by ODE, Equation (7), subject to m reonomic constraints, Equation (8), the dynamic equations are presented as follows:

$$\mathbf{M}\cdot\left[\ddot{q}_1\ \cdots\ \ddot{q}_{k+1}\ \cdots\ \ddot{q}_{k+m}\ \cdots\ \ddot{q}_n\right]^{\backslash}+\mathbf{B}(\mathbf{q},\dot{\mathbf{q}})=\left[S_1\ \cdots\ S_{k+1}\ \cdots\ S_{k+m}\ \cdots\ S_n\right]^{\backslash} \tag{9}$$

In Equation (9) the coordinates $\ddot{q}_i=\ddot{q}_i(t), i=k+1,k+2,..,k+m$ are known, while the generalized forces $S_i=S_i(t), i=k+1,k+2...,k+m$ are unknown. The dynamic equations, Equation (9), are transformed as follows:

$$\underline{\mathbf{M}}\cdot\left[\ddot{q}_1\ \cdots\ S_{k+1}\ \cdots\ S_{k+m}\ \cdots\ \ddot{q}_n\right]^{\backslash}+\mathbf{B}(\mathbf{q},\dot{\mathbf{q}})=-\underline{\underline{\mathbf{M}}}\cdot\left[\ddot{q}_{k+1}\ \cdots\ \ddot{q}_{k+m}\right]^{\backslash}+\underline{\mathbf{S}} \tag{10}$$

where the matrices $\underline{\mathbf{S}}$, $\underline{\underline{\mathbf{M}}}$, $\underline{\mathbf{M}}$ are compiled according to the indices of the coordinates.

The well know beam of Kane et al. [30] is an example of the dynamic analysis subject to a reonomic constraint. It is a horizontal cantilever beam that rotates around a vertical axis. The rotation is prescribed by its angular velocity and this example is a test for many researchers analyzing their methods. Here the same example is used to present FEAC method in case of reonomic constraints differentiating the velocity function to obtain the angular acceleration as inpt data. In Figure 5 the results of the simulation are presented. The angular velocity of the

beam input shaft (coordinate q_1) are presented in the Figure 5 (a). The mass and inertia characteristics of the beam are: (all measures are in SI UNIT): modulus of elasticity $E = 7 \cdot 10^{10}$; shear modulus $G = 2.8 \cdot 10^{10}$; length L=10.; density $\rho = 3000$; cross section area $S = 4 \cdot 10^{-4}$; cross-section moments of inertia $I_x = I_z = \frac{1}{2} I_c = 2.10^{-7}$. The beam discretization is of three elements. In Figure 5 (b) the experimental results are presented while in Figure 4 (c) the results of the simulation using FEAC are depicted.

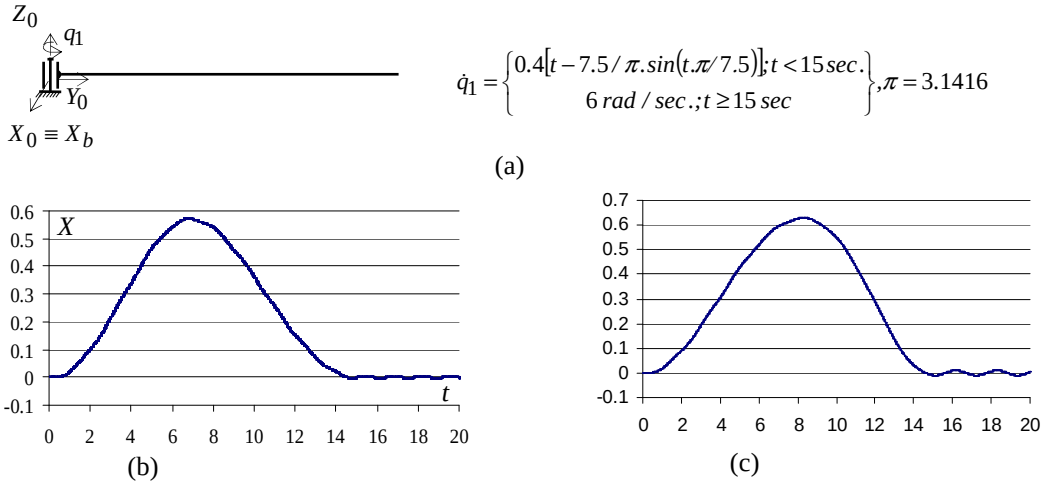


Figure 5: Kane's flexible beam [30]:
(a) the beam and driving motion; (b) experimental results; (c) results of the FEAC.

5 EXAMPLE

In Figure 6 an example of space flexible structure compiled of rigidly connected beams that build many closed contours is presented. The flexible beams are consequently numbered, as well as the nodes are also numbered by numbers in ellipses. The structure is mounted on a basement imposed on external excitation – one dimensional motion q_1 in the horizontal plane and rotational excitation q_2 along the vertical axes. Because of the external excitations the basement implements two dimensional motion which functions of the accelerations are also shown in the figure. In the function of $\ddot{q}_1$ **G** is the earth acceleration. The structure will be simulated using the method of FEAC proposed in the paper.

In Figure 7 the nodes of the beams are shown as a moving coordinate system. The nodes connected to the basement are assumed connected to a rigid body (the basement). The nodes are loaded by internal elastic forces $\mathbf{F}_i, 1,2,...,16$ and torques $\mathbf{L}_i, 1,2,...,16$ caused as a result of the flexible deflections. The nodes are loaded by inertia forces and torques (not shown on the figure) exaggerated because of forced motion of the basement and the resulting space motion of the whole structure. The nodes 1 – 4 are connected to the basement and are considered part of the basement as a rigid body, i.e.: their motion characteristics coincide with that of the basement q_1 and q_2.

The size, the mass and the stiffness properties of the vertical beams are the same as these of the beam of Figure 5. The lengths of the horizontal beams are 0.7 of the lengths of the vertical beams.

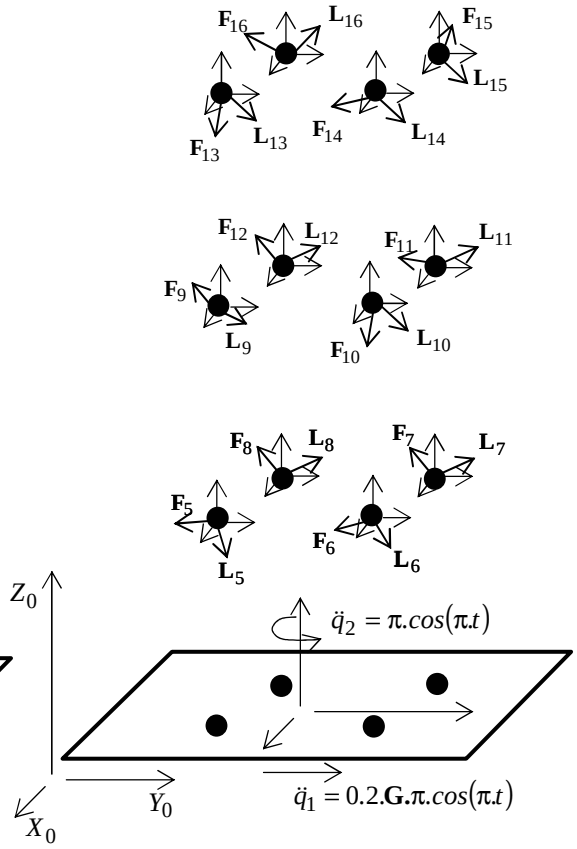

Figure 7: The dynamic model of the structure as free nodes – coordinate system

The dynamic model of Figure 7 is derived using the method proposed in the paper and the incremental approach for numerical integration of the dynamic equations [29, 31]. In Figure 8 the configuration of the structure for three instants of time are depicted.

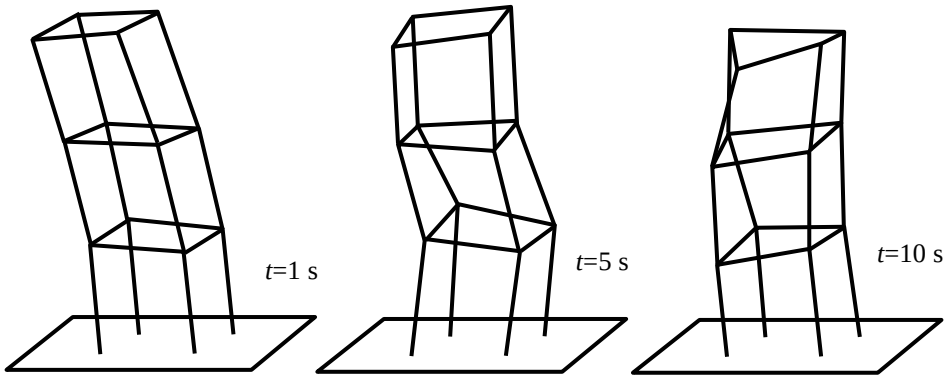

Figure 8: Configuration of the structure for three instants of time

6 CONCLUSIONS

- A method of Finite Elements in Absolute Coordinates is applied for dynamic simulation of large flexible structures subject to external excitations.
- The method is applicable for structures with many flexible elements and degrees of freedom. It is realized using simple and straight forward procedure with no kinematic constraints, as well as, algebraic constraint to the dynamic equations.
- Since the kinematic constraints are substituted by internal elastic forces of the elements large amplitudes of these forces are observed that could decrease the precision of the numerical algorithm and increase the time of simulation. This effect could be observed in the test example of Figure 5.
- The next step in application of the method will consist in development of a numerical procedure for solution of ordinary differential equations that truncate the high amplitudes of the elastic forces.

Abstract.

The paper reports the first results of an experimental campaign aimed at the validation of a procedure, proposed in previous theoretical works by one of the writers, for the structural identification in frequency domain of linear structural systems subjected to base seismic excitation. Differently from the classical identification techniques based on the transfer-function processing, that require to measure the excitation (input-output problem), such procedure allows the solution of the identification problem also in case of unknown input (output-only problem) if the responses of at least three degrees-of-freedom are available for the system.

An experimental campaign has been carried out on a three storeys shear-type frame, carefully designed in order to minimize the uncertainties and errors.

After validating the model setup and the measuring chain by means of a classical input-output procedure, the paper discusses the first results of the output-only identification. The outcomes show a fair agreement with the results obtained by including the input knowledge.

1 INTRODUCTION

Modal identification of frame structures is a widely acknowledged and effective technique for the Structural Health Monitoring (SHM) and the calibration of retrofitting interventions on existing structures. However, in many cases the practical applications of classical input-output procedures are limited by the need of a complete knowledge of both the excitation and the structural response. This happens especially in the case of existing structures subjected to seismic motion; in fact, in this instance, the records of the input can be often unavailable or not sufficiently accurate.

A possible solution to these limitations has been already given, among the others, in a previous paper of one of the writers [1], where an extension of the classical structural identification procedure in frequency domain (e.g. Goyder [2]) has been provided in the case of spatial frames subjected to unknown (time contents and direction) seismic input. The identification procedure is based on the analysis of only the structural response at the floor levels. More specifically, the uniqueness of the solution is demonstrated in the case in which the structural response is known for at least three different floors of the framed structure.

The present study is part of a research, still in progress, aimed at providing a comprehensive experimental validation of the above procedure, following a previous pilot work [3] where the original procedure was improved through a more refined minimization algorithm in the complex field.

An experimental campaign was carried out on a three storeys shear-type frame model subjected to unmeasured base displacements, simulating the effect of seismic excitation. The accuracy of the algorithms for numerical data treatment was preliminarily checked and optimized in the classical case of measured non-stationary base motion.

2 DYNAMIC IDENTIFICATION IN FREQUENCY DOMAIN

Classically, dynamic identification is aimed at deriving the modal properties of structural systems, namely natural frequencies, modal damping and modal shapes, by means of the processing of time-histories describing both the excitation and the structural response.

For what regards the nature of the excitation, a distinction has to be made between stationary random processes, including ambient excitations such as wind, traffic and so on, and non-stationary processes, as in the case of earthquakes.

However, in many civil applications it can be not possible or really arduous the recording of the loading forces; the structural identification should be consequently carried out by processing only the structural response of the system.

Two cases can therefore be distinguished:

- *Input-output problem*, where measures of the structural response at different degrees-of-freedom (dofs) of the system (e.g. time-history of displacements, velocities or accelerations of the floors) and of the loading actions (e.g. time-history of the base acceleration) are simultaneously available;
- *Output-only problem*, where only measures of the structural response at different dofs of the system are available, without any data about the loading actions [4].

In this paper the attention is focused on the dynamic identification of linear structural systems submitted to non-stationary input, by means of a numerical formulation developed in the frequency domain by one of the writers [1] in case of unknown input. It is based on the independence by the input measure of the ratio between the Fourier transforms (FT) of the responses measured at different dofs of the structure. The procedure has been numerically validated in [1] and checked by the writers in a preliminary experimental campaign [3].

A short descriptions is provided in the following for both the input-output and the output-only problems, to give a general overview of the theoretical basis of the procedure.

2.1 Input-output problem

In the case of structures subjected to a base motion, the structural identification can be carried out in the frequency domain by using the inertance transfer function $H_i(\omega)$ [5], expressed as follows with reference to a N-dofs system

$$H_i(\omega) = \frac{Y_i(\omega)}{A(\omega)} \qquad i = 1, 2, ..., N \tag{1}$$

where $Y_i(\omega)$ is the Fourier Transform (FT) of the relative acceleration measured at i-th dof, while $A(\omega)$ is the FT of the imposed base acceleration.

The inertance $H_i(\omega)$ depends on the unknown modal parameters (natural frequencies, modal shapes and damping) of the system under consideration [5][6]:

$$H_i(\omega) = \sum_{k=1}^{N} \frac{\omega^2 \vartheta_{ik}}{\omega^2 - \left(\omega_k{}^2 + 2j\omega\omega_k\xi_k\right)} \tag{2}$$

where i denotes the degree of freedom, k is referred to the mode, j is the imaginary unit, ω_k and ξ_k are the frequency and the damping coefficients corresponding to the k-th mode of the structure, respectively, while ϑ_{ik} is the modal shape component for the k-th mode at the i-th degree of freedom of the structure.

The identification problem can be solved by searching those modal parameters that allow to minimize the error (in the least square sense) between the theoretical expression of the transfer functions and its measured counterpart.

2.2 Output only problem

In many civil applications it can be necessary or simply useful to solve the identification problem by only referring to the measured response. Accessibility limitations or other technical and economic obstacles can make not possible the complete definition of the spatial and time distribution of the external actions on the structure; also when the spatial distribution is known (e.g. seismic input simulated by a unidirectional base motion, as considered here), the time-history of the external action can be difficult to measure. In this case, however, the identification problem can be solved [1] by evaluating the ratio between the FT of the output measured at two degrees of freedom i and j of the structure, that does not depend on the input:

$$R_{ij}(\omega) = \frac{Y_i(\omega)}{Y_j(\omega)} = \frac{H_i(\omega)A(\omega)}{H_j(\omega)A(\omega)} = \frac{H_i(\omega)}{H_j(\omega)} \tag{3}$$

As well as the transfer function introduced by the equations (1) and (2), the ratio $R_{ij}(\omega)$ in equation (3) depends only on the unknown modal parameters of the system, but does not require any information about the input excitation. The identification problem can be therefore solved, by minimizing the error between the theoretical expression of $R_{ij}(\omega)$ and its measured counterpart, that only depends on the measured response. As already demonstrated in [1], the problem thus defined admits only one solution if the measures of the structural response in at least three different dofs are available.

2.3 Numerical procedure for the dynamic identification

In both cases of *input-output* and *output-only* problems, the unknown modal parameters are found by minimizing the least-square error $E(x)$ between the theoretical expressions governing each type of identification problem, i.e. the equation (2) for $H_i(\omega)$ in the *input-output* problem and the equation (3) for $R_{ij}(\omega)$ in the *output-only* problem, and their measured counterparts.

The solution of the identification problem will correspond to the minimum of the error function, i.e. to the set of modal parameters minimizing such function, defined by means of a non-linear curve fitting algorithm expressed as follows:

$$\min_x E(x) = \min_x \sum_i \left(F\left(x, xdata_i\right) - ydata_i\right)^2 \tag{4}$$

where x represents the vector collecting all the unknown modal parameters of the structure, $F(x, xdata)$ is the vector collecting the values obtained by the curve fitting procedure, while *ydata* represents the vector of the data ($H_i(\omega)$ or $R_{ij}(\omega)$) corresponding to a suitable range of the angular frequencies ω, collected in *xdata*.

With the aim to guarantee the convergence of the error minimization procedure, the real and the imaginary parts of both the analytical functions and the components of the solution vector have been treated separately. Once defined the problem by changing the variables from complex to real, lower and upper bounds can be fixed to the unknown parameters, based on reliable information about their range of variation. The introduction of physical bounds to the range of variation of the unknown parameters can help to find the solution of the identification problem and is of course possible only in case of real variables. On the other hand, the modification of the unknown parameters from complex to real values is not in contrast with their actual nature; the modal parameters are in fact real values from a physical point of view, but become complex for their inclusion in complex-valued functions. Details of the procedure can be found in [3].

3 EXPERIMENTAL TESTS

3.1 Model details

In order to validate the proposed procedure, dynamic tests have been carried out on an experimental prototype, properly designed to ensure a typical behavior of shear-type frame. A particular attention has been given to all the details necessary to guarantee the shear-type behavior. The rotation of beam-column joints has therefore been prevented and a rigid floor displacement has been obtained by means of a large out-of-plane stiffness of the floor diaphragms. The tested model is a spatial frame with three floors and one span; the columns have been made with a much higher stiffness in one direction than the other, so as to get a plane frame behavior.

Several preliminary solutions have been studied with respect to the selection of the materials, the beam-column connections, the possibility to modify the mass and stiffness of the model, the excitation system to simulate both an applied force and the effect of a seismic input.

Some sketches of the final solution are reported in Figure 1, while in Table 1 the geometrical properties are resumed.

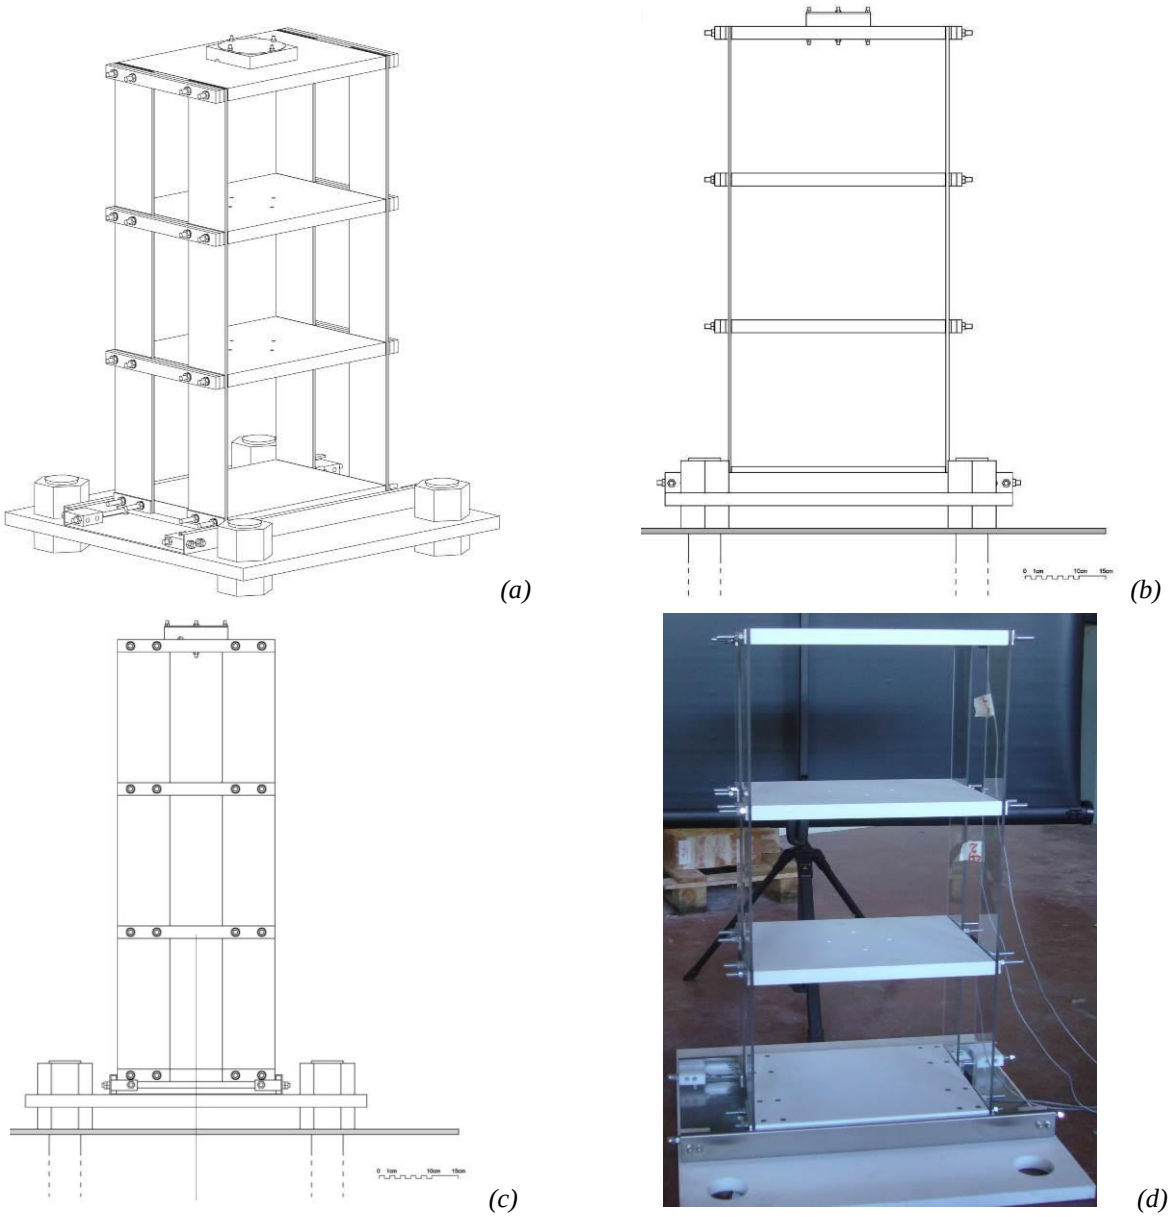

Figure 1: Details of the tested model: (a) axonometric, (b) front, (c) lateral view, (d) picture.

Element	Material	Width mm	Length mm	Thickness mm
Column	Polycarbonate	100	846	3 - 6
Floor	Corian®	300	400	24

Table 1: Geometrical characteristic of the tested 3 dofs shear-type model.

Polycarbonate and Corian® have been used for the model, both of them with high heat resistance, excellent workability and lightness.

The model is composed by four columns made of polycarbonate with cross-section 100 x 846 mm and a thickness variable from 3 to 6 mm. The inter-storey height is 250 mm.

To guarantee the out-of-plane floor stiffness, three rectangular decks made in Corian® have been used, having dimensions 300x400x24 mm. Each floor is anchored to the polycar-

bonate columns through a bolted system that allows to modify the mass and stiffness of the model.

A further panel of identical dimensions as decks has been used for the basement, that is anchored to a larger panel, also made in Corian®, with dimensions 650x650x24 mm, that can be fixed to the floor.

The base panel is equipped with two steel C-shaped profiles, which allow the sliding of the frame model through four nylon wheels with ball bearings. In this configuration the model can be excited by a time-varying base displacement, at the moment applied by hand, to simulate seismic actions. The sliding system can also be locked, obtaining in this way a fixed-base model to be used for free vibration tests or forcing time-histories at floor levels.

The mechanical properties of the materials used for the model are listed in Table 2.

Corian®			
Properties	Norm/Standard	Plate t= 6 mm	Unit
Density	DIN ISO 1183	1.73 - 1.76	[g/cm^3]
Flexural Modulus	DIN EN ISO 178	8920 - 9770	[MPa]

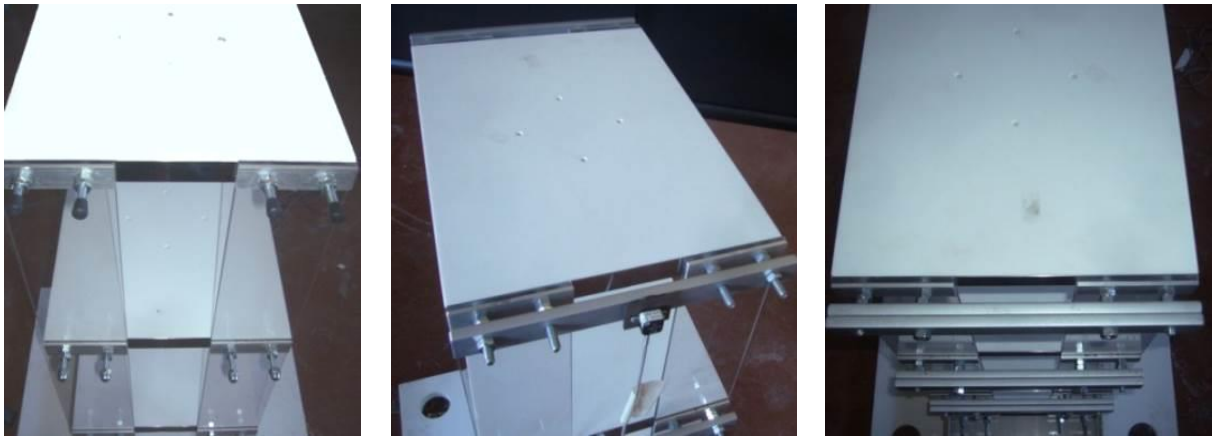
3.2 Test Setup

In order to work with different values of mass and stiffness of the model, modifications to the initial configuration have been considered.

In the first case, the floor mass has been increased by adding steel plates at each deck level, paying specific attention to keep unchanged the centroid position. The Figure 2 shows the three mass configurations available:

- configuration m_0: mass of each floor = 5.78 kg;
- configuration m_1: two steel plates added at each floor, with mass 2x0.57 kg = 1.14 kg;
- configuration m_2: four steel plates added at each floor, with mass 4x0.57 kg = 2.28 kg.



(a) configuration m_0 *(b) configuration m_1* *(c) configuration m_2*

Figure 2: Experimental model: (a) m_0=5.78 kg for each floor; (b) m_1=6.92 kg for each floor; (c) m_2=8.06 kg for each floor; mass of columns depending on their thickness.
Total mass of floors and columns is reported in Table 3 for each mass-thickness combination.

Also the stiffness of the columns has been changed. Four different values, i.e. 3, 4, 5 and 6 mm have been considered for the thickness of columns.

The natural frequencies for the different mass and stiffness combinations are shown in Table 3.

	m_0 *initial configuration*	**m_1** *3.42 kg added mass*	**m_2** *6.84 kg added mass*
	M_f^* = 17.34 kg	M_f^*= 20.76 kg	M_f^* = 24.18 kg
t_3 *t= 3 mm* M_c^{**} *= 1.22 kg*	f_1= 1.10 Hz f_2= 3.09 Hz f_3= 4.44 Hz	f_1= 1.01 Hz f_2= 2.82 Hz f_3= 4.07 Hz	f_1= 0.94 Hz f_2= 2.62 Hz f_3= 3.78 Hz
t_4 *t= 4 mm* M_c^{**}*= 1.63 kg*	f_1= 1.69 Hz f_2= 4.71 Hz f_3= 6.77 Hz	f_1= 1.54 Hz f_2= 4.32Hz f_3= 6.21 Hz	f_1= 1.43 Hz f_2= 4.01Hz f_3= 5.77 Hz
t_5 *t= 5 mm* M_c^{**}*= 2.03 kg*	f_1= 2.34 Hz f_2= 6.52 Hz f_3= 9.37 Hz	f_1= 2.14 Hz f_2= 5.99 Hz f_3= 8.61 Hz	f_1= 1.99 Hz f_2= 5.57 Hz f_3= 8.01 Hz
t_6 *t= 6 mm* M_c^{**}*= 2.44 kg*	f_1= 3.05 Hz f_2= 8.50 Hz f_3= 12.20 Hz	f_1= 2.80 Hz f_2= 7.82 Hz f_3= 11.22 Hz	f_1= 2.60 Hz f_2= 7.27 Hz f_3= 10.45 Hz

M_f^*= Total mass of the floors - M_c^{**} = Total mass of the columns

Table 3: Frequencies of the 3dofs model for the different configurations, as obtained by FE models.

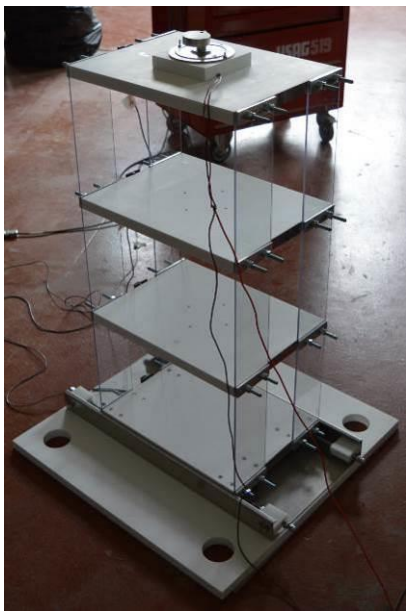
3.3 Testing program

The experimental campaign has been carried out by submitting the model to three types of dynamic tests:

- free oscillations (FO);

- forced vibrations (FV) induced by a rotating eccentric mass driven by an electric equipment, allowing sinusoidal force (vibrodyne);
- base motion (BM) simulating the effect of seismic excitation.

Figure 3 shows the different experimental configurations available for the tested frame, i.e. fixed during a forced vibration (left) and allowed to slide (right) for time-varying base displacement.



(a)

(b)

Figure 3: Experimental configuration of the tested frame: (a) fixed base; (b) sliding base

Each test has been performed and repeated several times, as reported in Table 4.

Test	Intensity or Type	Repetitions	Total No. Tests
free vibration	-	m_0, m_1, m_2	3
forced vibration	$1^{st} – 2^{nd} – 3^{rd}$ *	m_0, m_1, m_2	9
base motion	L – H – V **	m_0, m_1, m_2	9

** 1^{st} = at first floor, 2^{nd} = at second floor, 3^{rd} = at third floor*
*** L= low intensity, H = high intensity, V= variable intensity during the time-interval*

Table 4: Dynamic tests for thickness of columns t = 5 mm

3.4 Response measurement

The dynamic response has been recorded using four unidirectional piezoelectric accelerometers with a full scale, resolution and linearity range, equal to ± 2 g, 10 μg and 0.3-4000 Hz, respectively. The accelerometers have been installed at each floor to record the acceleration response in the horizontal direction. A fourth accelerometer has been fixed at the basement to record the imposed input in the BM cases. The tests were performed using a sampling rate of 250 Hz. The acquisition was provided by a multichannel analyzer equipped with 24-bit A/D card. The equipment used is shown in Figure 4.

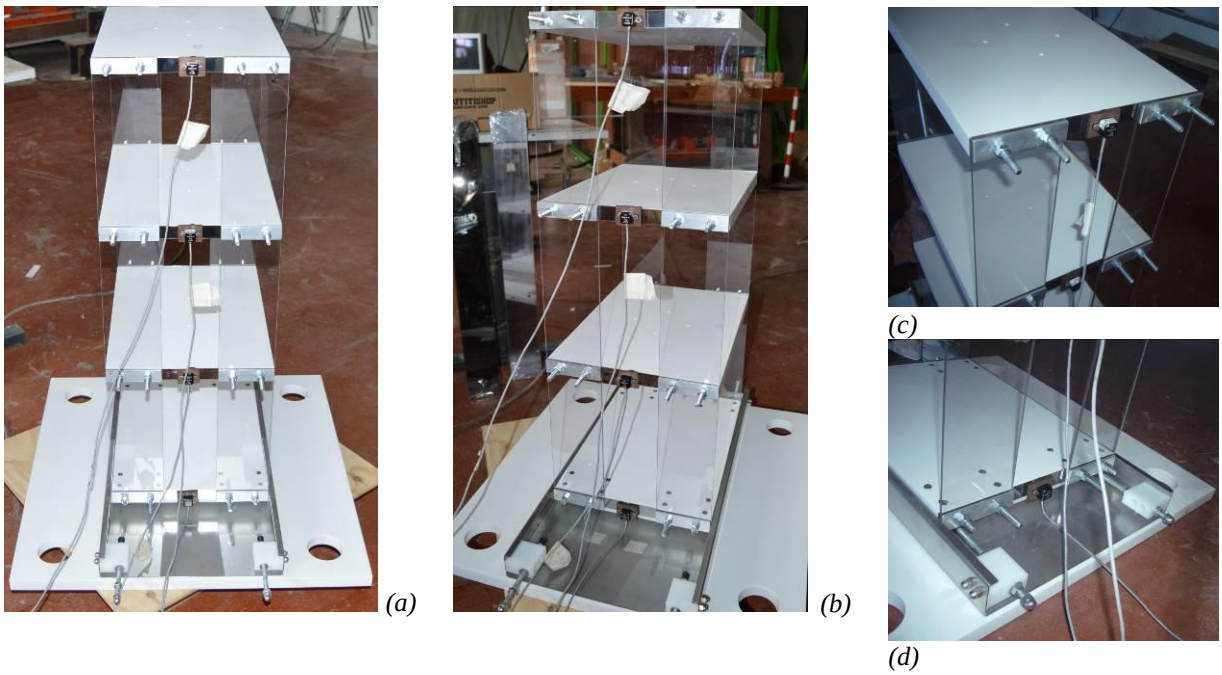


Figure 4: Experimental equipment: (a) – (b) measurement stations, (c) detail of the accelerometer at third floor, (d) detail of the accelerometer at the basement (sliding panel).

4 RESULTS AND DISCUSSION

In order to verify the effectiveness of the identification procedure described in Section 2, an experimental validation has been carried out by using the data obtained from the dynamic tests performed with the shear-type model of Section 3.

As already explained, the model can be excited by impressing, at the moment by hand, time-varying base displacements to the sliding-base configuration, to simulate the effects of seismic actions.

The data for the identification procedure are given by records of the absolute acceleration, reported in Figure 5 for a sample case (m_0t_5, in Table 3). .

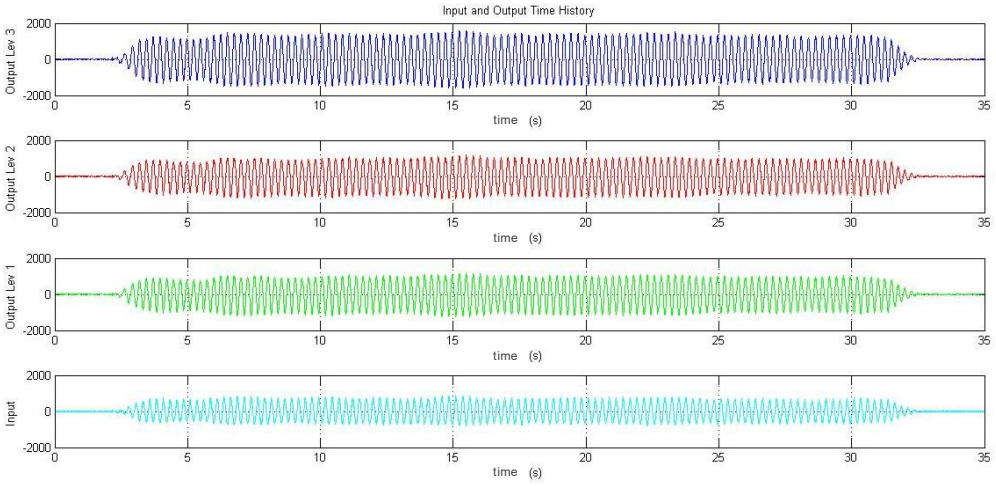

Figure 5: Input and output records of the 3 dofs frame model m_0t_5 of Table 3.

Table 5 lists the identified modal parameters obtained by means of the classical *input-output* Goyder procedure [2].

Mode	frequency Hz	damping ratio [%]	modal displacements		
			1st floor	2nd floor	3rd floor
1	2.63	1.61	-0.605	-0.880	-1.377
2	6.79	1.63	-0.285	-0.177	0.283
3	9.63	2.40	-0.088	0.139	-0.048

Table 5: Modal parameters identified by the Goyder procedure for the case m_0t_5 of Table 3.

Based on the same experimental data of case m_0t_5, Table 6 reports the modal parameters identified by means of the *output-only* procedure described in Section 2; as a starting point of the error minimization, natural frequencies, damping ratios and modal constants fairly distant from those identified with the *input-output* technique have been assumed (30 % difference), in order to test the robustness of the procedure; the *output-only* solution has been found with the minimization algorithm described in Section 2.3, within the boundaries ± 30 % with respect to the reference solution, i.e. the solution identified with the Goyder procedure.

As shown by comparison between modal parameters in Table 5 and Table 6, the *output-only* procedure, introduced in [1] and modified in [3] with an improved minimization algorithm, provides, for the sample case described here, a good agreement with the classical *input-output* procedure, as also shown by the comparison of modal shapes in Figure 6.

Mode	frequency [Hz]	damping ratio [%]	modal displacements		
			1st floor	2nd floor	3rd floor
1	2.64	1.57	-0.664	-0.956	-1.590
2	6.79	1.52	-0.306	-0.194	0.330
3	9.64	2.36	-0.078	0.157	-0.054

Table 6: Modal parameters identified by the output-only procedure for the case m_0t_5 of Table 3.

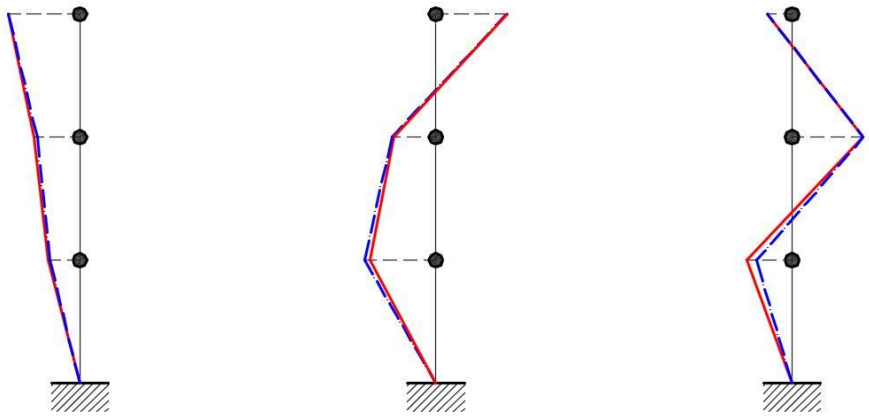

Figure 6: Comparison between modal shapes identified via the Goyder procedure (red line, values of Table 5) and via the output-only procedure (blue line, values of Table 6).

5 CONCLUSIONS

This paper describes the first results of an experimental campaign on a 3-dofs shear-type frame model, carried out to validate the *output-only* procedure proposed by one of the writers [1] to identify the modal parameters of a structure subjected to unmeasured base motion.

The modal parameters are identified by means of a minimisation algorithm, improved from the computational point of view as described in [3]. The error function to be minimised compares, in the least square sense, the analytical relationships of the dynamic response and their experimental counterparts.

As shown by the results reported, the *output-only* procedure provides a good agreement with a classical *input-output* procedure.

A larger experimental campaign is currently in progress for the validation of the procedure. A particular attention will be given to all the uncertainties emerged in the present work, as for example the dependence of the identified modal parameters on their initial estimate and the boundaries, and on the intensity and the time-length of the imposed base motion.

Keywords: Concave Surface Slider, bi-axial interaction, frictional force, equivalent uniaxial accelerogram, bi-directional motion, base-isolation.

Abstract. *Concave Surface Slider (CSS) devices represent an effective solution for base-isolation design problems. In such isolators the energy dissipation capability is induced by the sliding motions which occur at one or more sliding interfaces. The spherical shape of the sliding surfaces provides a significant recentering behavior, by means of the stepwise projection of the applied vertical load with respect to both horizontal directions. One of the most important assumptions states that the lateral response of a CSS device can be considered as the direct summation of the recentering force and the frictional force. For two-components earthquake excitations, the recentering force is computed as a linear spring with respect to displacements along the main directions of motion; whereas, the frictional response is returned by the stepwise projection of the total frictional force, which is aligned with respect to the trajectory of the device: thus, a bi-axial interaction of the directions of motion has to be accounted for, when a friction-based device is modelled. However, available commercial software which can capture such a behavior are limited. In this work an analytical procedure is defined, for the computation of an "equivalent uniaxial accelerogram" for the seismic assessment of a base-isolated structure, subjected to a bi-directional earthquake. Thanks to the proposed theory, it is possible to compute a single ground acceleration time-history, related to a proper direction angle, which can reproduce the same effects of a two-components seismic event on a base-isolated structural system: the analogy between the equivalent uniaxial and the bi-directional events has been studied in terms of acceleration, velocity and displacement spectra respectively. Results for the base-isolated structure have been analyzed in terms of displacement, absolute acceleration and interstorey shear responses.*

1 INTRODUCTION

Concave Surface Slider (CSS) devices are widely used in real applications for seismic vulnerability mitigation all over the world. Thanks to the easy geometric and mechanical definition of such isolators, it is possible to achieve high values of dissipated energy and, consequently, lower internal forces are induced into the superstructure during the seismic event [10]. Nonetheless, a lot of research, both numerical and experimental, has been developed in last years, aiming at getting a better understanding of the lateral response characteristics of friction-based devices [3, 6]. One of the key points of the behavior of CSS isolators is represented by the frictional response under bi-directional seismic events [4, 6, 8]. Generally, the force response of a CSS device can be considered as the direct summation of a recentering force and a frictional force. The recentering contribution can be modelled as a linear spring with respect to displacements along both x and y directions, whereas the frictional force is a complicated function of vertical load, sliding velocity and cyclic effects, and it is parallel to the trajectory of the device [1]. Thus, the main frictional force has to be stepwise projected along the main directions of the reference system, and a bi-axial interaction has to be considered. This aspect has been noticed in experimental results as well as in analytical simulations [3, 5]. In Figure 1 the analytical hysteretic responses along x and y directions of a single device subjected to a cloverleaf displacement trajectory are shown (friction coefficient: 7% ; Equivalent radius of curvature: 3.1m).

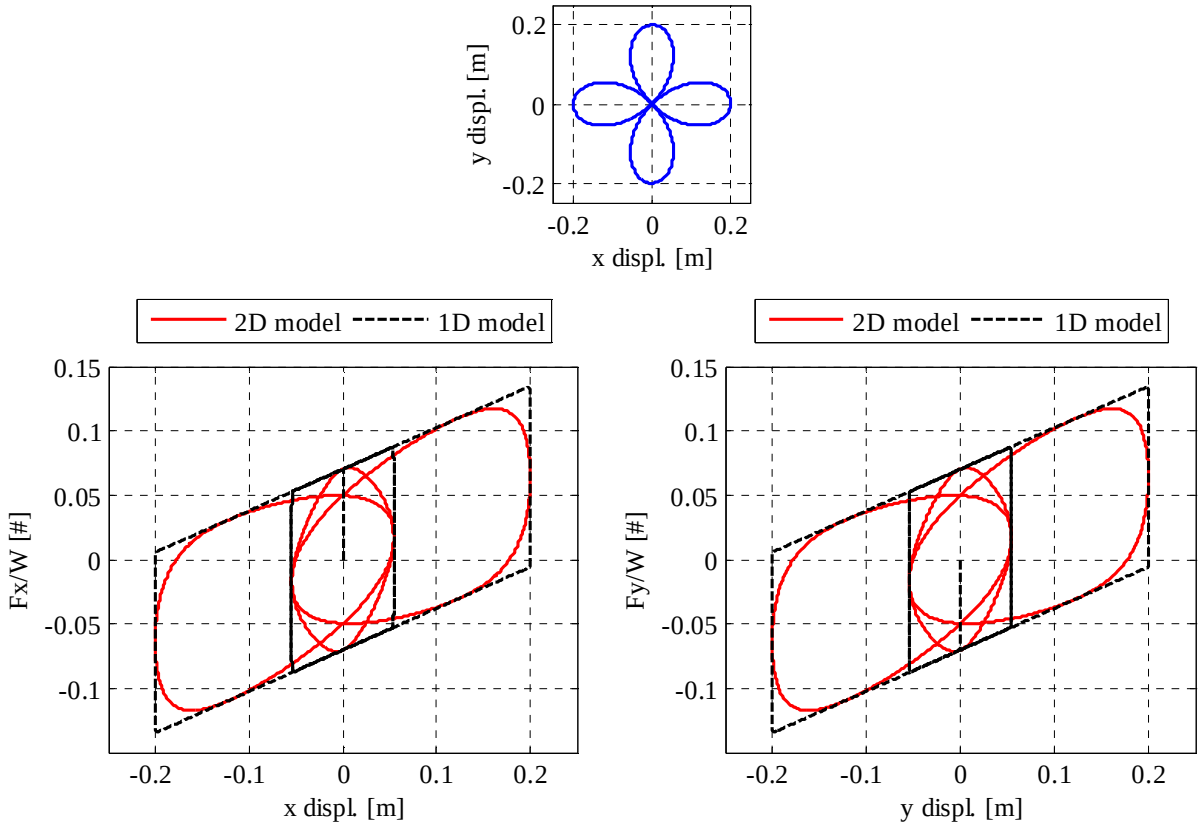

Figure 1: Analytical simulation the CSS hysteretic response under a cloverleaf trajectory.

It can be noted that by accounting for bi-axial interaction of the directions of motion, the maximum force value decreases along both x and y directions, due to the changing in orientation of the main frictional force during motion, in comparison to the unidirectional model, which considers the frictional force parallel to the recentering one at each time step. Hence,

the seismic response of a base-isolated structure can be strongly affected by the bi-axial interaction of the directions of motion. However, most of the design and verification procedures are based on simplified unidirectional approaches [9]; moreover, testing protocols for such a kind of devices mainly consist of unidirectional tests, according to UNI:EN15129 standard code [7], and bidirectional tests can be substituted by a unidirectional motion along an orthogonal direction. Furthermore, only recent versions of commercial softwares can model such behavior, and significantly high run times may be experienced.

In this work an analytical procedure is presented, which can return an equivalent uniaxial accelerogram representative of a bi-directional seismic event. Thanks to the present theory, it is possible to apply a uni-directional radial motion to the structure, for the evaluation of structural internal forces and displacements under a general bi-directional earthquake. Results of a base-isolated building structure have shown a good agreement of the response under the equivalent uniaxial event in comparison to the bi-axial one, in terms of displacement, absolute acceleration and interstorey shear values.

2 EQUIVALENT UNIAXIAL EVENT

In this section the presented procedure for the computation of the equivalent uniaxial event of a bidirectional earthquake is reported.

Generally, a bidirectional seismic event is represented by two individual ground acceleration time-series along x and y directions respectively, where x and y are plan orthogonal directions of the reference system of the analyzed structure. Since there are a lot of aspects which influence the propagation of seismic waves during an earthquake (such as rupture mechanism, soil mechanical characteristics, topographic and stratigraphic distributions, etc…), the resulting diagram which represents both the ground acceleration time series together, that is $\ddot{y}_g$ vs. $\ddot{x}_g$, consists of a scatter plot of acceleration points, and no preferential direction of motion can be immediately detected. In Figure 2 the ground acceleration diagram related to the Irpinia earthquake 1980 is reported.

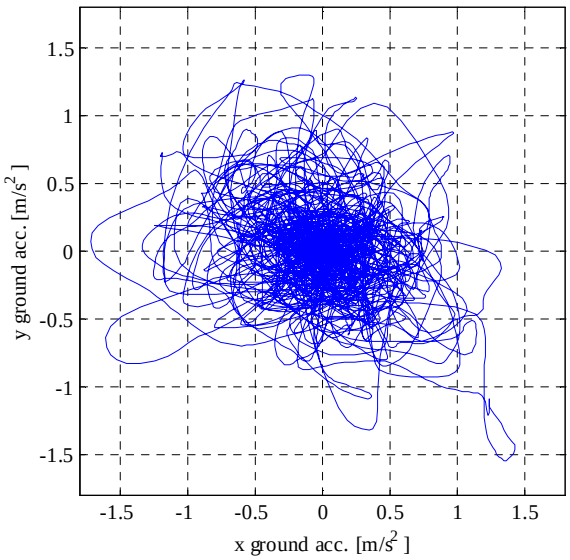

Figure 2: Irpinia earthquake 1980 – Ground acceleration diagram.

Thus, the response spectrum of the seismic event has to be considered. A response spectrum of the bi-directional event has been defined, by means of the direct integration of the

equations of motion along both x and y directions of a linear single oscillator with different values of structural periods T and for a given damping ratio ξ:

$$\begin{aligned} \ddot{x} + 2\xi\omega\dot{x} + \omega^2 x &= -\ddot{x}_g \\ \ddot{y} + 2\xi\omega\dot{y} + \omega^2 y &= -\ddot{y}_g \end{aligned} \tag{1}$$

Hence, the maximum vectorial displacement and absolute acceleration are detected.

$$\begin{aligned} S_d^{2D}(\xi, T) &= \max\left(\sqrt{x^2 + y^2}\right) \\ S_a^{2D}(\xi, T) &= \max\left(\sqrt{\left(\ddot{x} + \ddot{x}_g\right)^2 + \left(\ddot{y} + \ddot{y}_g\right)^2}\right) \end{aligned} \tag{2}$$

By considering several period values, the reference response spectrum related to the bidirectional earthquake is finally obtained. Therefore, for a given direction angle, the projection of each acceleration point shown in Figure 2 is obtained, in order to compute a single ground acceleration component along the considered direction. In Figure 3 the projection procedure is reported.

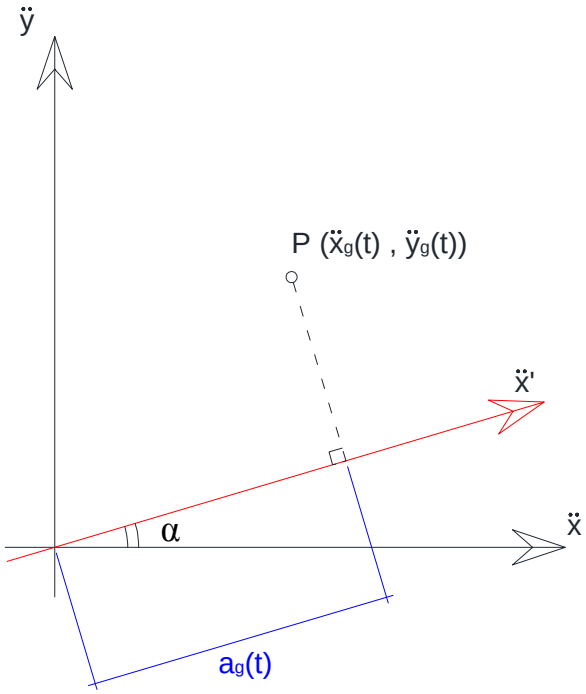

Figure 3: Equivalent uniaxial event – Projection procedure.

According to the aforementioned scheme, the uniaxial projection of the bidirectional earthquake $a_g(t)$ is defined for the given orientation α as follows:

$$a_g(t) = \ddot{x}_g(t)\cos(\alpha) + \ddot{y}_g(t)\sin(\alpha) \tag{3}$$

Consequently, the ordinary 1D acceleration and displacement response spectra associated to $a_g(t)$ can be obtained, by assuming the same damping ratio of the reference 2D response spectrum. Then, a parameter which describes the discrepancies between the reference 2D and the 1D response spectra is defined, by computing the square root of the Mean Squared Error:

such a parameter can be computed by considering either the acceleration or the displacement response spectrum; both the approaches have been evaluated for sake of comparison.

$$E^{S_d}(\xi,\alpha) = \sqrt{MSE^{S_d}} = \sqrt{\frac{1}{n_T}\sum_{i=1}^{n_T}\left(S_d^{2D}(\xi,T_i) - S_d^{1D}(\xi,\alpha,T_i)\right)^2}$$
$$E^{S_a}(\xi,\alpha) = \sqrt{MSE^{S_a}} = \sqrt{\frac{1}{n_T}\sum_{i=1}^{n_T}\left(S_a^{2D}(\xi,T_i) - S_a^{1D}(\xi,\alpha,T_i)\right)^2} \quad (4)$$

Where n_T is the total number of structural periods, considered for the computation of the response spectra. Finally, by considering the direction angle α within a range between 0° and 180°, the optimum direction angle which returns the minimum error parameter can be obtained. In Figure 4 and Figure 5 the aforementioned procedure has been applied to the Irpinia earthquake 1980, by considering a damping ratio equal to 5% and acceleration and displacement spectra respectively.

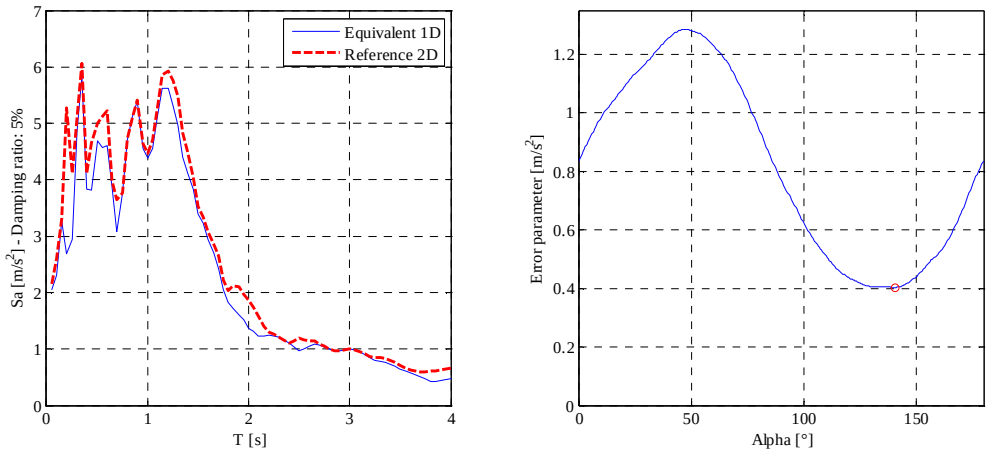

Figure 4: Equivalent uniaxial event – Irpinia earthquake – acceleration-based procedure.

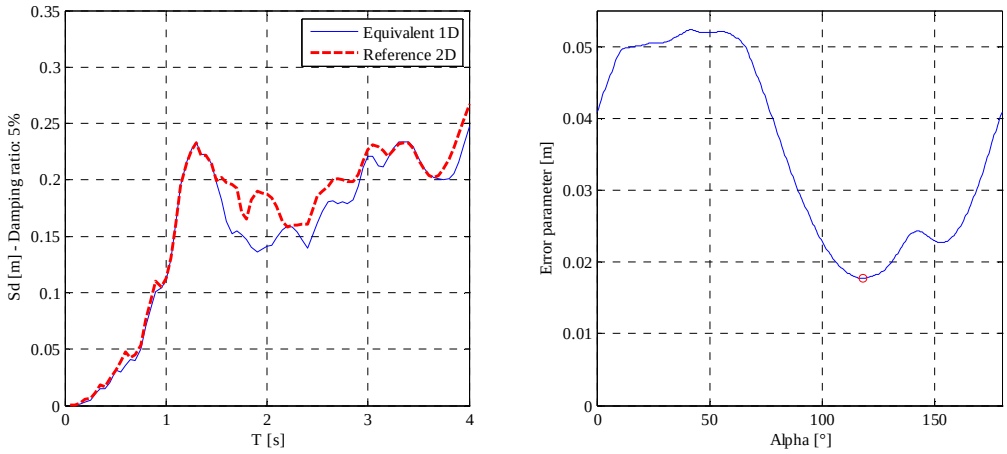

Figure 5: Equivalent uniaxial event – Irpinia earthquake – displacement-based procedure.

In what follows results for three different bidirectional earthquakes are reported, by varying the damping ratio; the analyzed seismic events are listed in Table 1.

Event #	Location	Year	Mw	PGA_x [m/s^2]	PGA_y [m/s^2]
1	Irpinia	1980	6.9	1.718	1.550
2	Emilia	2012	6.1	2.574	2.591
3	L'Aquila	2009	6.3	6.442	5.352

Table 1: Equivalent uniaxial event – seismic events characteristics.

Results are shown in terms of both optimum direction angle and error parameter values as a function of the damping ratio. In Figure 6 and Figure 7 results are shown, by considering acceleration and displacement error respectively.

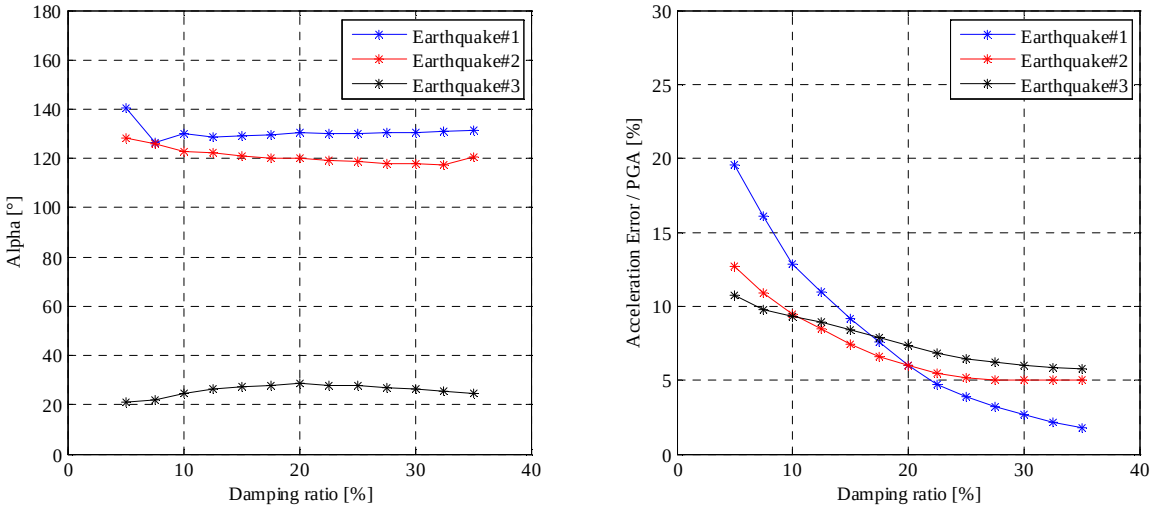

Figure 6: Equivalent uniaxial event – damping analysis – acceleration-based procedure.

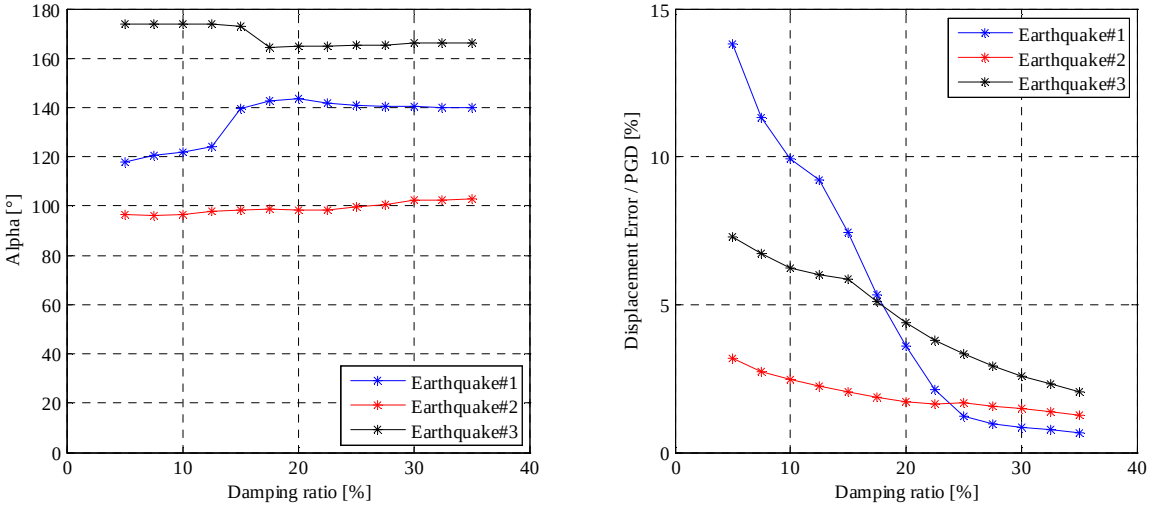

Figure 7: Equivalent uniaxial event – damping analysis – displacement-based procedure.

It can be noted that the acceleration spectrum approach leads to more stable results, in terms of optimum direction angle value, which can be considered approximately constant with respect to increasing values of damping ratio; in addition, as the damping ratio increases, the acceleration error parameter significantly decreases, and a similar decay trend of the acceleration error has been found among the considered earthquakes. On the other hand, the dis-

placement-based procedure returns more irregular results: the optimum variation angle value can be affected by the damping ratio and, decreasing trend of the displacement error parameter is found at high values of damping ratio as well as for the acceleration procedure.

3 ANALYTICAL MODEL DEFINITION

In this endeavor the structural model presented in Furinghetti and Pavese 2015 has been used [4], which consists of a Multi Degrees Of Freedom (MDOF) scheme, base-isolated by means of an equivalent CSS device, which is representative of the entire isolation system (Figure 8).

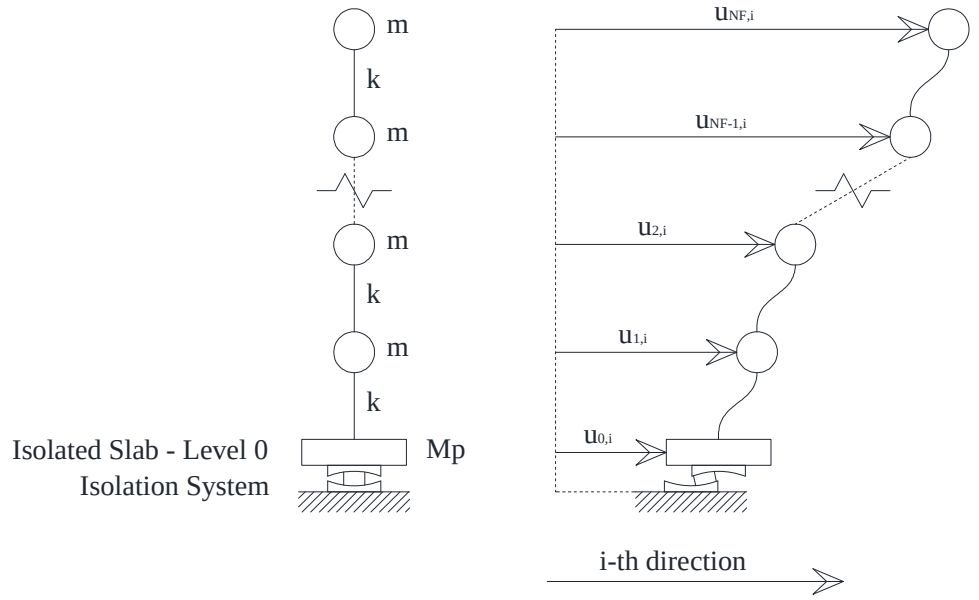

Figure 8: Dynamic model of the isolated structure.

This assumption can be adopted when a building with a large plan development is considered. Thus, all the isolators have averagely the same vertical load, directly equal to the total weight of the isolated structure divided by the number of devices. Hence, the horizontal force along both x and y directions of the isolation system can be computed as follows:

$$\frac{F_{is}}{m} = g \cdot N_F \cdot \left(1+\frac{1}{r}\right) \cdot \left\{ \frac{1}{R_{eq}} \begin{bmatrix} u_{0,x} \\ u_{0,y} \end{bmatrix} + \mu(W,v,E) \cdot \tanh\left(\frac{v}{v_s}\right) \cdot \begin{bmatrix} \dfrac{\dot{u}_{0,x}}{\sqrt{(\dot{u}_{0,x})^2+(\dot{u}_{0,y})^2}} \\ \dfrac{\dot{u}_{0,y}}{\sqrt{(\dot{u}_{0,x})^2+(\dot{u}_{0,y})^2}} \end{bmatrix} \right\}$$

being (5)

$$\frac{W_{tot}}{m} = \frac{g}{m} \cdot \left(M_B + M_P\right) = \frac{g}{m} \cdot M_B \cdot \left(1+\frac{M_P}{M_B}\right) = \frac{g}{m} \cdot M_B \cdot \left(1+\frac{1}{r}\right) = g \cdot N_F \cdot \left(1+\frac{1}{r}\right)$$

Where M_B is the total mass of the building, and M_P is the mass of the isolated plate. Finally, the normalized dynamic system of the isolated structure is consequently defined for direction

i = x, y. The contribution of the isolation system has to be added in the first equation only for both directions, which represents the translational dynamic equilibrium of the isolated slab.

$$\left[\frac{M_{tot}}{m}\right]\begin{pmatrix}\ddot{u}_{0,i}\\ \hline \ddot{u}_{1,i}\\ \ddot{u}_{2,i}\\ \vdots\\ \ddot{u}_{N_F,i}\end{pmatrix}+\left[\frac{C_{tot}}{m}\right]\begin{pmatrix}0\\ \hline \dot{u}_{1,i}-\dot{u}_{0,i}\\ \dot{u}_{2,i}-\dot{u}_{0,i}\\ \vdots\\ \dot{u}_{N_F,i}-\dot{u}_{0,i}\end{pmatrix}+\left[\frac{K_{tot}}{m}\right]\begin{pmatrix}u_{0,i}\\ \hline u_{1,i}\\ u_{2,i}\\ \vdots\\ u_{N_F,i}\end{pmatrix}+\frac{F_{is,i}}{m}\begin{pmatrix}1\\ 0\\ 0\\ \vdots\\ 0\end{pmatrix}=-\left[\frac{M_{tot}}{m}\right]\cdot\ddot{u}_{g,i} \qquad (6)$$

The damping matrix is obtained by accounting for Rayleigh damping, with a target damping ratio equal to 5% [11].

4 CASE STUDY STRUCTURE AND SEISMIC INPUT

The case study building consists of a three storey R.C. frame structure, with a total mass equal to 2048 tons [2], which is base-isolated by means of CSS devices, and a R.C. isolated slab with a thickness of 0.5m, as shown in Figure 9.

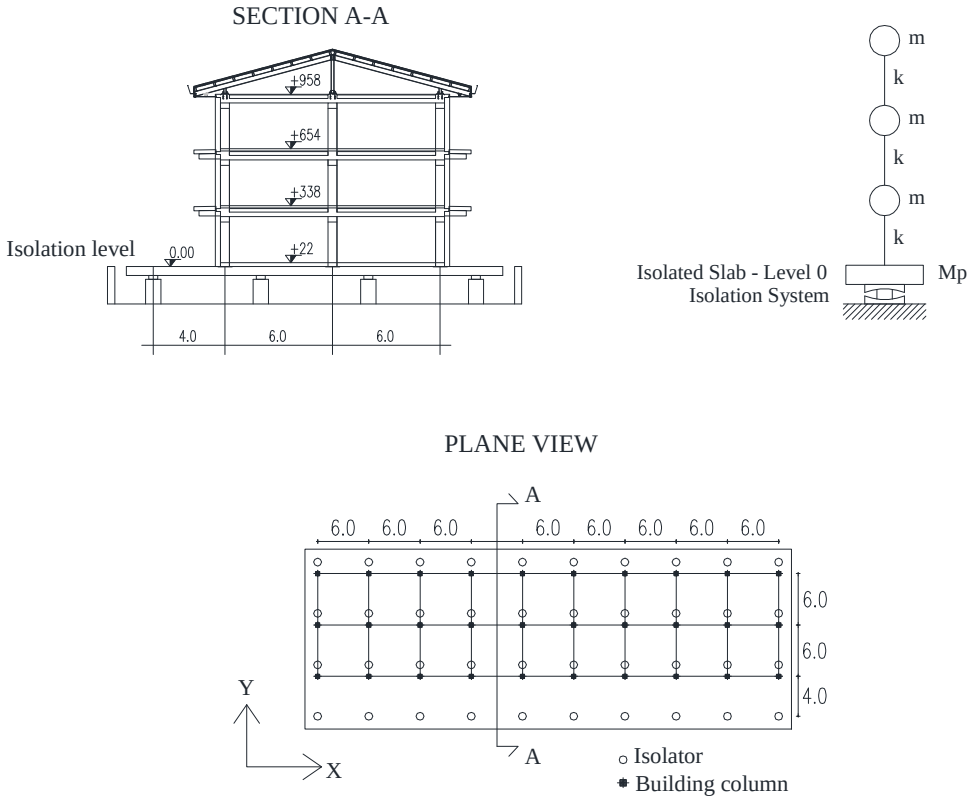

Figure 9: Case study structure.

The isolated plate has a total mass equal to 1496 tons: thus, according to the aforementioned analytical model, the ratio between the masses of the building and the isolated plate is equal to 1,37. The first mode period is equal to 0,48s and a target damping ratio of 5% has been set for all the modes. CSS devices have been modelled with a an equivalent radius of curvature equal to 3,1m; furthermore, in this work the friction coefficient has been considered

as a constant function of vertical load, sliding velocity and dissipated energy: the numerical value is equal to 7% [3, 4].

For what concerns the input signals, all the previously analyzed earthquakes have been applied to the case study structure. Since the displacement demand and the associated hysteretic damping ratio is not a priori known, for all the bi-directional earthquakes the optimum direction angle of the equivalent uniaxial event has been computed with a damping ratio equal to 5% and both acceleration and displacement approaches have been processed. In Table 2 the characteristics of the seismic events are listed.

Event #	Location	Scale factor	1D angle [°] acc. approach	1D angle [°] displ. approach
1	Irpinia	1.5	140.5	118.0
2	Emilia	1.5	128.0	94.5
3	L'Aquila	1.5	21.0	179.5

Table 2: Case study– seismic events characteristics.

A scale factor for both x and y components equal to 1.5 has been used for all the considered seismic events, in order to achieve a maximum displacement demand comparable to the design displacement capacity of the devices.

5 ANALYSES RESULTS

In the followings the results are shown in terms of displacement, absolute acceleration and interstorey shear profiles of the case study structure, subjected to the bidirectional event in comparison to the equivalent uniaxial cases.

In Figure 10 , Figure 11 and Figure 12 displacement results are reported for earthquake #1, #2 and #3 respectively, and by accounting for acceleration (left) rather than displacement (right) approach.

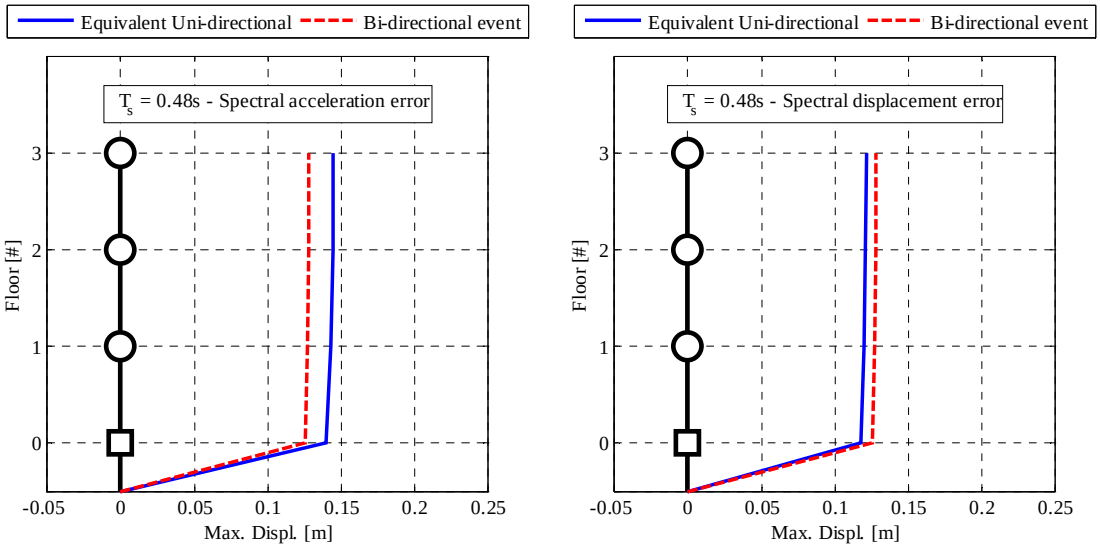

Figure 10: Results – Eqk#1 – displacement profiles.

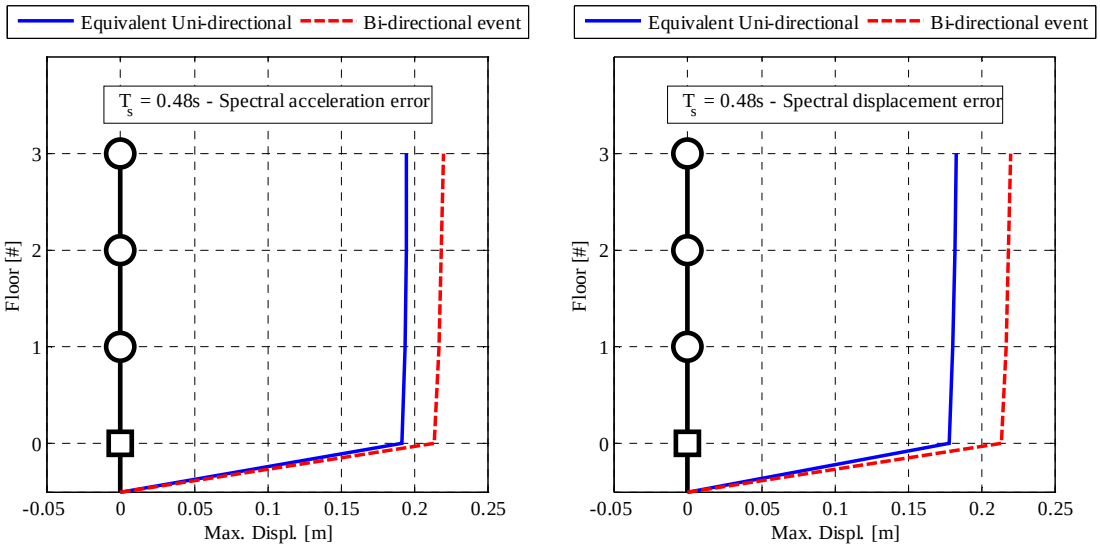

Figure 11: Results – Eqk#2 – displacement profiles.

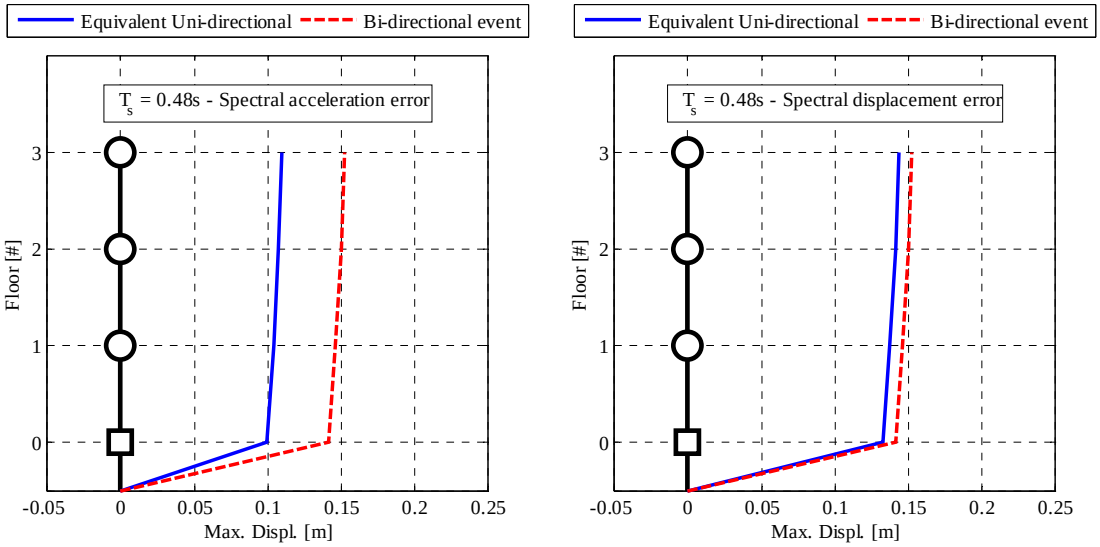

Figure 12: Results – Eqk#3 – displacement profiles.

In Table 3 the variation percentages at all levels of the displacement demand related to the equivalent uniaxial earthquake in comparison to the biaxial seismic event.

	Eqrthquake #1		Eqrthquake #2		Eqrthquake #3	
Level #	Acc. approach	Displ. approach	Acc. approach	Displ. approach	Acc. approach	Displ. approach
0	11.9%	-6.3%	-10.7%	-17.0%	-29.6%	-6.0%
1	12.4%	-5.8%	-10.8%	-16.8%	-28.7%	-5.8%
2	13.0%	-5.3%	-11.1%	-16.8%	-28.2%	-5.7%
3	13.3%	-5.0%	-11.4%	-16.8%	-28.1%	-5.6%

Table 3: Results – Variation percentages – displacement response.

As can be noted, for earthquake #1 and #3 the best agreement is achieved by using the displacement spectrum approach, whereas for the second earthquake the direction angle returned by the acceleration procedure leads to better results. Generally, the displacement demand decreases at all levels, if the equivalent uniaxial event is considered; only for earthquake #1 with acceleration approach opposite evidences have been found.

In Figure 13 , Figure 14 and Figure 15 absolute acceleration results are reported for earthquake #1, #2 and #3 respectively, and by accounting for acceleration (left) rather than displacement (right) approach.

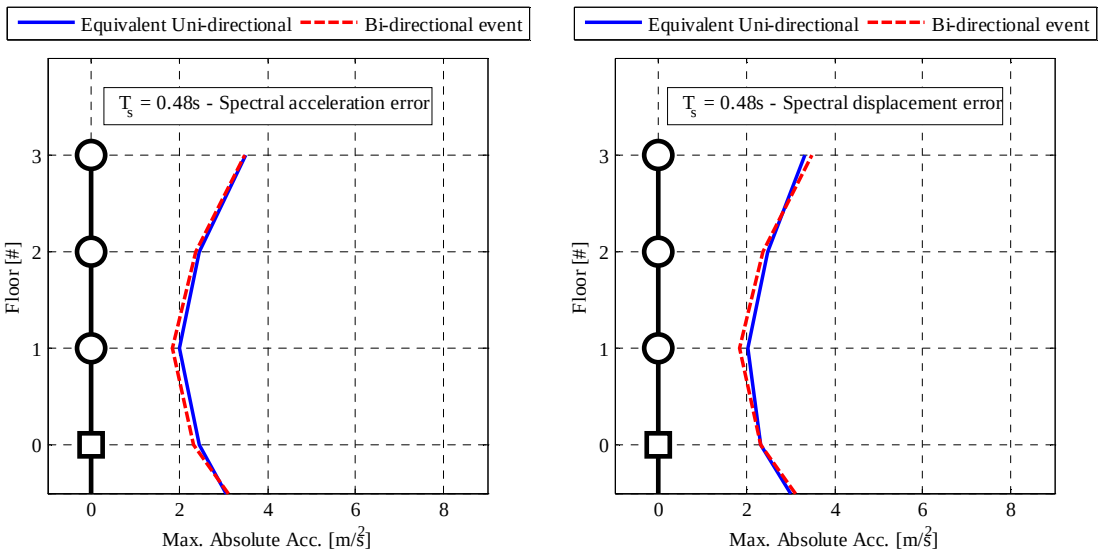

Figure 13: Results – Eqk#1 – absolute acceleration profiles.

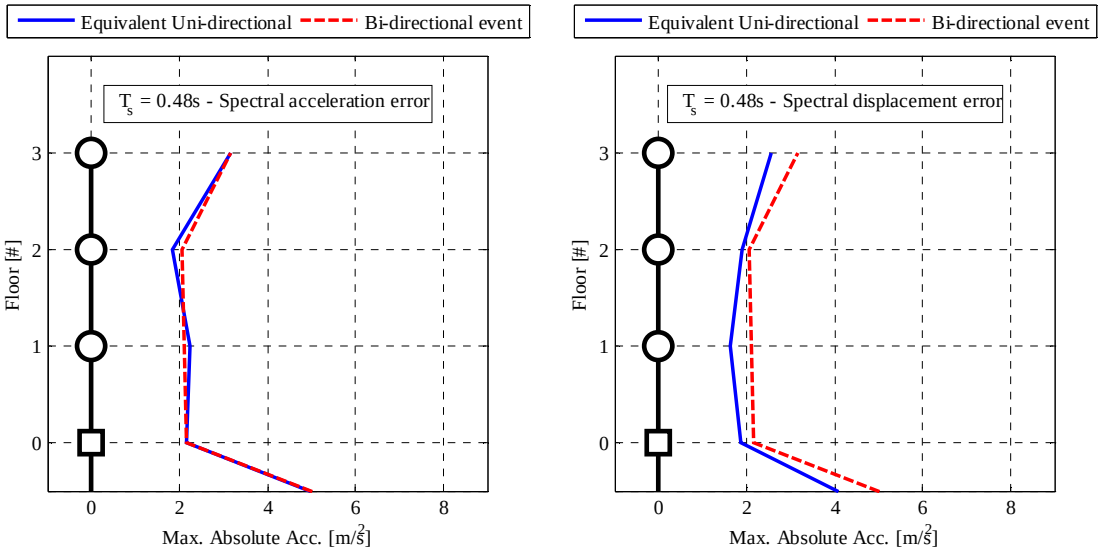

Figure 14: Results – Eqk#2 – absolute acceleration profiles.

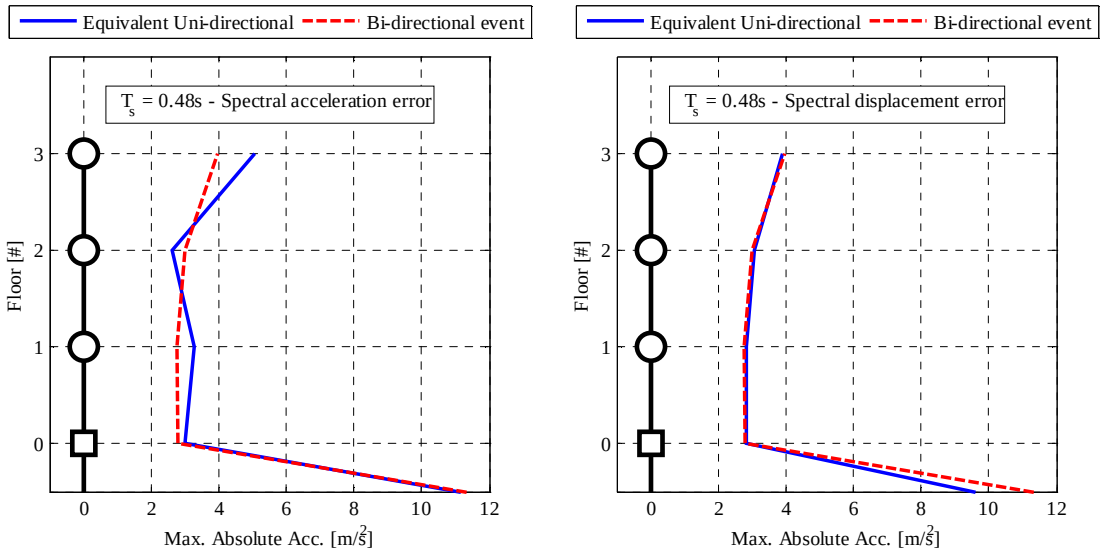

Figure 15: Results – Eqk#3 – absolute acceleration profiles.

In Table 4 the variation percentages at all levels of the absolute acceleration demand related to the equivalent uniaxial earthquake in comparison to the biaxial seismic event.

	Eqrthquake #1		Eqrthquake #2		Eqrthquake #3	
Level #	Acc. approach	Displ. approach	Acc. approach	Displ. approach	Acc. approach	Displ. approach
0	4.8%	0.0%	0.3%	-13.1%	7.5%	0.9%
1	7.9%	9.0%	6.0%	-22.5%	17.6%	2.3%
2	3.9%	4.3%	-10.1%	-7.9%	-12.2%	2.6%
3	0.7%	-4.8%	0.1%	-19.1%	28.2%	-1.4%

Table 4: Results – Variation percentages – absolute acceleration response.

In all cases acceleration profiles relative to the biaxial seismic event are almost overlapped to the ones associated to the equivalent uniaxial earthquake: thus, even though 5% damping is assumed for the computation of the optimum direction angle for both displacement and acceleration approaches, the acceleration response can be properly captured by applying an equivalent radial motion. For eqk#1 and #2 the best comparison is obtained by accounting for the acceleration procedure, whereas for eqk#3 the displacement approach provides a better estimates of the bidirectional acceleration profile.

In Figure 16 , Figure 17 and Figure 18 interstorey shear results are reported for earthquake #1, #2 and #3 respectively, and by accounting for acceleration (left) rather than displacement (right) approach.

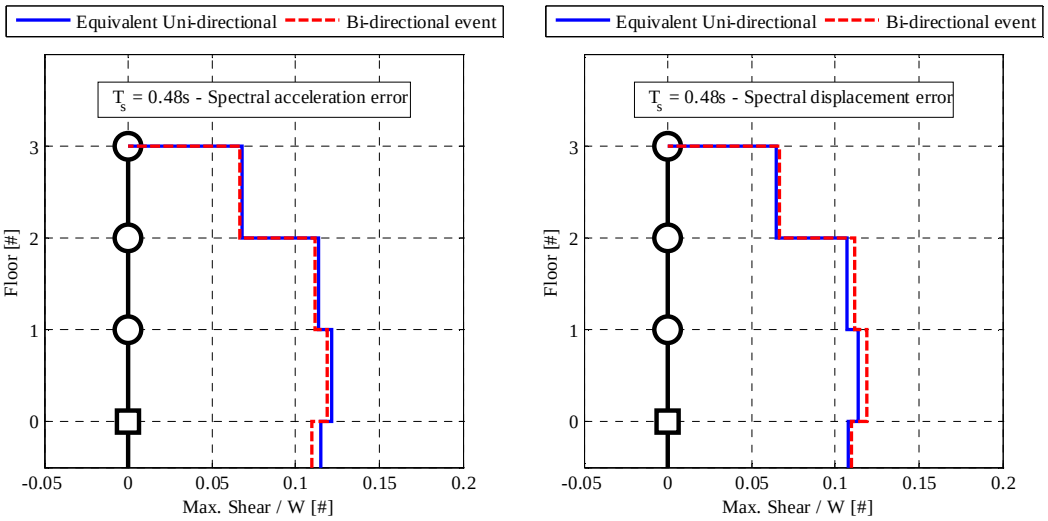

Figure 16: Results – Eqk#1 – interstorey shear profiles.

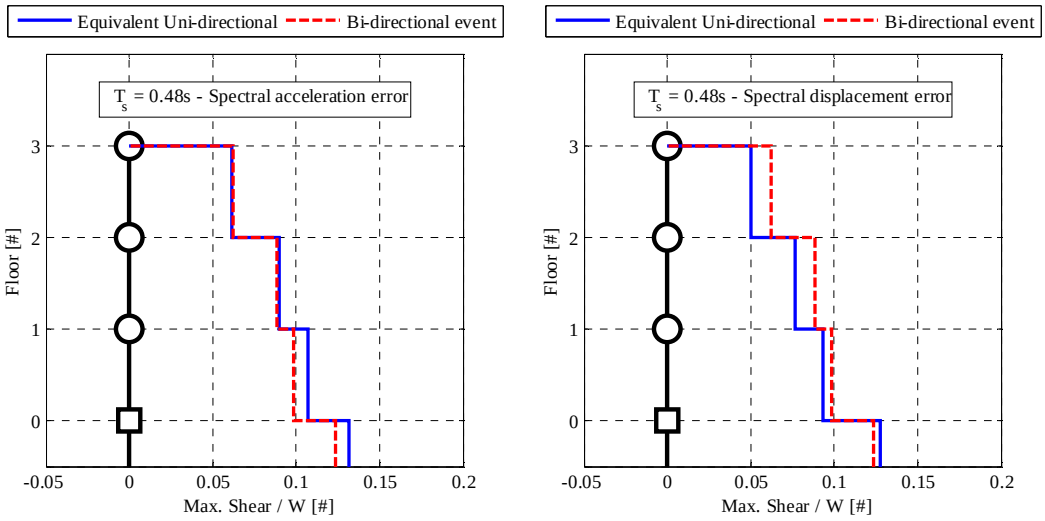

Figure 17: Results – Eqk#2 – interstorey shear profiles.

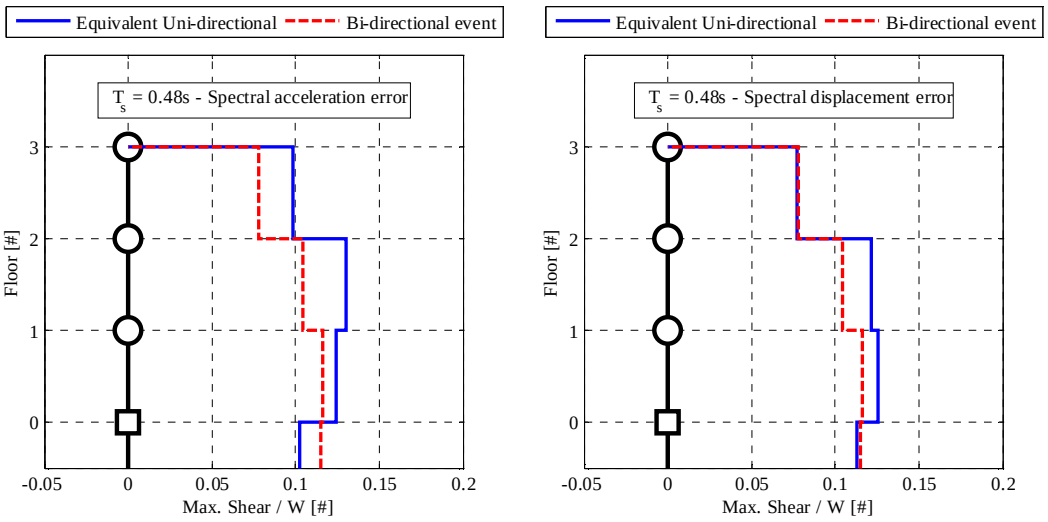

Figure 18: Results – Eqk#3 – interstorey shear profiles.

In Table 5 the variation percentages at all levels of the interstorey shear demand related to the equivalent uniaxial earthquake in comparison to the biaxial seismic event.

	Eqrthquake #1		Eqrthquake #2		Eqrthquake #3	
Level #	Acc. approach	Displ. approach	Acc. approach	Displ. approach	Acc. approach	Displ. approach
0	5.1%	-1.6%	6.8%	3.3%	-11.1%	-1.7%
1	2.2%	-4.3%	8.8%	-4.9%	6.5%	7.7%
2	2.1%	-4.1%	1.4%	-13.4%	25.0%	16.6%
3	1.9%	-2.9%	-1.1%	-19.2%	26.4%	-1.1%

Table 5: Results – Variation percentages – interstorey shear response.

Also concerning shear profiles, the equivalent unidirectional event provides a good estimate of the bidirectional response at all levels. Again, the acceleration procedure leads to better results for eqk#1 and #2.

6 CONCLUSIONS AND FUTURE DEVELOPMENTS

In this work an analytical procedure for the computation of an equivalent uniaxial seismic event for a bidirectional earthquake is presented. Such a procedure allows to compute the optimum direction angle of the equivalent radial motion, by projecting along several directions all the acceleration points of the bidirectional earthquake and evaluating the associated error parameter between the biaxial and the uniaxial response spectrum; both acceleration and displacement response spectra have been considered. Three different bidirectional seismic events have been studied and then applied to a case study base-isolated structure, in order to underline differences between the biaxial and the equivalent uniaxial responses, in terms of displacement, absolute acceleration and interstorey shear demands.

For the analyzed earthquakes it has been noticed that the optimum direction angle can be approximately considered constant with respect to the damping ratio and the error parameter significantly decreases with increasing values of damping ratio, if the acceleration spectrum approach is used; on the other hand the displacement approach leads to more irregular results.

Concerning structural responses, displacement demands at all levels are underestimated when the equivalent uniaxial earthquake is applied, exception made for earthquake #1, with acceleration approach. The best approximation is returned by the acceleration approach, which leads to variations in the range between 5% and 15%, whereas higher variations can be experienced with displacement approach. Regarding absolute acceleration responses, a good agreement between biaxial and equivalent uniaxial events is reached with both the approaches, even though in most of the cases the lowest variations can be found with the acceleration-based procedure (less than 10%). Similar conclusions can be drawn also for interstorey shear responses.

Future developments of the present work will consist of a wide numerical study on a real application, modelled with a commonly used commercial software, in order to underline influences in the main response parameters of the effective horizontal and vertical spatial distribution of the structural elements, by accounting for both biaxial and equivalent uniaxial earthquakes; furthermore, a wider set of seismic events will be analyzed, aiming at generalizing all the previously discussed aspects.

Keywords: Slender beam and shell, mixed formulations, 3D solid element, Koiter analysis

Abstract. *The reasons of the better performances of mixed, stress–displacements, 3D solid finite elements in the analysis of slender elastic structures are explained. It will be shown that mixed or compatible description, also when derived from the same finite element and then completely equivalent from the discretization point of view, behave very differently when implemented in both asymptotic and path–following solution strategies due to the occurrence of a pathological locking phenomenon in the compatible formulation. The notable advantages of the used of a 3D mixed solid finite element in Koiter asymptotic analysis are also highlighted.*

1 INTRODUCTION

In recent years an increasing amount of research has aimed at developing new efficient solid finite elements [1] for the linear and nonlinear analysis of thin structures. This is due to the advantages of solid elements in comparison to classical shell elements. In particular in the elastic nonlinear analysis of slender structures they allow the use of the 3D continuum strain and stress measures employing translational degrees of freedom only [1, 2, 3, 4]. In this way it is possible to avoid the use of complicated and expensive rules for updating the rotations and, by using the Green-Lagrange strain measure, to coherently describe the structural behavior through a low order dependence on the displacement field. Moreover in this context, solid elements allow: a simpler expression of the strain energy and its variations with a gain in computational efficiency; the recovery of the complete 3D stress state and the application of nonlinear constitutive laws; simpler geometric and kinetic descriptions; the simple discretization of structures with both solid and shell-like regions. Furthermore the independence of the model from rigid body motion or change in the observer (objectivity) is automatically fulfilled without the need to employ complex, geometrically exact formulations, which are not always available or accurate [5, 6, 7].

However, formulating robust solid-shell elements is more demanding than shell elements. To maintain an acceptable number of degrees of freedom, the elements proposed are usually based on a low order displacement interpolation. Consequently they have the disadvantages of *interpolation lockings*: the shear and membrane locking also present in classical shell elements and trapezoidal and thickness locking, typical of low order solid-shell elements [8]. Interpolation lockings are usually sanitized by means of Assumed Natural Strain, Enhanced Assumed Strain [9, 10, 11, 12] and mixed (hybrid) formulations [1, 4, 13, 14]. In this way solid-shell elements have now reached a high level of efficiency and accuracy and have also been used to model composites or laminated beams [11, 15, 13, 16] and shell structures in both the linear [9, 3] and nonlinear [12, 2, 1] range. Among the most effective and interesting proposals we refer to are the mixed solid-shell elements of Sze and coauthors [1, 13, 17, 18, 19, 20, 21, 16, 22, 23] which extend the initial PT18β hybrid element of Pian and Tong to thin shell.

When comparing mixed and compatible finite elements many authors (see for example [1] and [2]) observe that the mixed ones are more robust and allow larger steps in path–following geometrically nonlinear analyses. However the reasons for these better performances are, in our opinion, not clear, as they are often wrongly attributed to the properties of the finite element interpolation. One of the goals of this paper is therefore to clarify the true reason and the origin of this phenomenon, extending the results presented some years ago [24, 25] in the context of path-following and Koiter [26, 27, 28] asymptotic analyses of 2D framed structures.

Mixed and compatible description, while completely equivalent at the continumm level, behave very differently when implemented in path-following and asymptotic solution strategies even when they are based on the same finite element interpolations, that is when they are equivalent also at the discrete level. This is an important, even if frequently misunderstood, point in developing numerical algorithms and it has been discussed in [24, 25, 29] to which we refer readers for more details. To represent the strain energy in a *smooth enough* way in order to make the truncation error of its Taylor expansion up to a given order as small as possible is crucial: in path-following analysis, this ensures a fast convergence of the Newton (Riks) iterative process; in asymptotic analysis, which is based on Taylor series the expansion of the strain energy [26, 28] implies an accurate recovery of the equilibrium path. Since the smoothness of a nonlinear function strictly depends on the set of variables used for its description, a key point to

be considered when approaching the solution of a nonlinear problem is the selection of the most appropriate set of variables. In fact mixed and compatible descriptions are characterized by a different smoothness of the strain energy and so they behave very differently when used within a numerical solution process. In particular representing the strain energy by using displacements only (compatible description) as variables has to be considered the least suitable choice as, in this case the truncation error of a Taylor expansion depends, pathologically, on the presence of directions with very different stiffness, while this is not the case in a mixed format. For shells or beams, in the presence of large displacements (rigid rotations) and high membranal/flexural stiffness ratios, the truncation error of the compatible description becomes large and causes a very slow convergence rate in path-following analysis and an unreliable estimate of the bifurcation point and of the post–critical coefficients in the asymptotic analysis. As will be shown, using solid elements means the mixed description is unaffected by this kind of locking, that we call *extrapolation locking*.

In this paper a mixed and a compatible description are derived for the same finite element, so obtaining two completely equivalent discrete problems, in order to show that their different behavior is not due to the interpolation fields and that the extrapolation locking occurs for any compatible finite element. This is an important aspect not taken into account by the scientific community because, usually, lockings are attributed to the interpolation only.

Moreover, note that the solid element based on the quadratic Green-Lagrange strain measure, minimizes the strain energy dependence on the finite element (FE) discrete variables: the fourth order dependence on displacement variables in the compatible formulation and the third order in stress and displacement variables in the mixed case. Although this does not produce any real important benefit with respect to the extrapolation locking it does however have a significant effect on the efficiency, robustness and coherence of the asymptotic analysis when the mixed description is used. It allows, in fact, the zeroing of all the strain energy variations of an order greater than the third and, consequently, permits light numerical formulations and an improvement in accuracy. In this way it is possible to develop new asymptotic algorithms well suited to the imperfection sensitivity analysis of structures presenting coincident or almost coincident buckling loads, which are more accurate and computationally efficient than those based on classical shell elements. This advantage holds in standard path-following analysis where however it only allows simpler expressions of the tangent stiffness matrix and the structural response.

Finally it is worth mentioning that the use of both displacement and stress variables increases the dimension of the problem, but generally the computational extra–cost, with respect to a compatible analysis, is very low. This is because the global operations involve displacement dofs by performing a static condensation of the stress variables, when locally defined at element level. This small computational extra-cost is largely compensated for: in path-following analysis by larger steps and fewer iterations with respect to the compatible case; in asymptotic analysis by the zeroing of the computationally expensive fourth order strain energy variations. We will also show how the small nonlinearity that the equilibrium path assumes when represented in mixed variables allows, in path following analyses, an efficient use of the modified Newton method with a further significant reduction in the computational cost.

2 MIXED AND COMPATIBLE DESCRIPTIONS

In this section, two equivalent descriptions, one in stresses and displacements called *mixed description* and another in displacement parameters only, called *compatible description*, are derived. We refer to [29, 28, 7, 6] for a description of the asymptotic method.

2.1 The discrete nonlinear equations

We consider a slender hyperelastic structure subject to conservative loads $p[\lambda]$ proportionally increasing with the amplifier factor λ. The equilibrium is expressed by the virtual work equation

$$\Phi[u]'\,\delta u - \lambda \hat{p}\,\delta u = 0 \quad , \quad u \in \mathcal{U}\ ,\ \delta u \in \mathcal{T} \tag{1}$$

where $u \in \mathcal{U}$ is the field of configuration variables, $\Phi[u]$ denotes the strain energy, $\mathcal{T}$ is the tangent space of $\mathcal{U}$ at u and a prime is used to express the Frechèt derivative with respect to u. We assume that $\mathcal{U}$ will be a linear manifold so that its tangent space $\mathcal{T}$ will be independent of u. When a mixed format is adopted the configuration variables u collect both displacement and stress fields.

The element strain energy can, as usual in a FE context, be expressed as a sum of element contributions that, using a mixed interpolation for the displacement and the stress field $\boldsymbol{\sigma}$ and letting with Ω_e the element domain, becomes

$$\begin{aligned}
\Phi[u] &\equiv \sum_e \Phi_e[u] = \sum_e \int_{\Omega_e} \left(\boldsymbol{\sigma}^T \boldsymbol{\varepsilon} - \frac{1}{2}\boldsymbol{\sigma}^T \mathbf{C}^{-1} \boldsymbol{\sigma} \right) dV_e \\
&= \boldsymbol{\beta}^T (\mathbf{L} + \frac{1}{2}\mathbf{Q}[\mathbf{d}])\mathbf{d} - \frac{1}{2}\boldsymbol{\beta}^T \mathbf{H} \boldsymbol{\beta} \\
\Phi_e[u] &= \boldsymbol{\beta}_e^T (\mathbf{L}_e + \frac{1}{2}\mathbf{Q}_e[\mathbf{d}_e])\mathbf{d}_e - \frac{1}{2}\boldsymbol{\beta}_e^T \mathbf{H}_e \boldsymbol{\beta}_e
\end{aligned} \tag{2}$$

where $\boldsymbol{\varepsilon}$ is the Green-Lagrange strain measure $\mathbf{L}$ and $\mathbf{Q}[\mathbf{d}]$ are the linear and quadratic discrete compatibility matrices, $\mathbf{d}$ is the vector collecting all the finite element displacement variables while $\boldsymbol{\beta}$ is the vector collecting all the stress parameters, $\mathbf{C}$ and $\mathbf{H}$ are the continuum and discrete elastic matrices and a subscript 'e' denotes the corresponding finite element quantities. It is worth to note as, by using the Green strain measure, the mixed strain energy (2) has a third order nonlinearity with respect to the configuration variable vector $\mathbf{u} = \{\boldsymbol{\beta}, \mathbf{d}\}$.

The element can also be described in a compatible format by requiring that the discrete form of the constitutive laws is "a priori" satisfied. As in the present FE model the stress variables are locally defined at the element level we have

$$\boldsymbol{\beta}_e[\mathbf{d}_e] = \mathbf{H}_e^{-1}(\mathbf{L}_e + \frac{1}{2}\mathbf{Q}_e[\mathbf{d}_e])\mathbf{d}_e \tag{3}$$

where, to highlight that in the compatible format the stresses are not independent variables, we explicitly report the dependence of $\mathbf{d}_e$.

Substituting Eq.(3) in Eq.(2) we obtain the *compatible description* of the element strain energy

$$\Phi_e = \frac{1}{2}\left\{ \mathbf{d}_e^T (\mathbf{L}_e + \frac{1}{2}\mathbf{Q}_e[\mathbf{d}_e])^T \mathbf{H}_e^{-1} (\mathbf{L}_e + \frac{1}{2}\mathbf{Q}_e[\mathbf{d}_e])\mathbf{d}_e \right\} \tag{4}$$

that has a 4th order dependence on the displacement variables only.

Similarly a fourth order dependence of the strain energy from the displacements parameters, is obtained with any compatible finite element interpolation when a 3D solid formulation is employed. In this paper we intentionally use the compatible description derived from the mixed finite element in order to have the same discrete approximation for both the description, i.e. the finite element is the same but the format of the problem changes. This allows us to focus of the way as the problem description affects its solution in large deformation problems (see

also [24, 25]) and then to show the reasons of the better performance of the use of a mixed description. The conclusions are general and hold for any other compatible or mixed finite element. In the numerical experiments the Pian and Tong PT18 element [50] will be used.

2.2 Tangent stiffness matrix for mixed and compatible descriptions

Eq.(2) allows the expression of the strain energy as an algebraic nonlinear function of the element vector

$$\mathbf{u}_e := \begin{bmatrix} \boldsymbol{\beta}_e \\ \mathbf{d}_e \end{bmatrix} \tag{5}$$

related to the vector $\mathbf{u}$, collecting all the parameters of the FE assemblage, through the relation

$$\mathbf{u}_e = \boldsymbol{\mathcal{A}}_e \mathbf{u} \tag{6}$$

where matrix $\boldsymbol{\mathcal{A}}_e$ contains the link between the elements. Furthermore we denote with $\delta\mathbf{u}_{ei} = \{\delta\boldsymbol{\beta}_{ei}, \delta\mathbf{d}_{ei}\}$ the element vector corresponding to the variation $\delta\mathbf{u}_i$.

Exploiting the linear dependence of $\mathbf{Q}_e[\mathbf{d}_e]$ from $\mathbf{d}_e$ and its symmetry we have

$$\begin{aligned} \mathbf{Q}_e[\mathbf{d}_{e1}]\mathbf{d}_{e2} &= \mathbf{Q}_e[\mathbf{d}_{e2}]\mathbf{d}_{e1}, \quad \forall \mathbf{d}_{e1}, \mathbf{d}_{e2} \\ \boldsymbol{\beta}_e^T \mathbf{Q}_e[\mathbf{d}_e]\mathbf{d}_e &= \mathbf{d}_e^T \boldsymbol{\Gamma}_e[\boldsymbol{\beta}_e]\mathbf{d}_e \end{aligned} \tag{7}$$

and the second strain energy variation on the mixed element is obtained as

$$\begin{aligned} \Phi_e'' \delta u_1 \delta u_2 &= \begin{bmatrix} \delta\boldsymbol{\beta}_{e1} \\ \delta\mathbf{d}_{e1} \end{bmatrix}^T \begin{bmatrix} -\mathbf{H}_e & \mathbf{B}_e[\mathbf{d}_e] \\ \mathbf{B}_e[\mathbf{d}_e]^T & \boldsymbol{\Gamma}_e[\boldsymbol{\beta}_e] \end{bmatrix} \begin{bmatrix} \delta\boldsymbol{\beta}_{e2} \\ \delta\mathbf{d}_{e2} \end{bmatrix} \\ &= \delta\mathbf{u}_{e1}^T (\mathbf{K}_{0e} + \mathbf{K}_{1e}[\mathbf{u}_e]) \delta\mathbf{u}_{e2} \end{aligned} \tag{8}$$

where δu_i are generic variations of the configuration field u and $\delta\mathbf{u}_i$ the corresponding FE vectors. Eq.(8) provides the element tangent stiffness matrix $\mathbf{K}_e[\mathbf{u}_e] = \mathbf{K}_{0e} + \mathbf{K}_{1e}[\mathbf{u}_e]$ as a sum of the linear elastic contribution $\mathbf{K}_{0e}$ and the geometric matrix $\mathbf{K}_{1e}[\mathbf{u}_e]$ implicitly defined in Eq.(8).

For the compatible description we have

$$\Phi_e'' \delta u_1 \delta u_2 = \delta\mathbf{d}_{e1}^T \left\{ \mathbf{B}_e^T[\mathbf{d}_e] \mathbf{H}_e^{-1} \mathbf{B}_e[\mathbf{d}_e] + \boldsymbol{\Gamma}[\boldsymbol{\beta}_e[\mathbf{d}_e]] \right\} \delta\mathbf{d}_{e2} \tag{9}$$

where the tangent stiffness matrix has a second order dependence on $\mathbf{d}_e$. To emphasize this we write

$$\mathbf{K}_e = \mathbf{K}_{0e} + \mathbf{K}_{1e}[\mathbf{d}_e] + \mathbf{K}_{2e}[\mathbf{d}_e, \mathbf{d}_e] \tag{10}$$

Finally the evaluation the whole matrix is obtained by standard asseblage as

$$\mathbf{K} = \sum_e \boldsymbol{\mathcal{A}}_e^T \mathbf{K}_e \boldsymbol{\mathcal{A}}_e. \tag{11}$$

2.3 Advantages of mixed solid finite elements in path-following and asymptotic analysis of slender structures

FE models directly derived from the 3D continuum using the Green strain measure have a low order dependence on the strain energy from the discrete FE parameters: $3rd$ and $4th$ order for mixed and compatible respectively. On the contrary geometrically exact shell and beam models [5, 6] or those based on corotational approaches [26, 47, 51], explicitly make use of

the rotation tensor and its highly nonlinear representation. This implies that the strain energy is infinitely differentiable with respect to its parameters and leads to very complex expressions for the energy variations with a high computational burden of path following and much more of asymptotic analyses. In this last case the high order strain energy variations become so complex that often "ad hoc" assumptions are required to make the solution process effective (see section 4.3 of [26]). The consequence is that the fewer global degrees of freedom that could be employed using a shell FE model do not necessarily imply a lesser computational cost as it depends, from the others, on the cost of evaluation of the strain energy variations. On the contrary for solid finite elements the strain energy, in both compatible and mixed form, has the lowest polynomial dependence on the corresponding discrete parameters and in particular in the mixed format of Eq.(2) has just one order more than in the linear elastic case. It implies the zeroing of all the fourth order strain energy variations required by the Koiter analysis with important advantages in terms of both computations and coherence of the method.

3 THE EXTRAPOLATION LOCKING AND ITS CURE USING MIXED SOLID ELEMENT

In this section the better performances of the mixed description in geometrically nonlinear analysis, in terms of robustness, efficiency and, relative to Koiter formulation, also in terms of accuracy, are shown and explained. In this context the compatible description of the problem, whatever the FE and the structural model used, is affected by a pathological *extrapolation locking* phenomenon investigated for the first time for 2D frames in [24, 25].

3.1 Mixed versus compatible description in path-following analysis

The convergence of the Riks scheme is as fast as the iteration stiffness matrix $\tilde{\mathbf{K}}$ is near to $\mathbf{K}_s$ and then, as slow $\mathbf{K}[\mathbf{u}]$ changes with $\mathbf{u}$. The similarity of the stiffness matrices in two different points $\mathbf{K}_j \equiv \mathbf{K}[\mathbf{u}_j]$ and $\mathbf{K}_{j+1} \equiv \mathbf{K}[\mathbf{u}_{j+1}]$ is evaluated by the difference (see [24])

$$\Delta k[\mathbf{u}] \equiv \mathbf{u}^T(\mathbf{K}_{j+1} - \mathbf{K}_j)\mathbf{u} = \Phi''_{j+1}u^2 - \Phi''_j u^2 \tag{12}$$

For the mixed description we have

$$\Delta k_M[\mathbf{u}] = \Phi'''_j(u_j - u_i)u^2 = \mathbf{d}^T\boldsymbol{\Gamma}[\boldsymbol{\beta}_{j+1} - \boldsymbol{\beta}_j]\mathbf{d} + 2\boldsymbol{\beta}^T\mathbf{Q}[\mathbf{d}](\mathbf{d}_{j+1} - \mathbf{d}_j) \tag{13}$$

while for the compatible description the same quantity becomes

$$\begin{aligned}\Delta k_C[\mathbf{u}] &= \Phi'''_j(u_j - u_i)u^2 + \frac{1}{2}\Phi''''_j(u_j - u_i)^2u^2 \\ &= \mathbf{q}_{j+1}^T\mathbf{H}^{-1}\mathbf{q}_{j+1} - \mathbf{q}_j^T\mathbf{H}^{-1}\mathbf{q}_j + \mathbf{d}^T(\boldsymbol{\Gamma}[\boldsymbol{\beta}[\mathbf{d}_{j+1}] - \boldsymbol{\beta}[\mathbf{d}_j]])\mathbf{d}\end{aligned} \tag{14}$$

where $\mathbf{q}_{j+1} = \mathbf{B}[\mathbf{d}_{j+1}]\mathbf{d}$ and $\mathbf{q}_j = \mathbf{B}[\mathbf{d}_j]\mathbf{d}$.

For slender structures it occurs that $\boldsymbol{\beta}_{j+1} \approx \boldsymbol{\beta}_j$ undergoing large rigid element deformations and very small stress and strain increments and then

$$\Delta k_M \approx 2\boldsymbol{\beta}^T(\mathbf{q}_{j+1} - \mathbf{q}_j) \tag{15}$$

and

$$\Delta k_C \approx f[\mathbf{q}_{j+1}] - f[\mathbf{q}_j] \quad \text{with} \quad f[\mathbf{q}] = \mathbf{q}^T\mathbf{H}^{-1}\mathbf{q} \tag{16}$$

When, as is usual for slender structures, the condition number of $\mathbf{H}$ is high due to very different stiffness ratios (i.e. membranal/flexural) the ellipsoids associated to $\mathbf{H}$

$$\mathcal{E} \equiv \{\mathbf{q} : \mathbf{q}^T\mathbf{H}\mathbf{q} = 1\}$$

are very stretched. As $f[\mathbf{q}]$ is related to the radius $r[\mathbf{q}]$ of $\mathcal{E}$ in the direction $\mathbf{q}$ by the following expression

$$f[\mathbf{q}] = r[\mathbf{q}]^2(\mathbf{q}^T\mathbf{q})$$

Δk_c becomes

$$\Delta k_C \approx r^2[\mathbf{q}_{j+1}]\mathbf{q}_{j+1}^T\mathbf{q}_{j+1} - r^2[\mathbf{q}_j]\mathbf{q}_j^T\mathbf{q}_j$$

In this case even small differences in the direction of $\mathbf{q}_{j+1}$ and $\mathbf{q}_j$ may produce a large Δk_C growing with the condition number of $\mathbf{H}$ even when the Euclidean norm of the two vectors is similar (see Fig.1). This produces, in path following analyses a pathological reduction in the

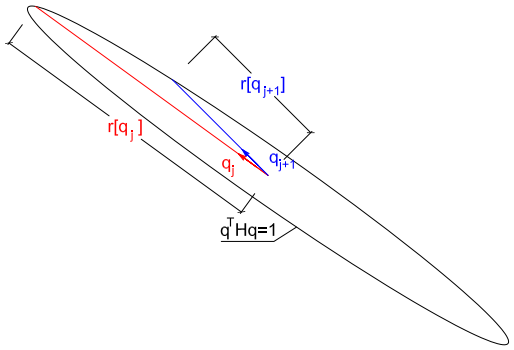

Figure 1: Graphical interpretation of Δk for the compatible description

step length, an increase in the total number of the iterations and, sometimes, the loss of convergence. This phenomenon is called *extrapolation locking* from which the mixed models are free because they are unaffected by the "hard terms" in $\mathbf{H}^{-1}$ and Δk_M is proportional to the difference $\mathbf{q}_{j+1} - \mathbf{q}_j$. As expressions like those in Eqs.(13) and (14) are obtainable using any mixed or compatible finite element the conclusions reported here can be generalized. In particular note that for any structural model the strain energy can be expressed as a quadratic function of the stress variables through the Hellinger-Reissner principle and so its higher order variations are not influenced by $\mathbf{H}$. On the contrary all the compatible strain energy variations always involve terms in $\mathbf{H}^{-1}$. This means that extrapolation locking heavily affects any compatible finite element/description while it does not occur in mixed formulation.

We show the occurrence of the locking in the simple case of the Euler beam, for which the geometry and load conditions are reported in fig. 2.

In tab.2 the number of steps and iterations (loops) to obtain the equilibrium path, directly related to the CPU time, are presented. The results of the mixed formulation, denoted by M, are unaffected by the coefficient $k = (t/\ell)^2$ while the compatible ones (C) pathologically depend on it.

Finally in Fig.3 we report the minimum ρ_{min} and maximum ρ_{max} absolute value of the eigenvalues of the matrix $\mathbf{K}_{n+1}\mathbf{K}_n^{-1}$ for both descriptions, where $n+1$ and n denote two equilibrium points. The set of points in which the ρs are evaluated belongs on the equilibrium path obtained by the mixed description. It is important to observe how the mixed description ρ_{max} is independent of k and has almost the optimal value 1.0 while for the compatible description it

	Compatible				Mixed
k	10^4	10^5	10^6	10^7	(all k)
steps	38	43	67	failed	27
loops	133	166	328	failed	75

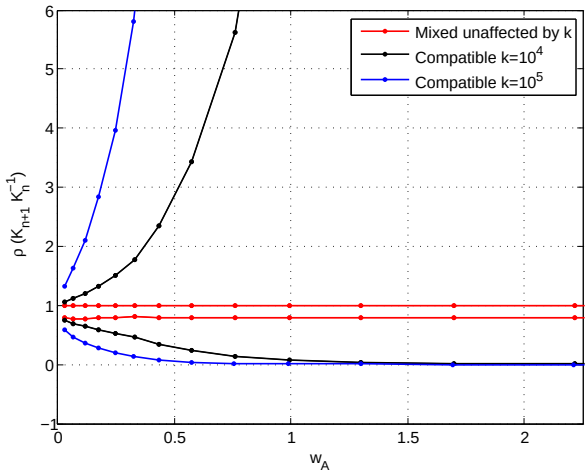

Figure 3: Minimum and maximum eigenvalues of matrix $\mathbf{K}_{n+1}\mathbf{K}_n^{-1}$ for the simple tests

increases with the step length. Also note that is the extrapolation locking that heavily affects also the convergence of the arc-length solution while the singular direction is filtered by the Riks constraint. We refer readers to [24, 25] for further details.

3.2 Mixed vs compatible description in Koiter analysis using 3D solid elements

As the Koiter method is based on Taylor expansion of the strain energy the use of a mixed description has a tremendous impact not only in terms of efficiency but also of accuracy. For any finite element (see [25, 35, 6]) the mixed description makes the truncation independent of $\mathbf{H}^{-1}$ and small with respect to the retained terms.

Using compatible format in Koiter analysis the locking already occurs in the evaluation of the buckling loads (see [25]). To avoid extrapolation locking usually the compatible bifurcation analysis is performed by zeroing the quadratic displacements terms into the tangent stiffness matrix (*direct extrapolation* hypothesis) or by evaluating the geometric terms using zeroed displacements (*frozen configuration* hypothesis). In both cases the bifurcation search reduces to a linear eigenvalue problem.

In Tab.1 the buckling loads obtained from the various descriptions and locking cures are presented for the Euler beam of Fig. 2 by changing both the aspect ratio k and the imperfection load amplitude ϵ. In particular we denote with (C) and (M) the results obtained respectively with the compatible and mixed description and by (F) and (D) those of the frozen configuration and direct extrapolation respectively. For this case which has small precritical nonlinearities it is worth noting that: i) the frozen configuration hyphothesis sanitizes the locking effect and fur-

Table 1: Bifurcation locking for the Euler beam/(exact value for the elastica)

k	$\epsilon = 0.01$		$\epsilon = 0.005$		$\epsilon = 0.001$		for all ϵ	
	C	D	C	D	C	D	F	M
10^4	failed	0.673	1.112	0.865	1.004	0.994	1.001	1.001
10^5	failed	0.309	failed	0.517	1.040	0.937	1.001	1.001
10^6	failed	0.111	failed	0.209	failed	0.673	1.001	1.001
10^7	failed	0.033	failed	0.071	failed	0.308	0.999	0.999

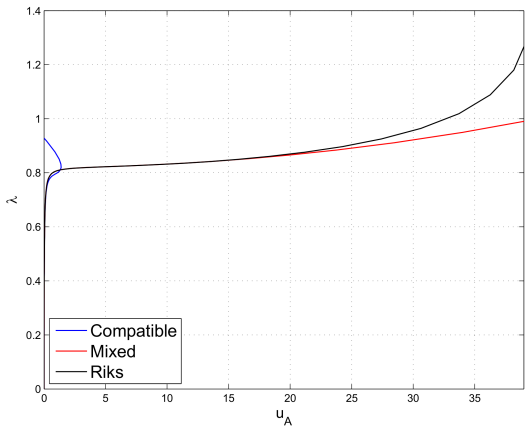

Figure 4: Equilibrium path for the Euler beam for $\epsilon = 0.001$ and $k = 10^4$

nishes accurate results; ii) the compatible description misses the bifurcation point and the direct extrapolation furnishes an inaccurate solution, getting worse with the precritical nonlinearity due to the transversal force. Inaccuracy on the bifurcation points obviously leads to completely wrong equilibrium path evaluation.

The zeroing of all the precritical displacements could, however, lead to inaccuracy when the precritical displacements are not negligible as in the shallow arc reported in Fig.5. In this case the frozen configuration is not capable of producing the correct bifurcation load and mode as reported in Tab.2. The buckling point is used to evaluate the energy terms also reported in Tab.2, so the equilibrium path obtained with the frozen configuration hyphothesis is very inaccurate. In Fig.6 the equilibrium path of the Koiter mixed formulation is presented and compared with the frozen one and path following solution.

However the great advantage in adopting mixed solid elements in Koiter analysis is in the evaluation of all the fourth order coefficients required by the formulation (see [29]) that, for mixed solid elements, requires only second variations for their evaluation since the usually very complex fourth order strain energy variations are automatically zero.

4 NUMERICAL RESULTS

In this section the effectiveness and reliability of both methods of analysis are tested in a series of benchmark problems. In particular for the path-following analysis the efficiency of the mixed description, which allows very large steps in comparison with the compatible one, is highlighted. For the asymptotic formulation we show the accuracy given by the mixed solid element.

For all the tests only one element in the thickness is used while the same convergence conditions and arc-length parameters are adopted for mixed and compatible path-following analyses. The label Riks denotes the equilibrium paths obtained by the arc-length scheme (the same for both the description), while labels Mixed and Frozen denote the asymptotic paths using mixed and compatible frozen descriptions.

4.1 Simply supported C-shaped beam

The first test, with geometry and material reported in figure 7, consists in a simply supported compressed beam with a C shaped section. It presents a nonlinear prebuckling behavior due to two forces (torsional imperfections) at the mid-span and coupled instability. For this reason it is a good benchmark to test the accuracy of the asymptotic analysis. A similar test was studied

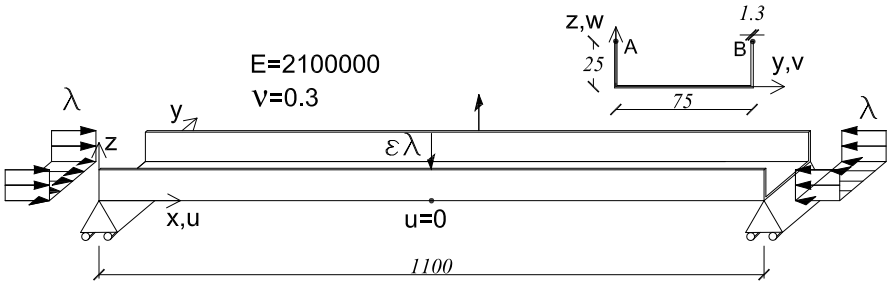

Figure 7: Channel section: geometry and loads.

in [35] using shell elements and in [52] using a generalized beam model. The buckling values, obtained by using a mesh of $(8+8+18)\times 50$ elements are reported in Table 3 and compared with those computed using the compatible description with the frozen configuration hyphothesis. The Koiter analysis uses the first four buckling modes plotted in Fig.8. It is possible to see how the first two modes are global, essentially flexural and torsional respectively, while the others are local modes.

The accuracy of the mixed asymptotic strategy in the evaluation of the limit load and of the initial postcritical behavior is shown in Fig.9. It is also possible to observe the poor accuracy of the frozen configuration analysis in estimating both the limit load and equilibrium path. In Fig.10 the equilibrium path of Koiter method, in terms of the modal contributions ξ_k, is plotted.

The strong effect of modal interaction between the third (local) mode and the first two flexural–torsional (global) modes is shown.

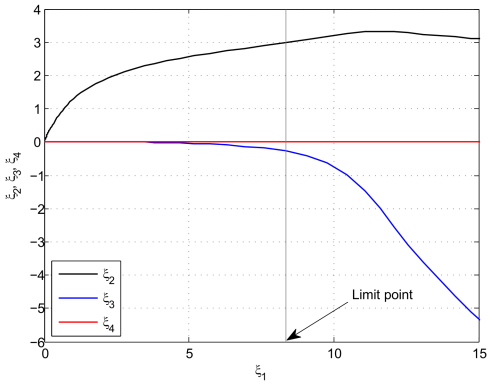

Figure 10: Channel section: Equilibrium paths in ξ_k space.

The results of the mixed asymptotic analysis are in good agreement with the path-following ones. In Tab.4 the steps and iterations of the mixed and compatible descriptions are compared. Obviously the equilibrium path is exactly the same but the better performances of the mixed description are evident even when a modified Newton-Raphson method (MN) is adopted.

4.2 A T beam

The second test regards the beam with data reported in Fig. 11. It consists in a simply supported beam with a T shaped section loaded by a shear force acting at the mid-span and by a small imperfection ($\epsilon = 1/1000$) load as reported in the same figure. The precritical behavior exhibits a strong nonlinearity and coupled bucklings are also present in this case. A mesh of $(9 + 9 + 18) \times 100$ elements has been used.

In Fig.12 the first 4 buckling modes, considered in the multimodal Koiter analysis, are plotted.

In Fig.13 the equilibrium paths recovered by using both asymptotic and path-following analysis are reported and compared. The solution is accurately recovered by the asymptotic strategy up to quite large displacements and the occurrence of a secondary bifurcation.

Also in this case (see Fig.14) the equilibrium path is plotted in terms of the modes amplitudes ξ_k showing a strong interaction among modes 1, 2 and 4.

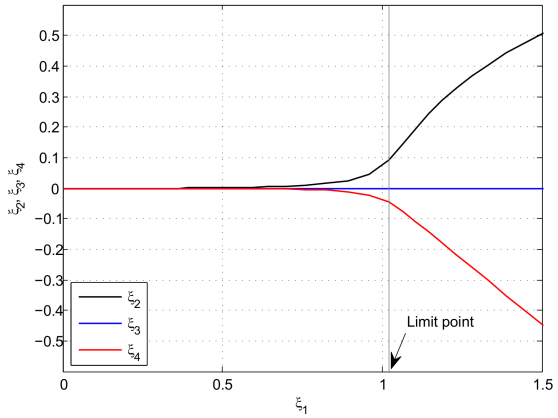

Figure 14: T section beam: Equilibrium paths in ξ_k space.

In Tab.6 the steps and iterations of the mixed, using both full o modified Newton (MN) methods, and compatible descriptions are compared. This example highlights the excellent performances of the mixed description even more than the previous test.

4.3 A simple frame

Finally Fig. 15 reports the geometry and the material properties of a simple portal frame, similar to that analyzed in [52]. It consists of two beams with a C shaped section loaded as depicted in the same figure. Coupled instability is present also in this case. Both the beams are discretized using a mesh of $(6+12+6)\times 40$ elements. The node discretization is automatically defined from those of the two beams.

In Fig.16 the first 3 buckling modes considered in the multimodal Koiter analysis are reported.

Also in this case the equilibrium paths recovered using both the asymptotic and path-following analysis are reported and compared in Fig.17. The frozen configuration asymptotic analysis furnishes a similar equilibrium path to the mixed one but an overestimate in the limit load. The mixed Koiter analysis accurately recovers the solution up to quite large displacements.

In Fig.18 the equilibrium path is plotted in terms of the modes amplitudes ξ_k showing a

strong interaction among modes 1, 2. In the same figure the deformed configuration at the limit point is also reported.

Finally in Tab.8 the steps and iterations required by the mixed, using full and modified Newton method, and compatible descriptions are compared.

5 Conclusions

In this paper the better performances of mixed elements in the nonlinear analysis of slender structures have been shown and explained. To focus on the origin of this behavior, which is independent of the finite element interpolation, a compatible description of a mixed 3D solid finite element has been derived. In this way it has been possible to show how the compatible description, and so any compatible finite element, is affected by an underhand and neglected extrapolation locking phenomenon that produces slow or lack of convergence for the path–following analyses and inaccurate solutions for the Koiter method. The occurence of the locking has been theoretically investigated and it has been indicated that it is due to the presence of directions with different stiffness as typically occurs for slender structures which are usually characterized by a high membranal/flexural stiffness ratio. These conclusions are general and hold for any nonlinear structural model and finite element.

Many advantages of solid elements in geometrically nonlinear analysis are already known in literature. In this paper we show further important properties of mixed solid FE within the Koiter asymptotic formulation. In fact, due to the simple 3rd order dependence of the strain energy on

	Mixed	Compatible	Mixed MN
steps	24	51	51
loops	73	196	198

Table 8: Simple Frame: steps and iterations for path–following analysis.

its FE parameters, all the higher order energy variations are null and so it is possible to have: i) an exact linear bifurcation analysis with improvements in its computational efficiency and accuracy for non near buckling loads; ii) simplification and greater accuracy in the evaluation of the energy variations required to recover the equilibrium path with a gain in terms of the computational cost; iii) a more simple and effective numerical method which is easy to include in FE packages.

Keywords: Local Buckling, Steel Structures, FE Analysis, Elastic-plastic Behavior, Thin-walled profiles, Imperfections

Abstract. *The present paper is focused on the development of an accurate computational method, based on the Finite Element (FE) approximation, for predicting the collapse behavior of thin-walled polygonal steel beams subject to bending. The numerical model has been created using the software ABAQUS, and has been validated with experimental data obtained from the literature, concerning rectangular hollow section (RHS) in the four-point-bending situation. The model has been improved by means of a thorough study of material hardening, imperfections and residual stresses. The computational results of the analyses have been compared with the design procedures provided by Eurocode 3 (effective cross-section method and reduced stress method), in order to check their suitability.*

1 INTRODUCTION

This paper describes the realization of a computational model for studying the flexural behaviour of polygonal, thin-walled sections at the ultimate limit state. This type of section is widely used as support of antennas in telecommunications, for lighting facilities and, in some cases, for small-scale wind turbines, see Figure 1.

(a)

(b)

Figure 1: Examples of application of beams with thin-walled polygonal cross-section: (a) lighting tower; (b) mast for small-scale wind turbines.

The main goal is to evaluate the flexural strength of the examined sections. Because of the high slenderness, these structures are subjected to local buckling phenomenon, which complicates the determination of the load-carrying capacity. After a literature survey, we realized that many Authors have considered the load-carrying capacity of polygonal section, even though in most cases the reference problem was represented by axial load only (see e.g. [1], [2], [3]). The basic formulation for local buckling due to bending can be retrieved in the classical textbook [4], which reports the stability assessment for elastic plates rigidly jointed along their edges, in order to obtain open and closed thin-walled profiles. An attempt for the numerical simulation of local buckling can be found in [5], which reports also some results of an experimental campaign. The load carrying capacity of such structures is widely influenced by the presence of imperfections: some relevant information on residual stresses and geometric information can be retrieved in [6], [7] and [8], whereas the effect of metalworking process has been considered in [9].

In this paper, a computational model has been devised and the results of the analyses are compared to the expeditious procedures provided by Eurocode 3 (effective cross-section method and reduced stress method), checking their suitability. The numerical model has been created using the software ABAQUS [10], and has been validated with experimental data obtained from the literature, concerning rectangular hollow section (RHS) [11]. The model was developed, improving on it with the addition of material hardening, imperfections and residual stresses. The relevant data have been taken from Eurocode 3, literature or by experimental tests. The critical comparison with respect to experimental data has been used in order to assess the validity of the model in terms of load-curvature response.

The analyses allowed us to understand the mechanisms by which the resistance develops in this type of sections. The comparison of the results of the numerical models with the Eurocode 3 ones has shown that often the legislation does not estimate accurately the resistance values. Moreover, in cases of tapered sections or lightened ones, the legislation proves to be deficient if not entirely inapplicable.

2 PROBLEM FORMULATION

The safety of slender steel beams can be endangered by the lack of stability in many different ways: global buckling refers to the overall collapse due to axial, bending, torsional or combined loads; distortional buckling is specially related to thin walled profiles, in terms of distortion of the cross-section with relative displacement of the nodes; local buckling, which is specifically treated in this paper, can be defined as the unstable behaviour of each single panel that constitute the cross-section, in the absence of global buckling and of relative displacement of the profile's nodes (which are basically fixed).

A simple treatment of local buckling is obtained by considering each panel as a plate subject to membrane loading and suitably constrained in order to account for the effect of adjacent plates. The axial compressive stress, which eventually lead to buckling, can be provided, for instance, by the overall bending moment, as shown in Figure 2.

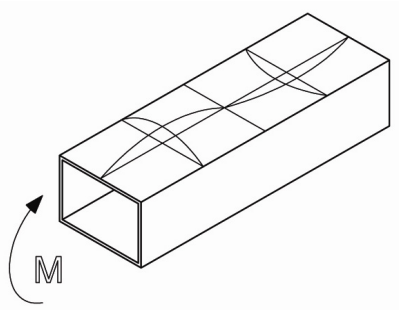

Figure 2: Local buckling of a thin-walled polygonal beam subject to bending moment M.

The simplistic approach is represented by the computation of the Eulerian critical load for elastic behaviour, in the case of simply supported rectangular plate (see [4]). In that way, one finds that the critical stress can be computed as:

$$\sigma_E = \frac{N_E}{t} = k_\sigma \frac{\pi^2 E}{12\left(1-\nu^2\right)}\left(\frac{t}{b}\right)^2 \tag{1}$$

where: b is the minimum width of the plate; t is its thickness; E and ν are the Young's modulus and the Poisson's ratio, respectively; k_σ is the load factor, which depends on the elastic distribution of axial stress. For instance, in the case of uniform compression (as it happens in the upper flange in Figure 2), one finds $k_\sigma = 4$; other values are reported in [4] for various non-uniform distributions.

A more reliable approach, which accounts for the post-critical behaviour, has been developed by Von Kármán on the basis of the concept of effective width [4]. Roughly speaking, the non-uniform stress distribution at plastic collapse is replaced by a piecewise constant distribution, with null value in the zone around the plate centre (which is assumed to be in the buckled configuration) whereas the lateral zones are subject to the yield stress for the given material. By enforcing the equivalence of the yield stress with the buckling tension of the effective zone, one finds:

$$\sigma_{cr}\left(b_{eff}\right)=f_y=k_\sigma\frac{\pi^2E}{12\left(1-\nu^2\right)}\left(\frac{t}{b_{eff}}\right)^2 \tag{2}$$

where b_{eff} is the sum of the length of the lateral zones subject to the yield stress.

This approach does not take into account the effect of imperfections, which play a paramount role in the evaluation of critical load. Imperfections in steel structures may have different nature but they can be divided into a couple of categories: mechanical imperfections and geometrical imperfections. The former include the presence of residual stresses, due to the specific metalworking procedure (e.g. hot rolling or cold forming), and the non-uniform distribution of pristine yield limit, due e.g. to the folding process. An example of this kind of imperfection, which is quite important for polygonal sections, is reported in Figure 3.

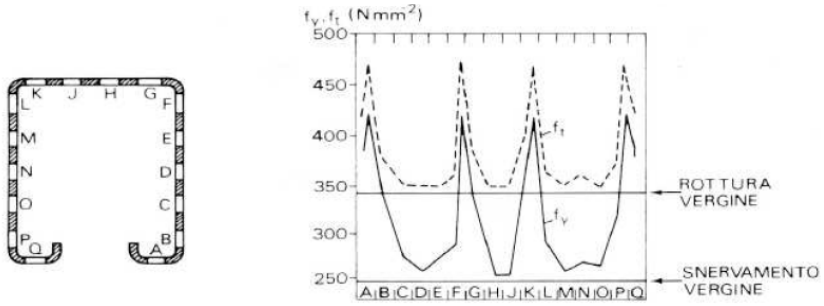

Figure 3: Typical distribution of the material properties on a cold-formed profile.

Geometric imperfections can be further divided into global defects (e.g. overall bow of the beam) and local defects (e.g. non-uniform thickness, lack of orthogonality, etc.). In the case of local buckling, the latter are by far more important. According to Eurocode 3 part 5, Annex C [12], the geometric imperfections can be modeled on the basis of the buckling modes (such as the one represented in Figure 2), with a recommended amplitude equal to 80% of the fabrication tolerances.

One theoretical approach, which accounts for the presence of imperfections, has been formulated by Winter [4]. The evaluation of the effective width is based on the dimensionless slenderness parameter λ_p:

$$\lambda_p=\sqrt{\frac{f_y}{\sigma_E}} \tag{3}$$

where the critical stress is referred to the whole width, see Equation (1). Winter proposed the following expression, which is assumed in the current code provisions [12]:

$$\frac{b_{eff}}{b}=\left(1-\frac{0.22}{\lambda_p}\right)\frac{1}{\lambda_p}\le 1 \tag{4}$$

A graphical comparison of the abovementioned approaches, in terms of the average collapse stress $\sigma_{L,}$ is reported in Figure 4.

In the present paper, a computational approach is preferred in order to capture the collapse load for the whole cross-section. A 3D Finite Element (FE) model has been devised, as better specified in the next section, and a set of non-linear static analyses have been carried out, encompassing the non-linear geometric effects and the elastic-plastic behaviour. In any case, a preliminary step has been represented by linear buckling analyses, in order to evaluate the

buckling modes which are used to model the geometric imperfections. The final load-curvature response has been obtained by applying an incremental (step-by-step) analysis with arc-length control. Such a provision is necessary in order to account for strongly unstable behaviour, such as snap-back or snap-through phenomena, that are likely to occur in the present structural case, dominated by imperfections. The analyses have been repeated for different width-to thickness ratios, with the purpose of evaluating the collapse behaviour in various cases. It is worth noting that the width-to-thickness ratio represent the basic parameter used to decide whether the considered section is prone to local buckling.

3 RESULTS

3.1 Finite Element model

The computational model has been tested with reference to experimental data, obtained at the University of Sidney, Australia, by Wilkinson and Hancock [11]. Those Authors have carried out a set of four-point bending tests on steel beams with rectangular hollow section (RHS). Several specimens with different thickness of the flanges have been tested, more specifically RHS 150x50x4, RHS 150x50x3 and RHS 150x50x2.3 (all the measurements are in millimeters); in that way, it was possible to evaluate the increasing sensitivity to imperfection for decreasing thickness. The scheme of the experiments is depicted in Figure 5a; conversely, Figure 5b shows a simplified model of a beam subject to pure bending. In the following, both models will be considered, since the *experiment model* (Figure 5a) was used for a direct comparison with the tests and the *simplified model* (Figure 5b) could be adopted for further generalization and application to cross-sections of different shapes. The main outcome of the experimental campaign was a set of moment-curvature plots, which are normalized with respect to the elastic limit moment (M_p, namely the moment that corresponds to the first attainment of yield stress in the worst point on the cross-section) and to the corresponding curvature (χ_p, given by the elastic limit moment M_p divided by the elastic stiffness EI).

The Finite Element model was represented by a fine discretization of the RHS beams, using quadrilateral shell elements. In view of the very small thickness of the flanges, we chose a formulation which is suitable for thin shells, thus neglecting the shear deformation. Linear, 4-node, elements have been used, with 5 degrees of freedom per node and reduced integration with hourglass mode control. The FE mesh has been chosen after the convergence analyses and is more refined in the central zone, as shown in Figure 6. The *experiment model* included also the discretization of the load posts and of the bearing devices.

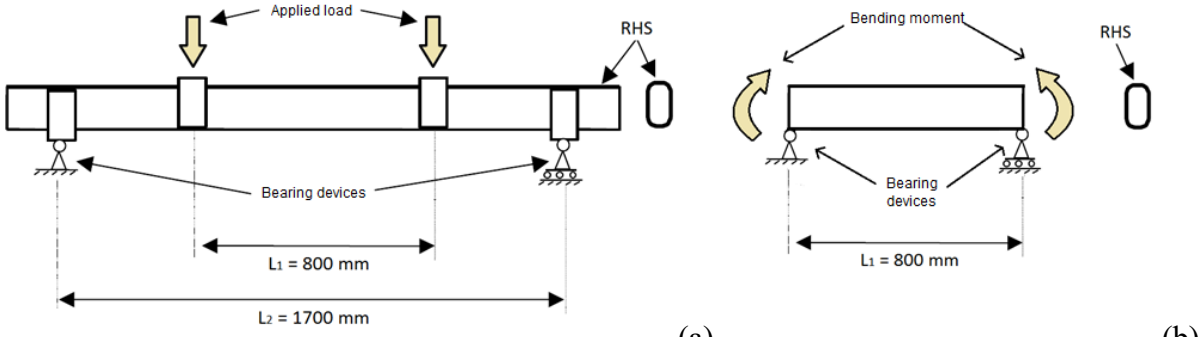

Figure 5: Scheme of the models considered in the computational analyses: (a) *experiment model*, which shares the geometric features with the tests in [11]; (b) *simplified model*, used for further generalization.

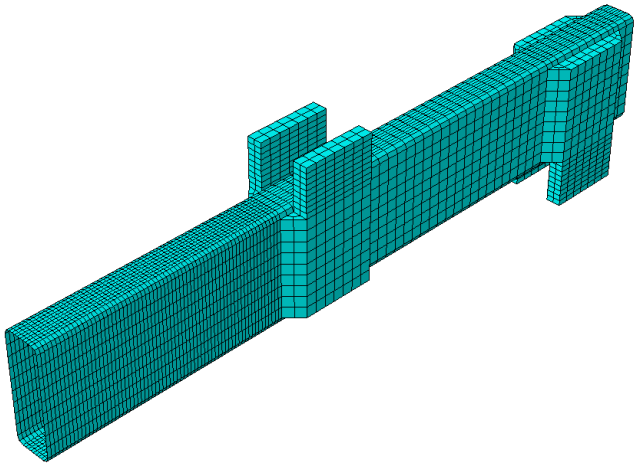

Figure 6: Typical FE model adopted in the non-linear analyses until collapse.

The preliminary step was represented by linear buckling analyses. In that way, it was possible to have an idea of the different buckling modes, shown in Figure 7: (a) local buckling due to compression on the upper flange; (b) local buckling due to bending on the vertical flanges; (c) local buckling due to shear on the lateral bays; (d) overall buckling. The knowledge of buckling modes was also necessary in order to include geometric imperfection in the subsequent non-linear analyses.

The collapse analyses, based on the arc-length method, included non-linearity from the geometric point of view and for material behavior. An elastic-plastic model, based on the Mises' yield function, has been adopted. Non-linear hardening was included, with the main purpose of simulating the actual behavior of steel specimens extracted from the tested structure [11]. It is worth noting that the material law was not uniform in space: indeed, due to fabrication process, the material close to the corners is more resistant and more brittle than the material in other locations. More specifically, three different zones have been considered: corners, horizontal flanges, vertical flanges (see Figure 8).

The optimal version of the FE model has been obtained after several parametric analyses. First, the effect of imperfections, both in terms of amplitude and in terms of shape, was considered. Nice results have been obtained by considering the imperfection as proportional to the first local buckling mode (see Figure 7a), with a typical amplitude equal to 1/250 ÷ 1/500 of the beam's height. The effect of residual stresses was included as well: we finally adopted the typical values proposed by [6] and [7] (ranging between 0.08 f_y and 0.17 f_y, in correspondence of the longitudinal weld and of other locations, respectively).

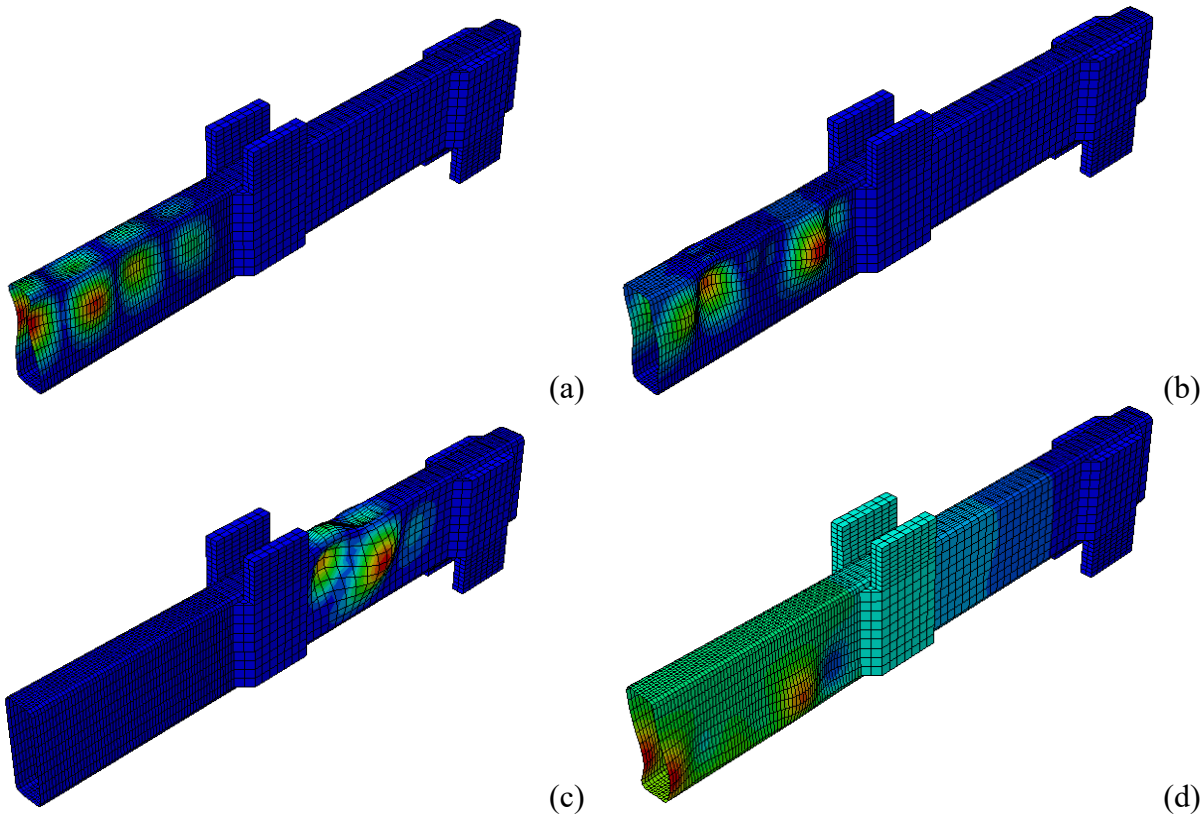

Figure 7: Results of the preliminary buckling analyses: (a), (b) local buckling for bending; (c) local buckling for shear; (d) overall buckling.

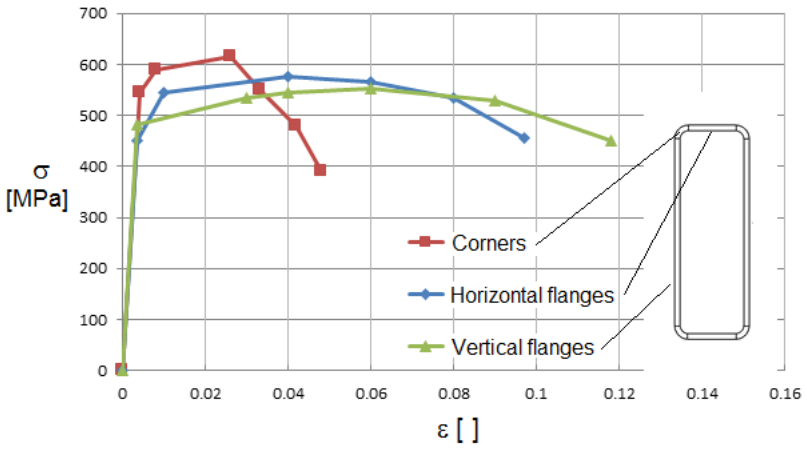

Figure 8: Uniaxial elastic-plastic material behavior for different zones of the RHS cross-sections.

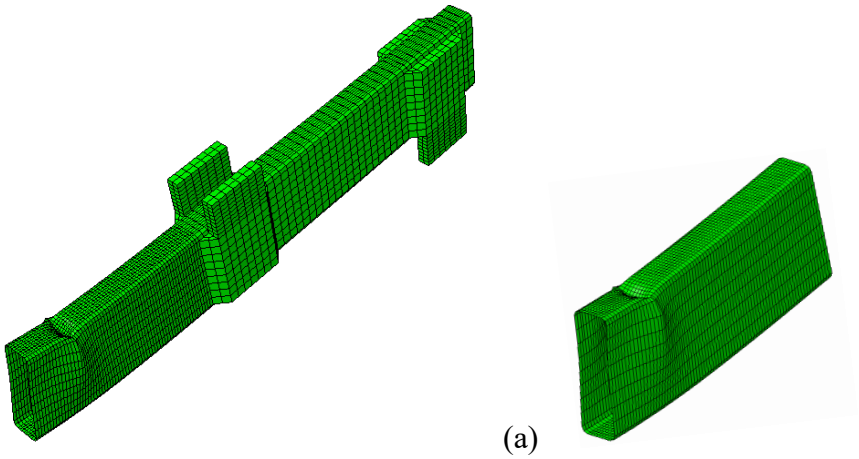
3.2 Comparison of load-curvature responses

The optimal FE model, which did not include any fitting parameter, provided us the collapse load (see Figure 9 for the final deformed shape) and (after some post-processing) the load-curvature response (see Figure 10-12).

Generally speaking, satisfactory agreement between experimental and numerical data was obtained. The ultimate bending moment was captured with a reasonable relative error in all the considered cases; the ultimate curvature (as well as the initial stiffness) was very well simulated; also the deviation from linearity, owing to second-order geometric effects, was attained at the same load level with respect to the experimental outcomes.



(a) (b)

Figure 9: Deformed shape at collapse: (a) *experiment model*; (b) *simplified model*.

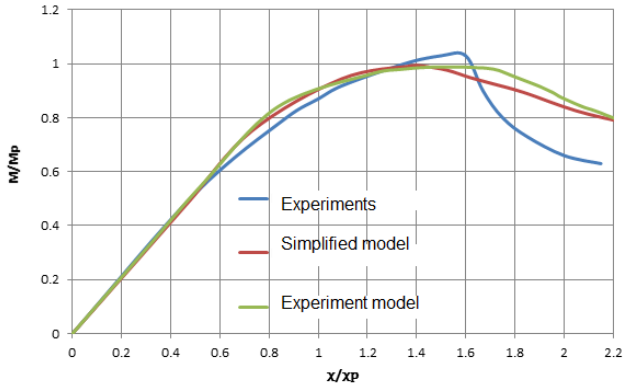


Figure 10: Load-curvature response for RHS 150x50x2.3.

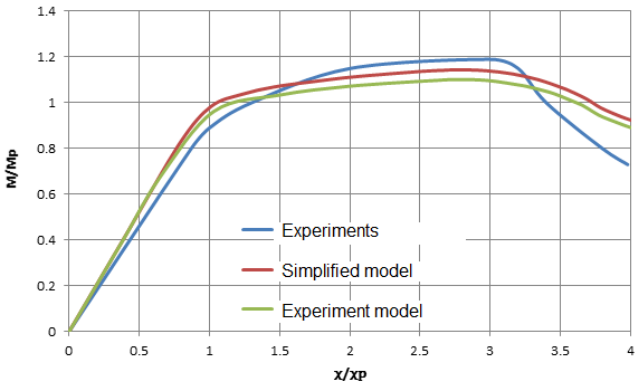

Figure 11: Load-curvature response for RHS 150x50x3.

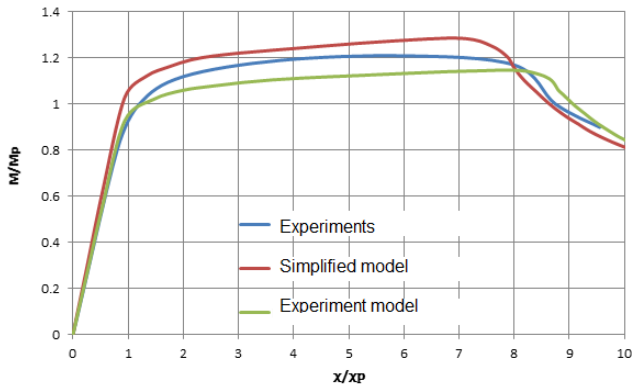

Figure 12: Load-curvature response for RHS 150x50x4.

Some differences between the curves could be due to the spatial discontinuities of the constitutive law. In the real case, the stress-strain model is smoothly changing between the various parts of the section highlighted in Figure 8, conversely the FE model includes piecewise constant material laws. Another cause of discrepancies could be represented by the stochastic nature of imperfections, which turned out to play a paramount role in the definition of the collapse load.

All the analyses have been repeated by adopting the *simplified model*: as a matter of fact, some differences arose with respect to the *experiment model*. Even though the curves shared the same shape, the simplified model involved slightly larger ultimate loads. The difference could be explained by considering the effect of the loading posts, which have been completely modeled in the experiment model and are totally absent in the simplified model. However, both model revealed to be adequate to catch, with sufficient accuracy, the experimental response. This provided a sound validation of the computational models.

4 CONCLUSIONS

An optimized FE model for the collapse analyses of polygonal steel beams has been proposed and validated against reliable experimental data. Satisfactory agreement between the computational outcomes and the experimental data has been achieved, so that the computational model is basically ready to be used in other cases. As an example, the case of hexagonal or octagonal profiles could be considered, in order to execute the safety assessment of structures with practical interest.

The presence of a computational tool for that kind of structures is specifically important, since the application of simplified formulas, which can be retrieved in the Eurocode (EC) [15], is rather questionable for polygonal cross-section with six sides or more. As an example, we considered the theoretical computation of ultimate moment for three cases of RHS: the results are summarized in Table 1. One can easily realize that the formula proposed by the EC, though very simple to be used, finally yields poorly approximate results, which are not on the safe side (the ultimate moment is overestimated by the EC procedure). Some current research, which will be reported in a forthcoming paper, shows that the inaccuracy of EC formulas is even larger for sections with six sides or more

Section	*Class*	M_u *(EC)* *[kN·m]*	M_u *(FE)* *[kN·m]*	*Δ* *[%]*
RHS 150x50x2	3	12.36	11.91	+ 3.73
RHS 150x50x3	1	23.05	20.51	+ 12.38
RHS 150x50x4	1	29.95	28.69	+ 4.38

Table 1: Comparison between the ultimate moment obtained via the numerical procedure (FE) and the formula proposed by the Eurocode (EC).

Keywords: geometric nonlinearity, material nonlinearity, elastic constitutive laws, trusses, structural stability.

Abstract. *In this paper, the influence of several elastic constitutive laws upon the stability analyses of plane trusses is discussed. The chosen laws are connected to the engineering strain, Green's strain and logarithmic strain concepts. A geometrically exact nonlinear formulation for a truss bar element is developed for each of them and the correspondent tangent stiffness matrices are obtained.*

The stability analyses of some sample plane trusses are performed by finding the conditions when the determinant of their respective global tangent stiffness matrices is found to be zero. The first example is a symmetric two-bar structure and both limit loads and buckling loads are plotted for the full range of possible initial inclination angles of the bars, for the three chosen constitutive laws. A similar truss with an extra vertical bar is studied to discuss possible material instability if Green's strain concept is adopted.

1 INTRODUCTION

The presented direct formulation of the geometrically exact nonlinear theory of elastic trusses is of great simplicity and elegance and has already been obtained, for plane trusses and adopting the engineering strain concept, in a pioneer paper by Turner et al (1960) [5].

The central idea of this approach can be abstracted as follows, following Levy and Spillers (1995) [2]. Let the equation of equilibrium of a system be written as

$$\mathbf{P} = \mathbf{C}\mathbf{N} \tag{1}$$

where **P** represents the applied loads, **N** the internal forcers or stresses and **C** an appropriate equilibrium operator. Under a load perturbation *d***P**, the system responds as

$$d\mathbf{P} = \mathbf{C}\, d\mathbf{N} + d\mathbf{C}\,\mathbf{N} \tag{2}$$

For discrete systems such as trussed structures it turns out to be relatively simple matter to convert this equation into the usual

$$d\mathbf{P} = \mathbf{K_T}\, d\mathbf{q} \tag{3}$$

where $d\mathbf{q}$ represents the system's incremental generalized displacements and $\mathbf{K_T}$ is the tangent stiffness matrix containing the usual elastic and geometric stiffness matrices. With this approach, which is followed throughout this paper, nonlinear structural analysis becomes simply an application of Newton-Raphson's method of nonlinear equations solution.

2 GENERAL THEORY

In the geometrically exact theory for trusses, no restrictions are made to the amplitude of angular deflections. Let us consider the plane truss bar of Fig. 1. Its initial length is *L*. The relationships between the vector of nodal displacements **q** of a plane truss bar and the values of θ and L' (the angle between the displaced position of the bar and its original position and the deformed length of the bar, respectively) are

$$L' - L = \mathbf{c}\,\mathbf{q} \tag{4}$$

where

$$\mathbf{c} = \begin{bmatrix} -\cos\theta & -\sin\theta & \cos\theta & \sin\theta \end{bmatrix} \tag{5}$$

$$\mathbf{q} = \begin{bmatrix} q_1 & q_2 & q_3 & q_4 \end{bmatrix}^t \tag{6}$$

To compute the strain ε_i (with *i*= 1 for engineering strain, *i* = 2 for Green's strain and *i* = 3 for logarithmic or natural strain) the following expressions are used, according to Argyris *et al* (1960) [1],

$$\varepsilon_1 = \lambda - 1 \tag{7}$$

$$\varepsilon_2 = \frac{\lambda^2 - 1}{2} \tag{8}$$

$$\varepsilon_1 = \ln\lambda \tag{9}$$

where $\lambda = L'/L$.

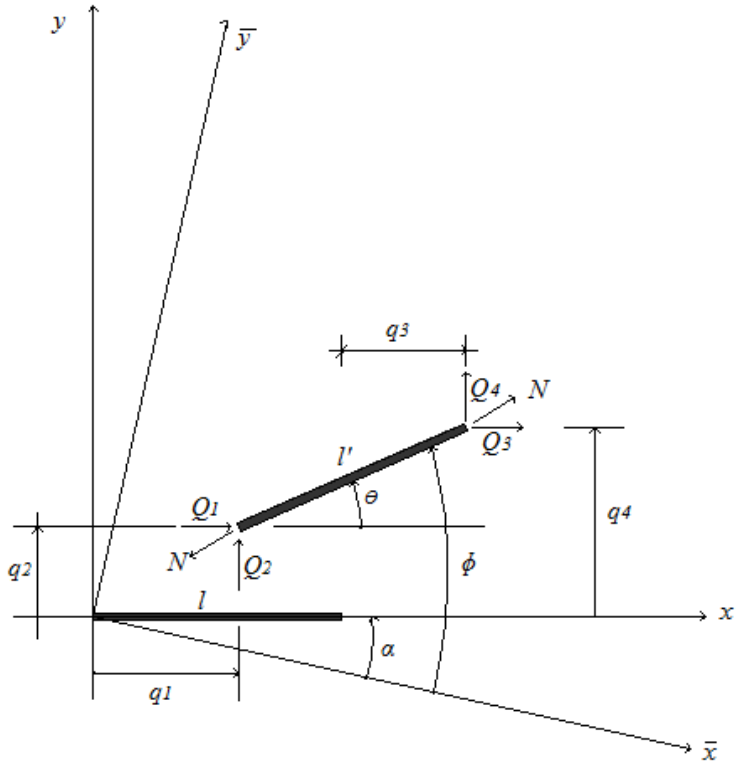

Figure 1: Reference and actual configuration of a truss element

The exact values of the components of nodal forces, as depicted in Fig. 1, are

$$\mathbf{Q} = N\,\mathbf{c}^t \tag{10}$$

where

$$\mathbf{Q} = \begin{bmatrix} Q_1 & Q_2 & Q_3 & Q_4 \end{bmatrix}^t \tag{11}$$

and N is the normal force in the bar. The constitutive laws render the actual normal stress σ_i by the following expressions

$$\sigma_1 = E_1 \varepsilon_1 \tag{12}$$

$$\sigma_2 = \lambda E_2 \varepsilon_2 \tag{13}$$

$$\sigma_3 = E_3 \frac{\varepsilon_3}{\lambda} \tag{14}$$

where E_i is the elastic modulus correspondent to the chosen strain concept.

Thus, the normal force is given, for each constitutive law, by

$$N_i = \sigma_i\, A \tag{15}$$

where A is the area of the cross section of the bar.

To obtain the expression of the tangent stiffness matrix $\mathbf{k_T}$, one must differentiate Eq. 10 to get

$$d\mathbf{Q} = \mathbf{c}^{\mathbf{t}}\, dN + N\,\mathbf{s}^{\mathbf{t}}\, d\theta \tag{16}$$

where

$$\mathbf{s} = \begin{bmatrix} \sin\theta & -\cos\theta & -\sin\theta & \cos\theta \end{bmatrix} \tag{17}$$

Next, one must establish relationships between the differentials $d\theta$ and dN and the displacement increments $d\mathbf{q}$. To that end, Eqs. 4 and 15 are used, to obtain

$$d\theta = \frac{1}{L}\mathbf{s}\, d\mathbf{q} \tag{18}$$

$$dN = \frac{1}{L} D_i\, A\mathbf{c}\, d\mathbf{q} \tag{19}$$

where

$$D_1 = E_1 \tag{20}$$

$$D_2 = \frac{E_2}{2}\left(3\lambda^2 - 1\right) \tag{21}$$

$$D_3 = \frac{E_3}{\lambda^2}\left(1 - \ln\lambda\right) \tag{22}$$

It is now necessary to introduce into Eq. 16 the values of $d\theta$ and dN given by Eqs. 18 and 19, to obtain

$$d\mathbf{Q} = \left(\frac{D_i A}{L}\mathbf{c}^{\mathrm{t}}\mathbf{c} + \frac{N_i}{L'}\mathbf{s}^{\mathrm{t}}\mathbf{s} \right) d\mathbf{q} \tag{23}$$

the equation that renders the tangent stiffness matrix of the exact theory for each of the elastic constitutive laws adopted:

$$\mathbf{k_T} = \frac{D_i A}{L}\mathbf{c}^{\mathrm{t}}\mathbf{c} + \frac{N_i}{L'}\mathbf{s}^{\mathrm{t}}\mathbf{s} \tag{24}$$

As in the usual matrix analysis of structures, once the tangent stiffness matrix of the bar in the local reference frame is known, its counterpart in the global one is easily obtained by the rotation formula, given, by example, by Meek (1991)[3],

$$\bar{\mathbf{k}}_{\mathbf{T}} = \mathbf{T}^{\mathrm{t}}\mathbf{k_T}\mathbf{T} \tag{25}$$

where

$$\mathbf{T} = \begin{bmatrix} \cos\alpha & \sin\alpha & 0 & 0 \\ -\sin\alpha & \cos\alpha & 0 & 0 \\ 0 & 0 & \cos\alpha & \sin\alpha \\ 0 & 0 & -\sin\alpha & \cos\alpha \end{bmatrix} \tag{26}$$

and α is the angle between the original direction of the bar and the $\bar{x}$ axis of the global reference frame, as shown in Fig. 1.

As a more practical alternative, one can introduce the new matrices

$$\bar{\mathbf{c}} = \begin{bmatrix} -\cos\phi & -\sin\phi & \cos\phi & \sin\phi \end{bmatrix} \tag{27}$$

$$\bar{\mathbf{s}} = \begin{bmatrix} \sin\phi & -\cos\phi & -\sin\phi & \cos\phi \end{bmatrix} \tag{28}$$

where $\phi = \theta + \alpha$, which are related to Eqs. 5 and 17 by

$$\bar{\mathbf{c}} = \mathbf{cT} \tag{29}$$

$$\bar{\mathbf{s}} = \mathbf{sT} \tag{30}$$

Thus, a new form of the tangent stiffness matrix of the truss member in the global reference frame is

$$\bar{\mathbf{k}}_{\mathbf{T}} = \frac{D_i A}{L}\bar{\mathbf{c}}^{\mathbf{t}}\bar{\mathbf{c}} + \frac{N_i}{L'}\bar{\mathbf{s}}^{\mathbf{t}}\bar{\mathbf{s}} \tag{31}$$

which is formally identical to Eq. 24.

To obtain the tangent stiffness matrix of the structure as a whole, the following summation process is extended to all members of the system

$$\mathbf{K}_{\mathbf{T}} = \sum \mathbf{A}^{\mathbf{t}}\bar{\mathbf{k}}_{\mathbf{T}}\mathbf{A} \tag{32}$$

where **A** is the usual incidence matrix of each bar.

3 THE FIRST EXAMPLE

The first chosen example is the classic two bars truss whose stability was studied by Ratzersdorfer (1936) [4], also known as von Mises truss, depicted in Fig. 2.

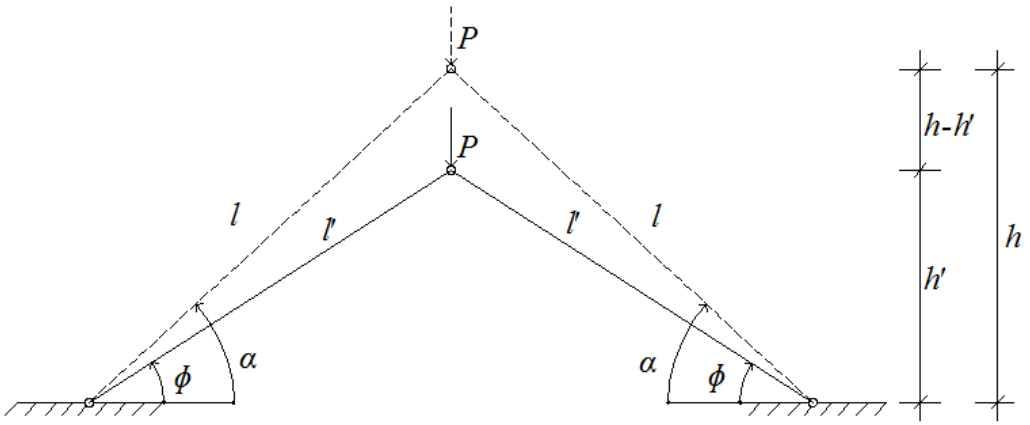

Figure 2. The first example

As it is well known, depending to the initial geometry, either bifurcation or limit point instabilities may happen. The original length of the bars is L and their original inclination α. After a vertical load P is applied to the central node the length of the bars becomes L' and their inclination ϕ.

If the exact theory is applied, the tangent stiffness matrix associated to the two degrees of freedom of the central node is

$$\mathbf{K}_{\mathbf{T}} = \frac{2D_i A}{L}\begin{bmatrix} \cos^2\phi & 0 \\ 0 & \sin^2\phi \end{bmatrix} + \frac{2N_i}{L'}\begin{bmatrix} \sin^2\phi & 0 \\ 0 & \cos^2\phi \end{bmatrix} \tag{33}$$

where the constant D_i and the normal force N_i depend on the particular constitutive law chosen.

The instability criterion is that the determinant of this matrix must be zero.

3.1 Engineering Stain

For the engineering strain constitutive law, the instability criterion is

$$\left(\sin^2\phi\cos\phi-\cos\alpha\right)\left(\cos^3\phi-\cos\alpha\right)=0 \tag{34}$$

The condition for lateral buckling of the structure is given by

$$\sin^2\phi\cos\phi=\cos\alpha \tag{35}$$

and the corresponding buckling load is

$$P_b=2E_1A\cos^2\phi\sin\phi \tag{36}$$

Limit point instability (snap-through) may be reached according to the condition

$$\cos^3\phi=\cos\alpha \tag{37}$$

and the corresponding buckling load is

$$P_l=2E_1A\sin^3\phi \tag{38}$$

In Fig. 3, both bucking and limit loads are plotted for the full range of possible initial inclination angles of the bars. One should note that for $\alpha > 68.898^o$ bifurcation instability (lateral buckling) will prevail with bucking loads given by the lower branch of the respective curve. For α bellow that value the structure may undergo snap through instability. It is important to see that this value, denoted as point A in the figure, is slightly different from that of the tangential point between the limit point and buckling curves, where $\phi = 45^o$ and $\alpha = 69.295^o$.

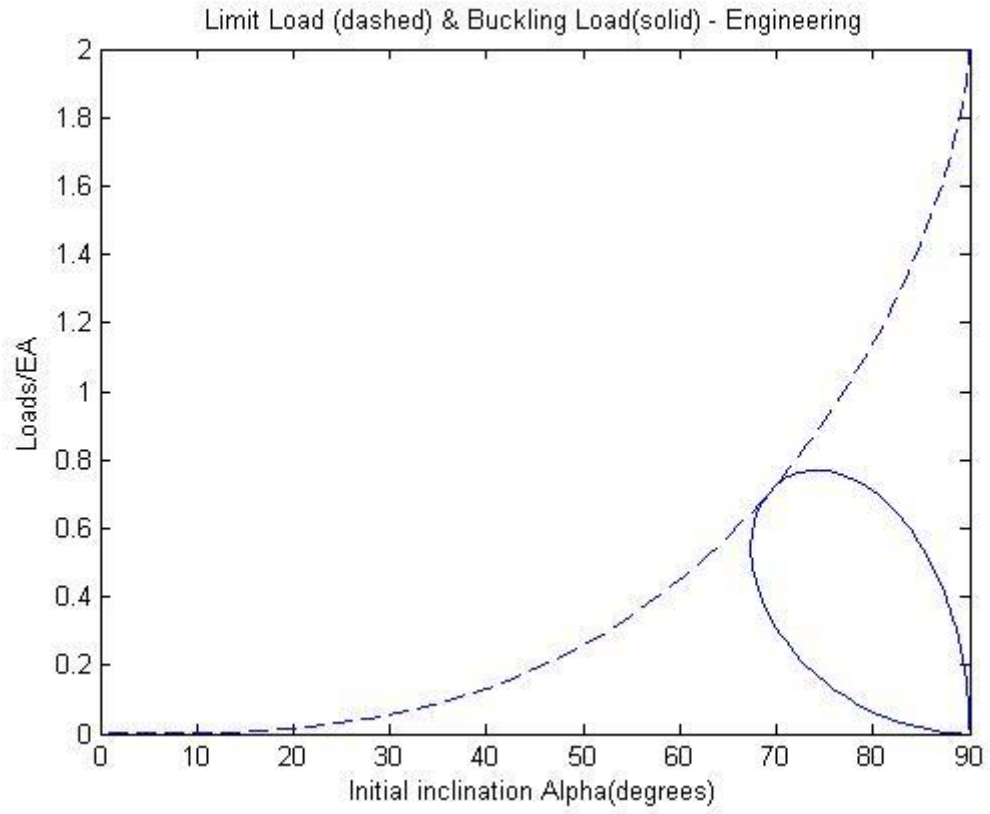

Figure 3: Instability loads, First Example, Engineering Strain

3.2 Green's Strain

For this strain definition, the condition for lateral buckling of the structure is given by

$$\tan^2 \phi = \tan^2 \alpha - 2 \tag{39}$$

and the corresponding buckling loads are

$$P_b = 2E_2 A \cos^3 \alpha \sqrt{\tan^2 \alpha - 2} \tag{40}$$

For Green's strain, limit point instability (snap-through) may be reached according to the condition

$$\tan \phi = \frac{\sqrt{3}}{3} \tan \alpha \tag{41}$$

and the limit load is

$$P_l = \frac{2\sqrt{3}}{9} E_2 A \sin^3 \alpha \tag{42}$$

In Fig. 4, both bucking and limit loads are plotted for the full range of possible initial inclination angles of the bars. One should note that for $\alpha > 60^o$ bifurcation instability (lateral buckling) will prevail with bucking loads given by the right branch of the respective curve. For α bellow that value the structure may undergo snap through instability. It is important to see that this value is exactly that of the tangential point between the limit point and buckling curves.

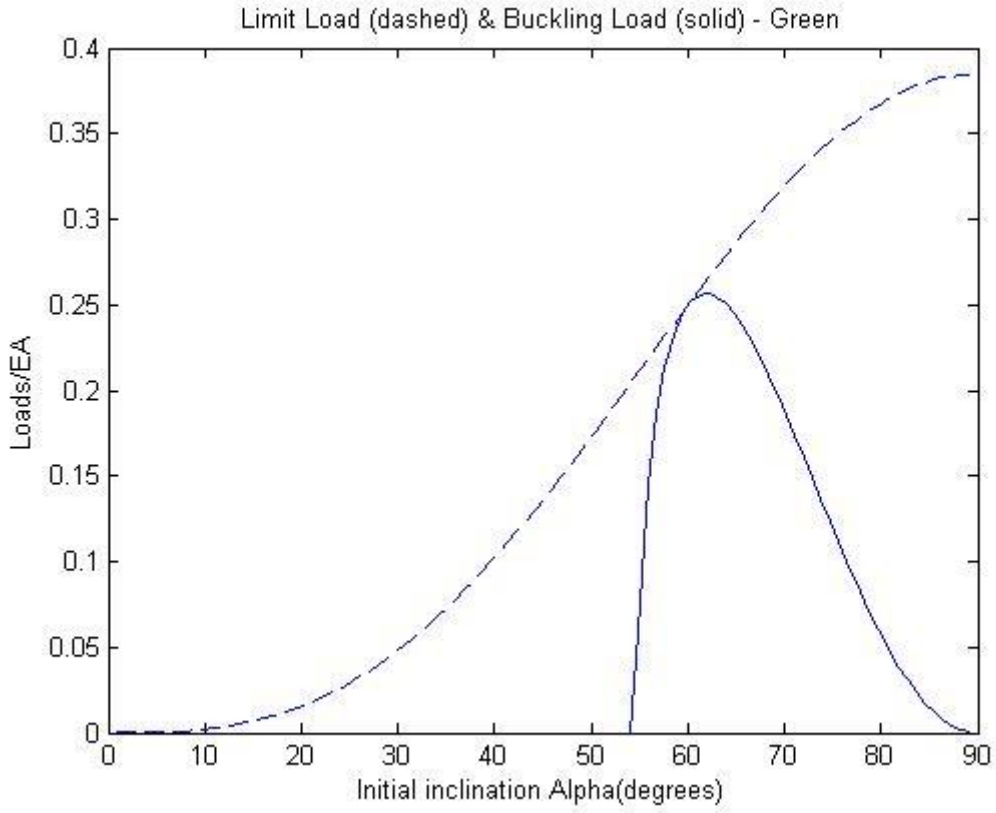

Figure 4: Instability loads, First Example, Green's Strain

3.3 Logarithmic Strain

For this strain definition, the condition for lateral buckling of the structure is given by

$$\lambda^2 \ln\lambda + (1-2\ln\lambda)\cos^2\alpha = 0 \tag{43}$$

For natural strain, limit point instability (snap-through) may be reached according to the condition

$$\lambda^2(1-\ln\lambda) - (1-2\ln\lambda)\cos^2\alpha = 0 \tag{44}$$

Instability loads for both cases are given by

$$P = -\frac{2E_3A}{\lambda^2}\ln\lambda\sqrt{\lambda^2-\cos^2\alpha}. \tag{45}$$

In Fig. 5, both bucking and limit loads are plotted for the full range of possible initial inclination angles of the bars. It is important to see that the two curves never touch each other and for α >71.278º bifurcation instability (lateral buckling) will prevail with bucking loads given by the lower branch of the respective curve. For α bellow that value the structure may undergo snap through instability.

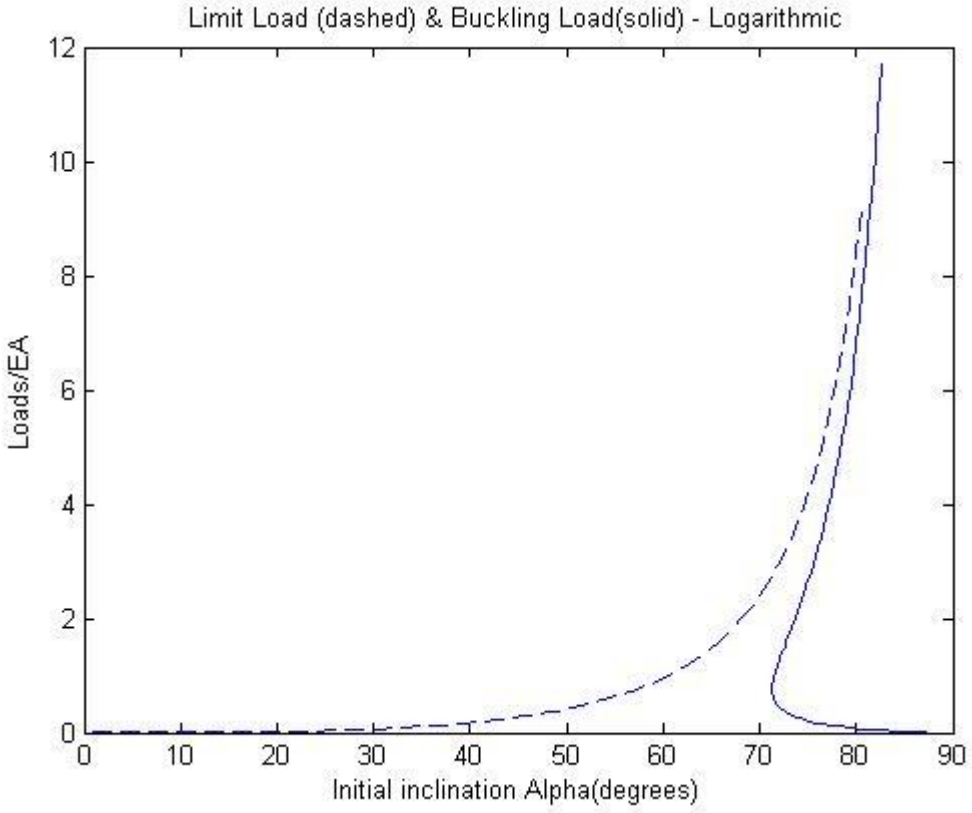

Figure 5: Instability loads, First Example, Natural or Logarithmic Strain

4 THE SECOND EXAMPLE

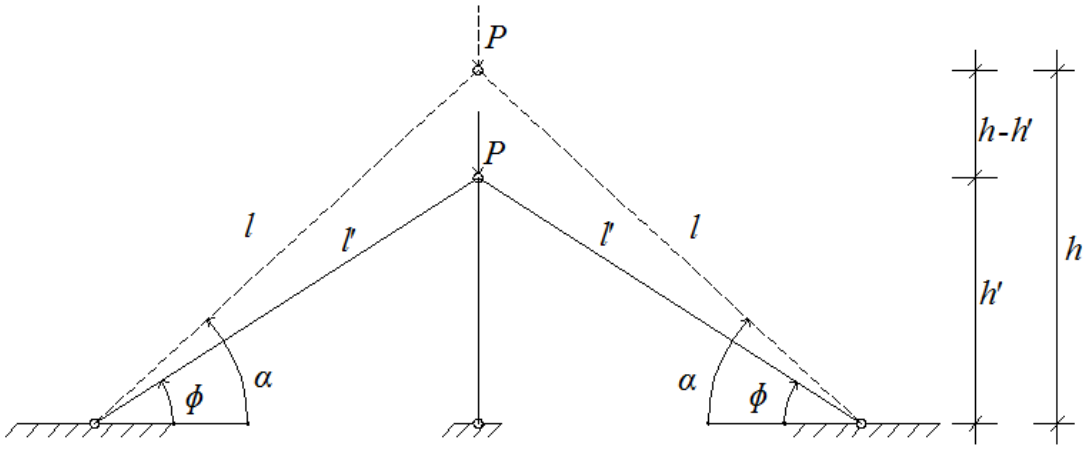

Figure 6: The Second Example

The structure of Fig. 6, similar to the first example except for an extra vertical bar under the upper node, is now analyzed using Green's strain constitutive law. The starting point is Eq. 32 which gives the contribution of the two inclined bars to the tangent stiffness matrix of the structure.

By adding to this equation the new term:

$$\mathbf{k_T} = \frac{E_2 A}{2h}\left(3\lambda_V^2 - 1\right)\begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix} + \frac{V}{h'}\begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \tag{46}$$

where

$$\lambda_V = \frac{h'}{h} = \frac{\tan\phi}{\tan\alpha} \tag{47}$$

is the stretching of the vertical bar, the complete $\mathbf{K_T}$ is found to be

$$\mathbf{K_T} = \frac{2D_2 A}{L}\lambda^2\begin{bmatrix} \cos^2\phi & 0 \\ 0 & \sin^2\phi\left(1+1/2\ \csc^3\alpha\right) \end{bmatrix} + \left(\frac{2N_i}{L'} + \frac{V}{L'}\csc\phi\right)\begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \tag{48}$$

In Eq. 47,

$$N = \frac{E_2 A\lambda(\lambda^2 - 1)}{2} \tag{49}$$

and

$$V = \frac{E_2 A\lambda_V(\lambda_V{}^2 - 1)}{2} \tag{50}$$

according to the assumed constitutive law.

The instability criterion requires the determinant of this matrix to be zero. The first condition, corresponds to the lateral buckling of the structure and leads to the buckling load:

$$P_b = 2E_2 A \cos^3 \alpha \tan \phi \tag{51}$$

The second condition corresponds to a null value of the stiffness coefficient related to the vertical displacement of the upper node. However, this is not an indication of a genuine snap snap-through phenomenon, but is a consequence of the material instability inextricably present in the constitutive law.

This assertion can be easily proven from Eqs. 13 and 21 and:

$$\sigma_2 = \lambda E_2 \varepsilon_2 = \frac{E_2}{2} \lambda(\lambda^2 - 1) \tag{52}$$

The zero value of its derivative is

$$3\lambda^2 - 1 = 0 \tag{53}$$

which gives the limit value:

$$\lambda_l = \frac{\sqrt{3}}{3} \tag{54}$$

This is the very value that is obtained combining the definition of λ_V given by Eq. 46 with the condition of Eq. 53:

$$\lambda_V = \frac{\tan \phi}{\tan \alpha} = \frac{\sqrt{3}}{3} \tag{55}$$

In Fig. 7, both bucking and limit loads are plotted for the full range of possible initial inclination angles of the bars. It is important to see that limit point and buckling curves touch each other in two points. One should note that for $\alpha < 10^o$ bifurcation instability (lateral buckling) will prevail with bucking loads given by the left branch of the respective curve. For $10^o<\alpha<50^o$the structure may undergo snap through instability. For larger values of α the structure may experience bifurcation (lateral buckling) instability, with buckling loads given by the right branch of the respective curve.

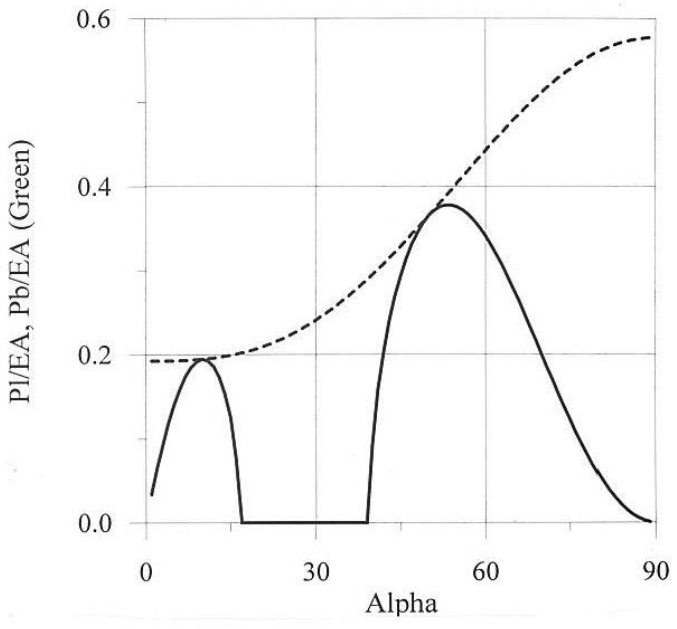

Figure 7: Instability loads, Second Example, Green's Strain

5 CONCLUSIONS

In this paper, the influence of several elastic constitutive laws upon the stability analyses of plane trusses is discussed. The chosen laws are connected to the engineering strain, Green's strain and logarithmic strain concepts. A geometrically exact nonlinear formulation for a truss bar element is developed for each of them and the correspondent tangent stiffness matrices are obtained.

The stability analyses of some sample plane trusses are performed by finding the conditions when the determinant of their respective global tangent stiffness matrices is found to be zero. The first example is a symmetric two-bar structure and both limit loads and buckling loads are plotted for the full range of possible initial inclination angles of the bars, for the three chosen constitutive laws. A similar truss with an extra vertical bar is studied to discuss possible material instability if Green's strain concept is adopted.

Keywords: Stiffened panels, Ultimate strength, Combined load, Nonlinear.

Abstract. *Ultimate strength of stiffened panels of Ship Structures can evaluate the bearing capacity of stiffened plate structure more accurately, and it provides a way to evaluate the safety and reliability of the hull structure. A lot of studies on ultimate strength of the hull structure are basically focused on stiffened panels under uniaxial compression, without considering combined load acting on the hull structure.But in the voyage, the hull structure is subjected to combined effect involved with various type of external loads at the same time. These external loads will inevitably have some impact on the ultimate strength of the hull structure. So it is necessary to study the ultimate strength of the stiffened panels under combined load. The nonlinear finite element method was introduced based on the assessment requirements of buckling and ultimate strength of stiffened panels in IACS Common Structural Rules for Double Hull Oil Tankers. Some important factors of influence such as the structural dimensions, element size, boundary conditions, initial imperfections and loading types are studied. To check the accuracy of the analysis performed in this method.Numerical results were compared with data in the Background Document of buckling strength assessment in CSR and results calculated by empirical formulations performed by other researchers. This paper focuses on investigating the effect of combined load on the ultimate strength of stiffened plates by calculating the ultimate strength of stiffened plates under combined biaxial compression and lateral pressure loads, by means of the famous nonlinear finite element software Ansys. The different influence on the ultimate strength of the stiffened plates are analyzed.*

1 INTRODUCTION

The traditional checking method of ship structure strength checking based on linear elastic rationale. The impact of material nonlinearity and geometric nonlinearity caused by other factors not be considered,therefore it can not accurately assess the true strength reserve hull structure. "Common Structural Rules for Double Hull Oil Tankers" (herein after referred to as CSR-OT) introduced the concept of the ultimate strength of stiffened panels what can evaluate the bearing capacity of stiffened plate structure [1]. A lot of studies on ultimate strength of the hull structure are basically focused on stiffened panels under uniaxial compression, without considering combined load acting on the hull structure. But in the voyage, the hull structure is subjected to combined effect involved with various type of external loads at the same time. These external loads will inevitably have some impact on the ultimate strength of the hull structure. So it is necessary to study the ultimate strength of the stiffened panels under combined load. The nonlinear finite element method was introduced based on the assessment requirements of buckling and ultimate strength of stiffened panels in IACS Common Structural Rules for Double Hull Oil Tankers. This paper focuses on investigating the effect of combined load on the ultimate strength of stiffened plates by calculating the ultimate strength of stiffened plates under combined biaxial compression and lateral pressure loads.

2 NON-LINEAR FINITE ELEMENT ANALYSIS

Ultimate strength can be performed using the element analysis software ANSYS. The paper adopts ANSYS nonlinear finite element method for ultimate limit state assessment.

2.1 Geometric and Material Properties

For the current research a VLCC double hull oil tanker structure designed by CSR method is studied. The deck panel is chosen for the analysis purposes. Geometrical properties of the stiffened panel of the deck of the object ship are tabulated as follows:

The length of the panel is L=5640 mm. The longitudinal stiffener spacing is w=850 mm, because the number of longitudinal stiffeners with the type of Tee bar is 6. Therefore, the total breadth of the stiffened panel is W=5100mm.The plate thickness is t=21mm. The stiffener height (dw) is 393 mm and the stiffener webthickness (tw) is 13 mm. The stiffener flange breadth (df) is 172 mm and the stiffener flange thickness (tf) is 17mm. Young's modulus of the material is E=205.8 GPa, and Poisson's ratio is v=0.3. The yield stress is σy =315 MPa for both plating and stiffeners. A plastic tangent modulus of 1000MPa is acceptable for higher strength steel.

2.2 Structural Modeling.

The extent of the model used in the ultimate strength assessment is to be sufficient to account for the structure that is surrounding the panel of interest, and to reduce the uncertainties introduced through the boundary conditions.

In general, the model is to include more than one stiffener span in the stiffener direction and the portion between two primary support members in the direction normal to the stiffeners [2].

The structural model and assessment method applicable for deck is to be taken as:

(a) parallel to the stiffener direction: at least two frame bays, in order to model imperfections between adjacent panels.

(b) normal to the stiffener direction: between primary support members, but maybe limited to six stiffener spacings.

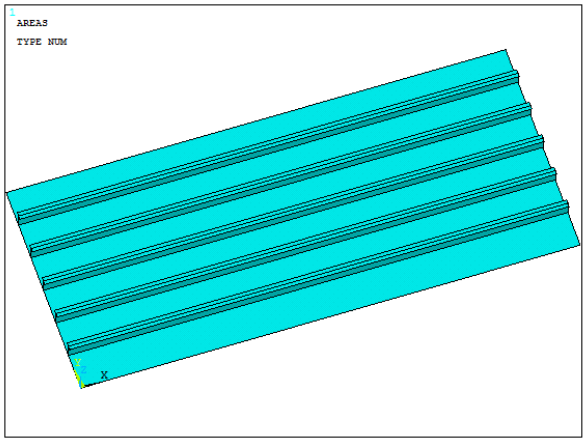

Figure 1: Stiffened plate geometry.

For the present nonlinear FEA, a half+one+half-bay model (1/2+1+1/2-bay model) in the length (x) direction is applied to accurately take into account the effect of rotational restraints along transverse floors, as described in Fig. 1. The meshing of the 3-D FE model of hull structure is to be carried out considering both calculation accuracy and computing time. The meshes are to be as square as possible.

The element type chosen for analysis is 'Shell181'. This element is most suitable for ultimate strength analysis [3]. Stiffened plate plate and stiffener (including panels and web) are modeled with 'Shell181'. The element size is to be small enough to describe the deflections accurately. A mesh size of 141 is chosen to mesh the area.

The coordinate system used within these Rules is shown in Figure 1. Motions and displacements are considered positive in the forward, up and to port direction. Angular motions are considered positive in the clockwise direction about the x, y or z axis.

2.3 Boundary Conditions

The boundary conditions are to represent the actual response of the stiffened panel. the simply supported boundary condition is often adopted in maritime industry . The edges of model may be taken as free to move in-plane, but forced to remain straight[4]. The panels can be taken as supported in the vertical direction at the primary support members. The stiffeners should be taken as horizontally supported at the crossing of primary support members. In this model, the transverse floor is not modeled. Instead appropriate boundary conditions are applied along the length of the transverse floor attached with plating and longitudinal stiffeners to account for the effects of the transverse floor [5]. The following are the boundary conditions of the nonlinear finite element model, namely

Longitudinal edges Y=0 and Y=W: UZ=0,ROTY=O,ROTZ=0.

At X=2L all nodes to have equal X-displacement.

At X=0 edge UX=0.

At Y=0 and Y=W: ROTY=0, ROTZ=0.

At Y=0 and Y=W all nodes to have equal y-displacement.

At transverse frame: All plate nodes UZ=0.

All stiffener web nodes all nodes to have equal Y displacement.

The boundary conditions for nonlinear analysis is shown in Figure 2.

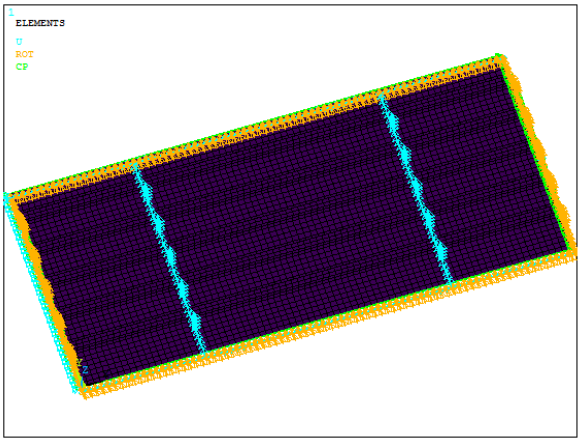

Figure 2: Boundary conditions of stiffened plate.

2.4 Initial Distortions

Initial distortions make significant impact on the result of the ultimate strength behavior of stiffened plate structures. Therefore, it is important to model the shape and magnitude of initial imperfections in a relevant way [6]. The imperfections may be divided into local imperfections (plate out-of-flatness and stiffener sideways out-of-straightness), and global imperfections of the stiffeners(stiffener lateral/vertical out-of-straightness). No residual stress is supposed to exist for this research study.

For performing a nonlinear finite element computations, the pattern of initial imperfections that are required to be generated for initiation of the buckling eigenvalue analysis is assumed to be the buckling mode of the structure that provides the minimum resistance against the actions.

2.5 Comparison of the Method.

To check the accuracy of the analysis performed in this method,Numerical results were compared with data in the Background Document of buckling strength assessment in CSR and results calculated by empirical formulations performed by other researchers.

In 2009, Shengming Zhang [7] calculated the ultimate strength of 132 Ship Common stiffened plate, and summed up the following empirical formula:

The following example is a single line equation:

$$\frac{\sigma_u}{\sigma_y} = \frac{1}{\beta^{0.28}} \frac{1}{\sqrt{1+\lambda^{5.2}}}, \text{take} \beta = 1, \text{if } \beta < 1 \tag{1}$$

The following example is a single line equation:

$$\beta = \frac{b}{t}\sqrt{\frac{\sigma_y}{E}} \tag{2}$$

The following example is a single line equation:

$$\lambda = \frac{a}{\pi r}\sqrt{\frac{\sigma_y}{E}} \tag{3}$$

Where B = (n + 1) b, n = the number of ribs, B = stiffened plate width, r = the radius of inertia ribs.

Background document lists the ultimate strength of stiffened plate[8], A quick comparison among the background document results, the non-linear FE results and empirical formula results for the six stiffened panels in Table 1 and 2 were carried out.

No.	L(mm)	w(mm)	t(mm)	d_w(mm)	t_w(mm)	d_f(mm)	t_f(mm)

Table 2: Comparison of ultimate strength.

Contrast to results in this paper, the calculation method is right. The paper will analyze the ultimate strength of stiffened plates under combined loads using the above method.

3 ULTIMATE STRENGTH OF STIFFENED PANEL

3.1 Different Proportions of Axis Pressure

The ultimate strength of stiffened panels under different proportions of axis pressure is studied, include: σx: σy = 1.0: 0,0.79: 0.21,0.4: 0.6,0: 1.0, where σx: σy = 1.0: 0 the corresponding longitudinal uniaxial compression, σx: σy = 0: 1.0 corresponds to transverse uniaxial compression, the following table shows the strength of stiffened panels under different proportions of axis pressure.

σx:σy	σxu（MPa）	σyu（MPa）
1.0:0	246.38	-
0.79:0.21	236.37	62.83
0.4:0.6	63.31	94.96
0:1.0	-	96.89

Table 3: Ultimate strength of stiffened panels under different proportions of axis pressure.

3.2 Combined Biaxial Compression and Lateral Pressure Loads

The ultimate strength of stiffened plates under combined biaxial compression and lateral pressure loads is studied.All calculations lateral pressure is added in 2.1, and remains constant lateral pressure, namely p = 0.16MPa throughout the calculation process [9]. Before the finite element calculation process, the lateral pressure is applied on the stiffened plates, and obtain the the ultimate strength of stiffened plates. The following table shows the ultimate strength of stiffened plates under combined biaxial compression and lateral pressure loads.

σx:σy	σxu（MPa）	σyu（MPa）
1.1:0	209.40	-
0.79:0.21	210.91	56.06
0.4:0.6	64.90	97.35
0:1.0	-	98.19

（c） σ x:σ y =0.4:0.6

（d） σ x:σ y =0:1.0\

Figure 3: stress-strain curves of stiffened plates under combined biaxial compression and lateral pressure loads.

4 CONCLUSIONS

- A FEA method of ultimate strength was put forward based on the analysis of the influence of different factors and the study on the CSR. Some important factors of influence such as the structural dimensions, element size, boundary conditions, initial imperfections and loading types are studied. A comparison among the background document results， the non-linear FE results and empirical formula results was provided to verify the method.
- By the calculation and analysis of stiffened plates under axial compression and lateral pressure, the results showed that lateral pressure make a negative impact on the ultimate strength of stiffened panels when t the proportion of Uni-axial compression in the direction of the stiffener is greater, and lateral pressure make a negligible impact on the ultimate strength of stiffened panels when the proportion of Uni-axial compression in the direction of the transverse is greater.

NUMERICAL ANALYSES OF THE INFLUENCE OF STRUCTURAL SLENDERNESS ON THE SEISMIC RESPONSE OF SINGLE AND CLUSTERED STRUTCURES

Keywords: Soil-foundation-structure interaction, slenderness, adjacent structures, numerical modelling, earthquake engineering

Abstract. *The seismic design of structures generally considers a fixed base assumption, thus neglecting interaction with the supporting soil. The main structural property considered is usually the fundamental period. However, when the influence of soil-foundation-structure interaction (SFSI) is taken into account, other parameters such as structural slenderness, may play an important role in the response. Current design codes, (e.g. FEMA-440 and FEMA-450), assume that SFSI always has beneficial effects in the form of a reduction in the fundamental period spectral acceleration or base shear. This assumption has been studied and discussed by several authors. Additionally, in major urban areas structures are generally closely adjacent, and this situation is more complex than that of a structure whose response may be considered independent of all others. This study sets-out to improve the understanding of the behaviour of a clustered structure-soil-structure system. A 2D numerical model is used to simulate the behaviour of single and multiple structures on sand considering a range of slenderness ratios. Linear single degree-of-freedom (SDOF) structures and nonlinear soil are considered. The role of key parameters, e.g. effective building period and slenderness ratio of the structure-foundation system, will be elucidated.*

1 INTRODUCTION

A common practice in structural design is to neglect the influence of foundation soil by assuming a fixed base condition. Also, the natural period of the fixed base structure, T, is usually considered as the main design parameter. Furthermore, when soil-foundation-structure interaction (SFSI) is considered, the possible effects are generally assumed beneficial (e.g. reducing the spectral acceleration or the base shear). The effects of SFSI have been discussed by e.g. Mylonakis and Gazetas [1] who presented a study showing an increase of seismic demand due to SFSI for certain soil conditions. The influence of structural slenderness has also been highlighted when SFSI is considered in the structural response [2]. Karaca and Turkeli [3] identified the relevance of the slenderness on the response of reinforced concrete chimneys. The increasing lack of space, especially in dense urban areas, has made the interaction between adjacent structures an active research field in the last decades. The concept of structure-soil-structure interaction (SSSI) was introduced e.g by Luco and Contesse [4] and Chouw and Schmid [5,6]. A literature review about SSSI was presented e.g by Lou, et al. [7]. However, most of the advances in SSSI are achieved with analytical solutions for simplified problems based on an assumption of linearity for the different components of the system (i.e. soil and structure). It is well known that an assumption of linear behaviour for soil is valid only for a very small range of deformation, which is clearly not the case in the seismic response..

The National Earthquake Hazards Reduction program (NEHRP) [8] developed guidelines to consider the influence of SFSI on structural design. This NEHRP publication highlights the limited application of SFSI and describes the effects in common engineering practice, while also summarising several methods presented in other codes and guidelines.

One of the methodologies is presented by FEMA-440 [9]. This guideline divides SFSI into the effects of the fundamental period ($\tilde{T}$) and the damping of the soil-structure system. Based on the foundation damping (β_f) a modified damping ratio (β_0) is proposed for the computation of the response spectrum. The design response spectrum is calculated with the damping ratio β_0. Other approach is presented by FEMA-450 [10]. This methodology considers a reduction of the base shear. The final outcome as to beneficial or detrimental effect of SFSI depends of the combined effect of the two factors: (1) increase in damping due to SFSI system and (2) period elongation of the SFSI system (Figure 1). It is possible for a structure with a fundamental fixed-base period on the ascending branch of the response spectrum to have an increase system spectral acceleration. This can be seen in the left most part of Figure 1. The opposite can be seen, an overall decrease of the spectral acceleration, for a structure with a fixed-base period on the descending branch.

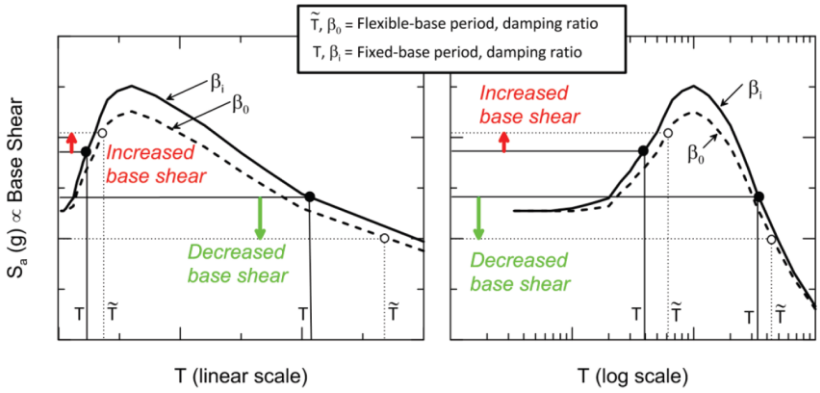

Figure 1: SFSI effects on spectral acceleration and base shear [5]

In previous studies the incorporation of the site-specific frequency content of the ground excitation, structural slenderness and the presence of the adjacent structures is hardly considered. This paper presents the results of the preliminary work to elucidate the consequence of structural slenderness λ and closely adjacent structures. λ is the ratio of the structural height (see Table 2) to the footing width of 6 m.

2 METHODOLOGY

2.1 FEM model

The finite element (FE) software GEFDyn [11,12] was used for all the studies performed. A 2D model and a plane-strain approach were utilised. A 30 m height soil profile was considered. Beneath the soil a 5 m thick layer of bedrock was assumed. Paraxial elements [13] were used at the lateral boundaries of each model. Those elements allow entry of the incident wave and, at the same time, satisfies radiation damping. The width of each model was selected to minimise the influence of the lateral boundaries. Figure 2 shows the FE model for 2 closely adjacent structures. When a single structure is considered it is located at the centre of the model to avoid asymmetry effects.

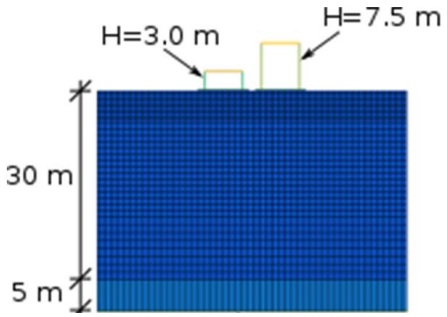

Figure 2: FE model considering adjacent structures

2.2 Soil parameters

The elasto-plastic multi-mechanism model developed at Ecole Centrale Paris (ECP) also known as Hujeux or ECP's model was used to represent the soil behaviour.

The following are the main hypotheses of the soil model:

- The model considers small deformations. The total deformation can be divided into elastic and plastic contributions.
- The formulation is based on the principle of effective stress.
- Isotropic behaviour is assumed for the elastic response.
- Shear behaviour is represented by three bi-dimensional mechanisms, each using a Mohr-Coulomb failure criterion.

Table 1shows some of the selected soil parameters. Refer to Aubry et al. [11] and Hujeux [12] for further information about the ECP's constitutive model.

Elasticity		**Critical state and plasticity**	
K_{ref} [MPa]	444	ϕ'_{pp} [°]	31
G_{ref} [MPa]	222	β [°]	43
n_e	0.40	d	3.5

		b	0.20
		p'_{co} [MPa]	-1.8
Flow rule and isotropic hardening		**Threshold domains**	
ψ [°]	31	r^{ela}	5.0×10^{-3}
a_{cyc}	1.0×10^{-4}	r^{ela}_{iso}	1.0×10^{-3}
a_m	4.0×10^{-3}	r^{hys}	3.0×10^{-2}
c	6.0×10^{-2}	r^{mob}	0.80
c_{cyc}	3.0×10^{-2}		
m	1.0		

Table 1: Soil parameters

The soil parameters utilised represent Toyoura sand with a relative density D_r = 37%.

A preliminary linear analysis was conducted for a soil column in the free field. A natural period of 0.46 s was obtained for the soil based on the ratio of the acceleration at the top to the acceleration at the base of the column in the frequency domain. A small amplitude input was used to guarantee linear behaviour of the soil. Considering the approximate expression presented in Equation (1) the shear wave velocity is $V_s = 260\ m/s$. Thus, the soil can be considered as medium-dense.

$$T_s \approx 4H/V_s \tag{1}$$

2.3 Structural models

The structures studied were single degree-of-freedom (SDOF) systems represented in 2D by elastic frame elements (2 m span) with two columns and a top beam. Three natural periods were selected. For each natural period a 3 m and 7.5 m high model was considered. All the seismic mass was concentrated in the top beam. To avoid differences in the confining stress in the foundation sand under the structure, the same mass (50 tonne) was considered for all models. The foundation was considered to be a massless beam of 6 m length. No uplift of the structural foundation was allowed at the soil-foundation interface. Table 2 shows some of the selected parameters for the SDOF structural models.

Structure	Height (m)	Columns (cm x cm)	Beam (cm x cm)	Natural period (s)
$T_{long} - L_1$	3.0	22×22	20×30	0.78
$T_{long} - L_2$	7.5	52×52	20×30	0.78
$T_{mid} - L_1$	3.0	28×28	30×45	0.44
$T_{mid} - L_2$	7.5	67×67	30×45	0.44
$T_{short} - L_1$	3.0	33×33	35×52.5	0.32
$T_{short} - L_2$	7.5	78×78	35×52.5	0.32

Table 2: Structural models parameters

2.4 Ground motion

Local site effects were directly included in the numerical model. The ground motion recorded on bedrock was used as the input motion. For all the analyses the strong motion recorded at the Gilroy station during the 1989 Loma Prieta Earthquake was utilised. A total duration of 10 s of the main shock was used (Figure 3).

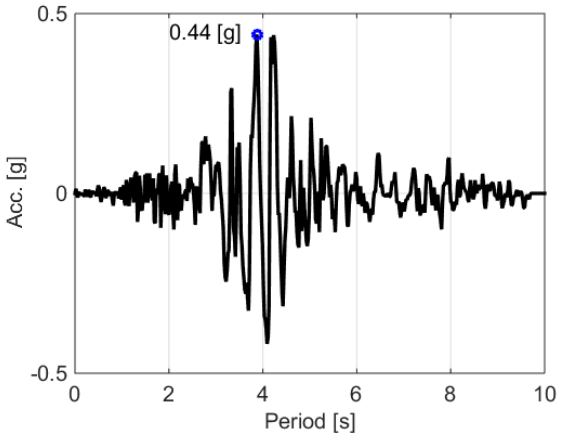

Figure 3: Ground motion (Loma Prieta, 1989)

3 RESULTS AND DISCUSSION

3.1 Stand-alone structures

The acceleration and displacement at the top of each model was calculated and the ratios of the maximum value to the maximum obtained for a free-field condition are presented for acceleration and displacement in Figure 4 and Figure 5, respectively as a function of the ratio of the natural period (T_{str}) of the SDOF to the natural period (T_{site}) of a 1D column of soil.

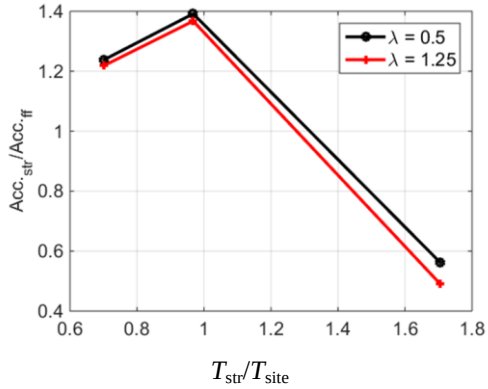

Figure 4: Ratio of maximum acceleration beneath the structure to the maximum on free-field

Regarding the maximum acceleration, the effect of slenderness is shown to be of minimal importance over the period range employed in this study. A higher slenderness ratio tends to give a marginally lower maximum acceleration for the same period.

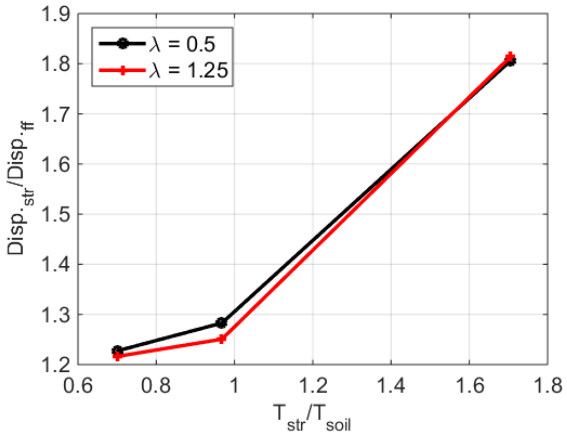

Figure 5: Ratio of maximum displacement beneath the structure to the maximum on free-field

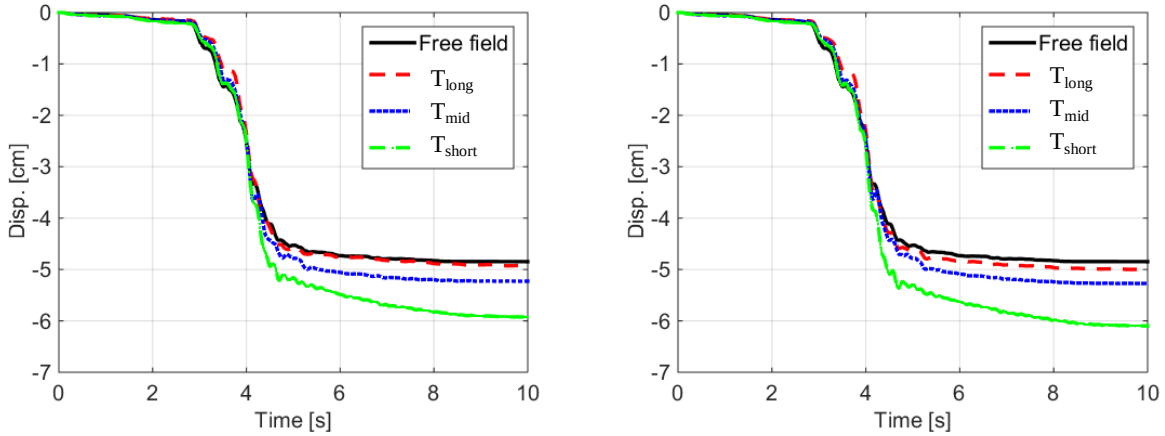
The effects of slenderness on the maximum horizontal displacement are shown to be small for structures with a natural period close to the natural period of the site. Otherwise, slenderness has very little effect for the three structures considered.

The settlement beneath the structure was also studied. Figure 6 shows the results for the different single structures .



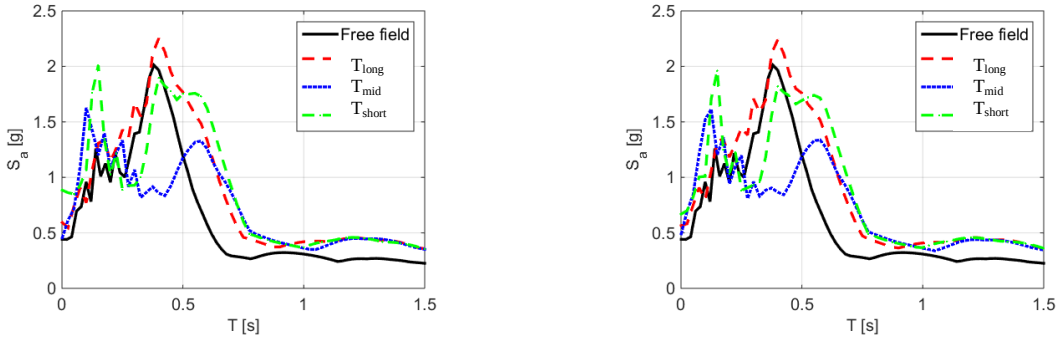
a. Lower slenderness models ($\lambda = 0.5$)

b. Higher slenderness models ($\lambda = 1.5$)

Figure 6: Settlement beneath the structure (alone on soil)

A similar trend is shown in Figure 6 for the settlement for both slenderness ratios. However, the lower period structures encountered higher settlement. The slenderness ratio has almost no effect. Thus, in the cases considered the natural period of the structure is more important than the slenderness ratio.

The influence of the structural slenderness and period on the response spectra of the acceleration beneath the structure are shown in Figure 7.



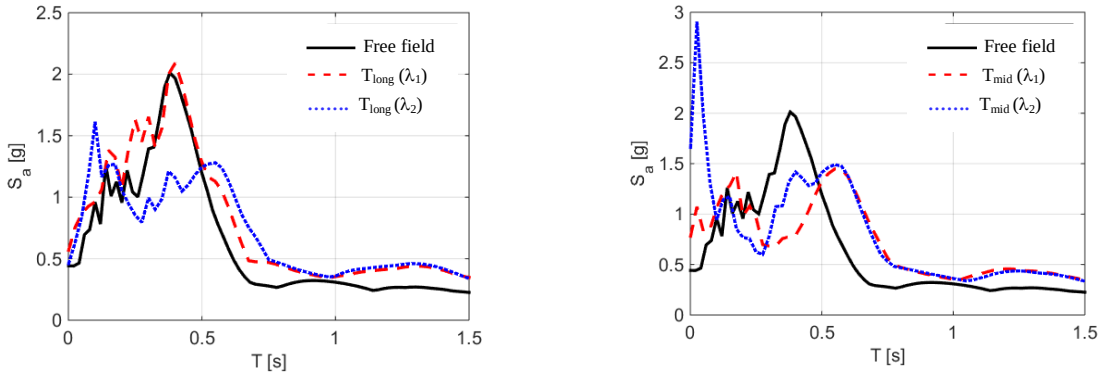
a. Lower slenderness models ($\lambda = 0.5$) b. Higher slenderness models ($\lambda = 1.5$)

Figure 7: Response spectra for acceleration beneath the structure

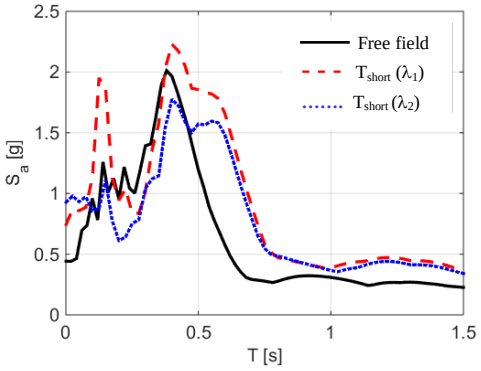
The obtained spectra were compared with the spectrum from free-field (black solid line). When stand-alone structures were tested the slenderness has very little influence.

3.2 Adjacent structures on soil

Each pair of structures with the same natural period but a different slenderness were tested with a one meter separation distance. In this case different response spectrum have been obtained beneath each structure (Figure 8). Again, the spectrum from free-field condition is also presented (black solid line).



a. High period structure (T_{long}) b. Intermediate period structure (T_{mid})



c. Low period structure (T_{short})

Figure 8: Effect of slenderness, structural period and an adjacent structure on the acceleration beneath the structure ($\lambda_1 = 0.5$ and $\lambda_2 = 1.5$)

Even though, no clear trends have been observed to define the influence of an adjacent structure there are significant differences between the spectra of the free field and the spectra beneath the structures. Differences can also be observed between the spectra of the soil beneath the two buildings. Further work is needed to clearify the observations.

4 CONCLUSIONS

FE models based on a 2D plain-strain approach were used to study the influence of slenderness on the structural response. The elasto-plastic multi-mechanism ECP constitutive model was used to represent the soil behaviour. Stand-alone structures and closely adjacent structures were considered. The influence of natural period, slenderness and an adjacent structure were studied.

In the cases considered the results for stand-alone structures show:

- The maximum displacement at the top of the structure increases with the natural period of the structure.
- Slenderness has marginal effect.
- Structures with the shortest period experienced the largest settlement. In contrast, for the highest slenderer ratio the permanent settlement was slightly bigger.

In the case of closely adjacent structures of equal period:

- Slenderness significantly effects the spectral acceleration for periods below 0.5 s.
- The natural period of the structures has a significant influence on SSSI.
- The free-field ground motions should not be used as a design structural excitation.

ACKNOWLEGEMENTS

Keywords: Nonlinear SFSI, higher modes, macro element, seismic response of structure.

Abstract. *To calculate the response of a multi-storey structure (MDOF model) with structure-foundation-soil interaction (SFSI), for simplicity the structure is often assumed as a SDOF model corresponding to the fundamental mode. However, depending on the distribution of mass and stiffness of the structure, the contribution of the fundamental mode may vary. The contribution of the higher modes to the response of the structure could become more significant. This study reveals the effect of higher modes on the response of structure including SFSI. The response of a multi-storey structure and the response associate with the fundamental mode of the structure are compared. To calculate the response of structures with SFSI, a macro element model is used to simulate the plastic soil deformation. The consequence of using a SDOF model for the structural response including nonlinear SFSI is discussed.*

1 INTRODUCTION

For structures with a shallow footing, seismic forces induced by a ground excitation may cause a moment at the footing to exceed the elastic limit of the foundation soil. Consequently, soil bearing failure may occur. It is commonly accepted that nonlinear soil behaviour should be avoided in seismic design by providing more than sufficient foundation bearing strength. However, it has been observed that although the footing has been properly designed, the structure can still experience plastic deformation of foundation soil during earthquake [1-6]. Examples can be found in almost all major earthquakes, e.g. Valdivia Earthquake 1960 [2], Michoacan Earthquake 1985 [3], Kobe Earthquake in 1995 [4], Izmit Earthquake 1999 [5, 6], and the 2010 Darfield and 2011 Christchurch earthquakes [7]. Study of the response of structure with nonlinear SFSI is thus relevant.

Observations of buildings following major earthquakes e.g. Housner [2] and Gazetas et al. [5] showed that structures experiencing minor nonlinear SFSI, in fact, performed better than expected. These observations triggered a number of analytical and numerical investigations. Yim and Chopra [8] developed one of the first SFSI models using a Winkler foundation. The flexibility and damping of the supporting soil were represented by independent spring-damper elements distributed over the width of the foundation. Psycharis and Jennings [9] extended the study by simplifying the Winkler foundation model using a two-spring foundation model. Psycharis [10] used the Winkler foundation model to conduct a parametric study. The influence of damping ratio, aspect ratio and stiffness ratio between the structure and the supporting spring on the structural response was investigated. Based on the results obtained from these analytical models [8-10], a series of response spectra were proposed to determine the seismic response of structures on flexible supporting ground. Recently, numerical methods were also developed to incorporate the nonlinearity of soil. The response of a structure with SFSI calculated using finite-element approach was discussed by Wolf [11]. Nova and Montrasio [12] proposed an equation to calculate the movement of the footing during soil plastic deformation. This equation was incorporated in a macro element model so that the response of structure with nonlinear SFSI can be calculated [13]. Chouw and Hao [14] also numerically studied and showed that SFSI can affect the pounding force between adjacent bridge structures.

For simplicity, most numerical studies of structures with SFSI use a single-degree-of-freedom (SDOF) system to represents the structure. The contribution of higher modes to the total response of the structure with SFSI was neglected. Depending on the distribution of mass and stiffness of the structure, the contribution of the higher modes to the response of the structure could be significant. This study reveals the effect of higher modes on the response of a structure with SFSI. The response of a two storey structure with SFSI was numerically calculated by representing the structure using a SDOF system and a 2-degree-of-freedom (2DOF) system. To include the effect of nonlinear SFSI, a macro element model is used.

2 NUMERICAL SIMULATION

2.1 Higher mode of structure

The structure used for this study was a two storey steel building. The structure had a storey height of 3 m and floor area of 25 m^2. For the 1st floor and the roof, the seismic mass was 42000 kg and 21000 kg, respectively. The columns of the structure were 250UC72.9 steel section. The footing mass (m_o) was 42000 kg. The beams and foundation were assumed rigid. The structure can be described using a 2DOF system. Each DOF represented the horizontal

movement at the floor level. The lateral bending stiffness of each floor can be calculated using the total bending stiffness of the columns.

The structure can also be represented using a SDOF system. An equivalent base shear method was used to obtained the effective mass (m^*) and height (h^*). The procedure is described e.g. by Chopra [15]. The effective mass and height of the SDOF system was determined to be 61000 kg and 4.3 m, respectively. The effective mass represented 96.8% of the total mass of the structure. The fundamental frequency of the SDOF system was defined to be the same as that of the two storey structure. Figure 1 shows the parameters of the 2DOF system and the SDOF system. The footing mass and size of the SDOF system were identical to that of the 2DOF system.

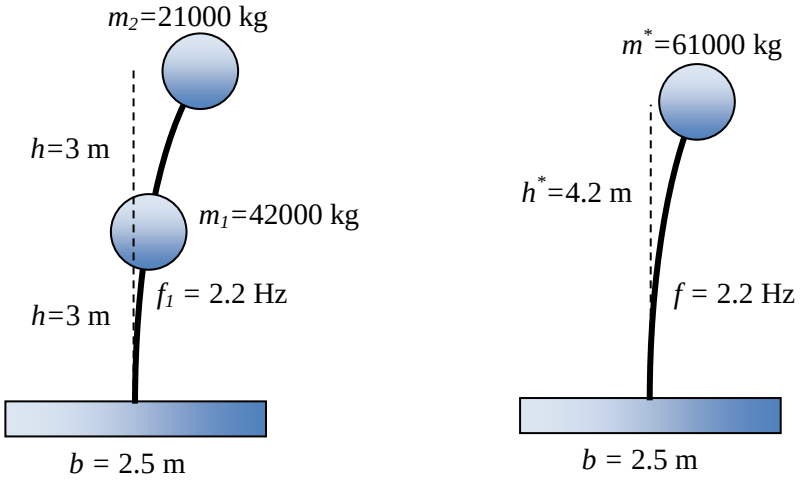

Figure 1: The 2DOF system and the equivalent SDOF system.

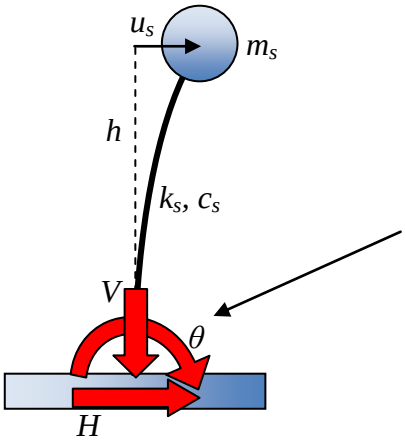
2.2 Macro element model

The response of a structure with nonlinear SFSI was calculated with the help of a macro element model. The concept of the model is to simplify the response of a foundation-soil system using three degrees of freedom. They are the vertical, horizontal displacements and rotation of the center of the foundation. With these additional DOFs at the footing location, the effect of footing response under the deformation of foundation soil can be included. Figure 2 shows the macro element model. The elastic stiffness of the 3DOF footing system can be calculated using the formulation described in Chouw and Hao [14].



$$\mathbf{m_F} = \begin{bmatrix} m_s + m_o & m_s h & 0 \\ m_s h & m_s h^2 + J_o & 0 \\ 0 & 0 & m_s + m_o \end{bmatrix}$$

$$\mathbf{k_F} = \begin{bmatrix} k_H & & \\ & k_\theta & \\ & & k_V \end{bmatrix} \quad \mathbf{c_F} = \begin{bmatrix} c_H & & \\ & c_\theta & \\ & & c_V \end{bmatrix}$$

$$\mathrm{u_F} = \begin{bmatrix} H & \theta & V \end{bmatrix}^T$$

Figure 2: The macro element model.

2.3 Nonlinearity of the foundation system

The nonlinearity of the structure-foundation-soil system is described at the 3DOF of the foundation system. The nonlinearity will be initiated when a bearing failure of soil is intitiated. To determine the initiation of the bearing failure, a bearing strength surface was considered. Nova and Montrasio [12] have proposed an equation for determining the initiation of a bearing failure of a strip footing on sand (Eq. (2)). The equation was developed and improved though a number of experimental and numerical studies (e.g. [16]).

$$f(\mathbf{F}) = \left(\frac{H}{\mu V_{\max}}\right)^2 + \left(\frac{M}{\psi B V_{\max}}\right)^2 - \left(\frac{V}{V_{\max}}\right)^2 \left(1 - \frac{V}{V_{\max}}\right)^{2\xi} \tag{2}$$

where B is the width of the foundation; V_{max} is the ultimate bearing capacity of foundation soil under vertical centered load; ψ, μ and ξ are the parameters of the bearing strength surface and suggested to be 0.43, 0.9 and 0.95, respectively [16]; **F** is a vector which contains the horizontal, vertical actions and moment at the foundation (H, V and M in Figure 2).

With **F** calculated using the product of the stiffness matrix ($\mathbf{k_F}$) and the displacement vector ($\mathbf{u_F}$) of the foundation. Eq. (2) can be evaluated. If $f(\mathbf{F}) < 0$, the combined action of a shallow foundation is below the bearing capacity of foundation soil. Bearing failure of the foundation soil does not occur. In contrast, a value of $f(\mathbf{F}) = 0$ indicates that the foundation action will cause bearing failure. Theoretically, it is impossible to have a value of $f(\mathbf{F}) > 0$, since the soil cannot sustain any actions greater than the bearing capacity.

Once the indication of bearing failure was confirmed, a non-associated flow rule (Eq. (3)) was applied to calculate the unrecoverable displacement and rotation of the foundation due to soil plastic deformation.

$$g(F) = \lambda^2 \left(\frac{H}{\mu V_{\max}}\right)^2 + \chi^2 \left(\frac{M}{\psi B V_{\max}}\right)^2 + \left(\frac{V}{V_{\max}}\right)^2 - 1 \tag{3}$$

where B is the width of the foundation; λ and χ are two non-dimensional parameters, and V_{max} is the maximum bearing capacity of soil under vertical loading.

This flow rule was originally developed by conducting a large scale shake table test to quantify the non-dimensional parameters of Eq. (3) [13, 16 and 17]. For sand, the values of λ and χ were suggested to be 2.5 and 3, respectively. In this study, the supporting soil was defined to be sand and had a shear wave velocity of 400 m/s. The Poisson's ratio and density were assumed to be 0.33 and of 1560 kg/m^3, respectively. It is assumed that the structure behaves elastically during the earthquake loading.

2.4 Earthquake excitation

The ground excitation for the nonlinear time history analysis was simulated based on a Japanese design spectrum [18]. In this study, medium soil category was considered. This is because in general, loose soil is of no practical interest for shallow foundation design. An alternative foundation scheme, such as foundation through piles, is usually preferred. On the other hand with dense or very-dense soil condition significant settlements are not likely to occur [19]. The applied ground acceleration is shown in Figure 3.

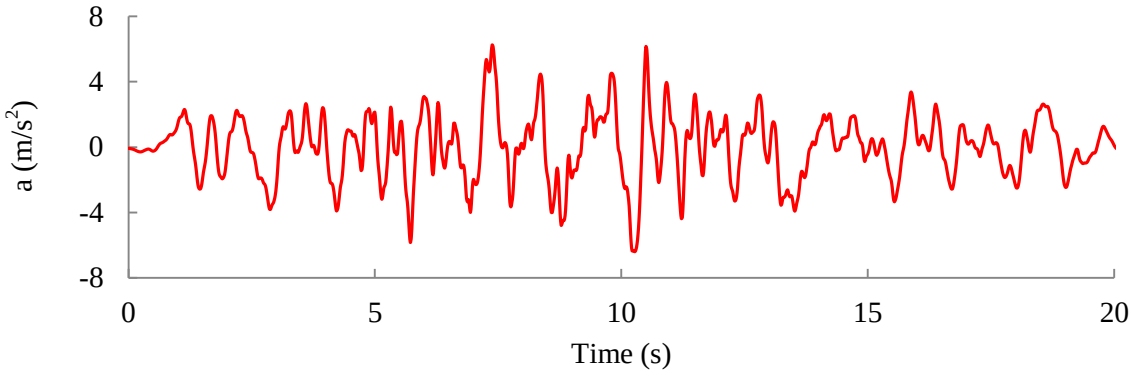


Figure 3: Ground acceleration.

3 RESPONSE OF STRUCTURE WITH SFSI

3.1 SFSI with elastic soil

Figure 4 shows the horizontal displacement (u) at the top of the structure relative to the ground. The structure was represented using the SDOF (dashed line) and 2DOF (solid line) system, respectively. Considering elastic soil, the horizontal displacement calculated using the SDOF system was larger than that using the 2DOF system. Using the SDOF system, the maximum top horizontal displacement was 66.4 mm. When considering the 2DOF system, the maximum top horizontal displacement was 59.1 mm. The maximum horizontal displacement of structure estimated using the SDOF system was 12.4% larger than that calculated using 2DOF system. It is shown that without considering the higher modes, horizontal displacement of structure can be overestimated.

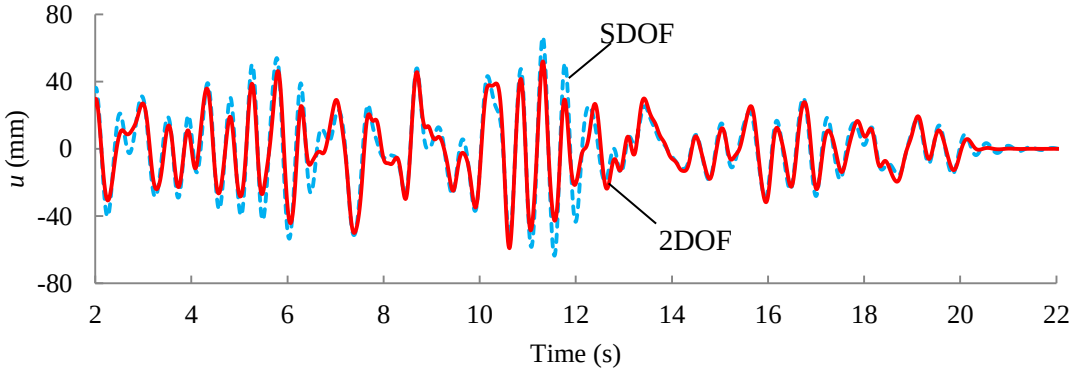

Figure 4: Influence of MDOF system on the structural response with linear SFSI

3.2 Response of structure with nonlinear SFSI

Figure 5 shows the horizontal relative displacement (u) at the top of the structure with non-linear SFSI. While the dashed line represents the result calculated using the SDOF, the solid line illustrates that obtained considering the 2DOF system. A residual horizontal displacement was found at the end of the excitation due to soil plastic deformation. When using the SDOF and 2DOF system, the residual horizontal displacement was 4.9 mm and 1.4 mm, respectively. Including the structural higher mode, the residual displacement of the structure was smaller. The maximum horizontal displacement at the top of the 2DOF system was also smaller than that of the SDOF system. The maximum horizontal relative displacement considering the SDOF and the 2DOF systems was 62.6 mm and 57.5 mm, respectively.

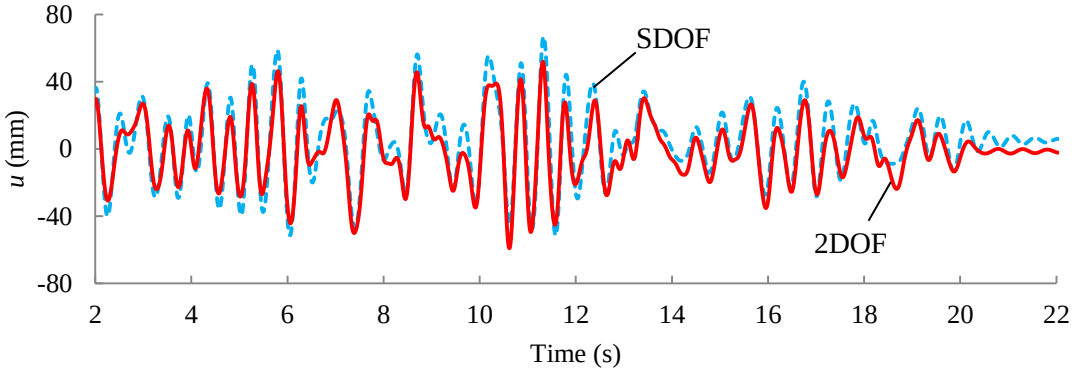

Figure 5: Influence of MDOF system on the structural response with nonlinear SFSI

Using the SDOF and 2DOF systems, the calculated footing rotation (θ) of the structure was also different. As shown in Figure 6, the maximum footing rotation calculated using the SDOF system was 0.17^o. Using the 2DOF system, the maximum footing rotation was -0.06^o. At the end of the excitation, the residual rotation of the footing was 0.06^o and -0.02^o for the case of the SDOF and 2DOF, respectively.

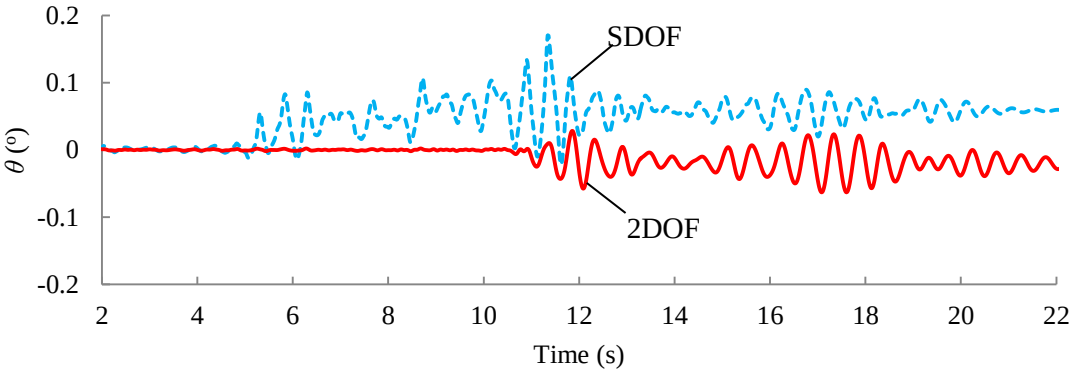

Figure 6: Effect of nonlinear SFSI and 2DOF system on footing rotation θ

4 CONCLUSIONS

This study focused on the effect of a higher mode on the response of a structure with SFSI. The response of a two storey structure was numerically calculated by representing the structure using a SDOF system and a 2DOF system. The effect of foundation soil deformation was included using a macro element model. Both elastic and nonlinear SFSI were considered. The mass of the SDOF system represented 96.8% of the total mass of the structure.

- Despite the mass of the SDOF system represents a large portion of the structural mass, the responses of the structure with SFSI calculated using the SDOF and the 2DOF system were different.
- With an elastic soil , the horizontal displacement of the structure calculated without including the higher mode was larger.
- Considering nonlinear soil, the maximum and residual horizontal displacement of the structure calculated using the SDOF system was also larger than the corresponding 2DOF system.
- Without considering the higher mode, the maximum and residual footing rotation of structures during earthquake can be overestimated.

Abstract. *Recent earthquakes, as the one that hit Fukushima in Japan in 2011 or the one that produced extensive damage in Turkish petrochemical facilities during the Kocaeli earthquake of 1999 or, more recently, the seismic events in May 2012 in Emilia (Italy), highlighted the increasing need of providing adequate protection to industrial installations. Industrial facilities often store a large amount of hazardous material and, in case of seismic event, there is a high probability that accidental scenarios as fire, explosion, toxic or radioactive dispersion may occur. In these cases, the ensuing disaster certainly harms the people working in the installation and it may endanger the population living in the neighborhood or in the urban area where the industrial installation is located. The consequences of such accidental scenarios can be disastrous in terms of casualties, economic losses and environmental damage. Within this work, the seismic behavior of an industrial structure is studied through several Incremental Dynamic Analyses, IDA, and particular attention is given to the selection of suitable performance criteria and the modelling of non linear phenomena (II order effects, buckling, mechanical non-linearity, etc.). The seismic behavior is then enhanced applying to the structure an innovative typology of self-centering hysteretic damper, whose mechanical characteristics are optimized through the execution of IDAs on the retrofitted structures. A final comparison between the seismic behavior of the original structure and of the retrofitted one highlights the advantages of the innovative self-centering hysteretic dampers.*

1 INTRODUCTION

Recent earthquakes, as the one that hit Fukushima in Japan in 2011, the one that produced extensive damage in Turkish petrochemical facilities during the Kocaeli earthquake of 1999 or, more recently, the seismic events in May 2012 in Emilia (Italy), highlighted the increasing need of providing adequate protection to industrial installations.

Industrial facilities often store a large amount of hazardous material and, in case of seismic event, there is a high probability that accidental scenarios as fire, explosion, toxic or radioactive dispersion may occur. In these cases, the ensuing disaster certainly harms the people working in the installation and it may endanger the population living in the neighbourhood or in the urban area where the industrial installation is located. The consequences of such accidental scenarios can be disastrous in terms of casualties, economic losses and environmental damage.

Even in the cases in which the content does not represent a direct threat to human lives or to the environment, damage to structural and/or non structural elements can result in huge indirect economic losses, as testified from the numerous studies [1] [2] devoted to the speedup of community recovery after the 2012 Emilia (Italy) earthquakes. From his point of view, for industrial buildings, it should be more appropriate to speak about "seismic resilience" than "seismic risk", that is more appropriate for civil building [3], meaning that it is necessary to take into account also the time necessary for the recovery of the production activities.

In this field, a parameter strictly correlated to the post-earthquake recovery is represented by the re-centering capability of the structure, defined as the capacity of minimizing the residual displacement after the end of the seismic action.

In this contest, a particular attention for the retrofit of existing industrial plants is given to the use of passive dissipation systems, such as Isolation Systems (IS) or Energy Dissipation Systems (EDS). The initial higher cost associate to a retrofit using an IS or EDS, comprised the ones consequent to the adaptation of the non-structural elements (e.g. pipelines), will be likely compensate by the avoided losses in case of moderate-to-strong earthquakes. This is especially true for industrial steel structures, where the substitution of the existing bracing elements with dissipative ones can be accomplished using simple operations. Modern codes [4] and guidelines [5] lists the recentering capability of the anti-seismic device as one of the fundamental capacities. In [5] it is evaluated, for linear analysis and seismically isolated structures, comparing the energy dissipated by the isolation device, E_H, with the reversibly stored (elastic strain and potential) energy, E_S :

$$E_S \geq 0.25 E_H \qquad (1)$$

Traditional hysteretic devices, however, does not provide a real "active" recentering force, resulting in the presence of residual forces within the devices at the end of the earthquake also in the case of negligible residual displacement and in the consequent complication of the substitution operations.

In order to mitigate such problems, re-centering devices have been the object of ever increasing research study ([6], [7], [8], [9], [10], [11], [12]). This type of dissipative device is characterized by the presence of a re-centering force that mitigates, and may even eliminate, the residual deformations in buildings and residual forces in the dissipative devices after earthquakes.

In the present paper, the influence, in terms of maximum displacement, interstorey drift, acceleration and dissipated energy, of the retrofit of an existing industrial steel building using the steel self-centering device (SSCD) developed in [13] is studied. The industrial building, selected within one of the most important Italian industrial plant, the ILVA S.p.A. plant, can

be considered as representative of the industrial structure sensitive to the seismic action, being characterized by an important mass placed at high altitude.

The case study building analysis is carried out indentifying, in the first phase, the structural and non-structural limit states, considering both the national and international standards and the peculiarity of the building itself. Given the need of simplifying, as much as possible, the structural scheme to obtain a reliable and time-saving nonlinear model, a preliminary comparison between a full-comprehensive linear model and the geometrically-simplified one is carried out, studying also the effect of the infill material modelling on the overall behavior. Several IDA are then carried out in order to identify the main seismic vulnerabilities, to define the seismic retrofit intervention and evaluate their effects on the structural behavior.

2 CASE STUDY DESCRIPTION: MODELLING, ANALYSIS AND SEISMIC VULNERABILITY

The selected case study, shown in Figure 1, has the function of filtering the gasses coming from the steelwork and can be schematized as made up of a supporting structure, the silos containing the filtering material and the roof.

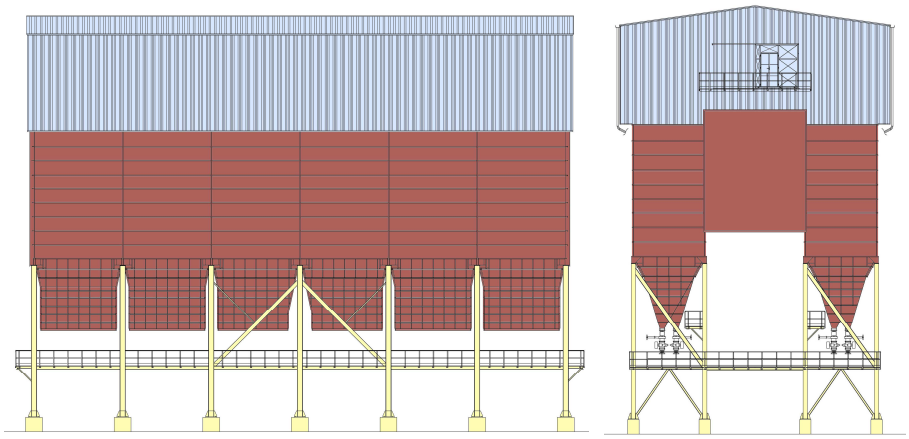

Figure 1. Front and lateral view of the Filter Building

The building has a regular plan, with overall dimensions 37.80 m x 16.94 m and total height 29.64m. The supporting structure, with a total height of about 10.80 m, has six bays in the longitudinal direction and three in the transversal one. Different horizontal resisting systems can be individuated such as moment resisting frames, inverted V bracings, diagonal bracings, as shown in Figure 2 .

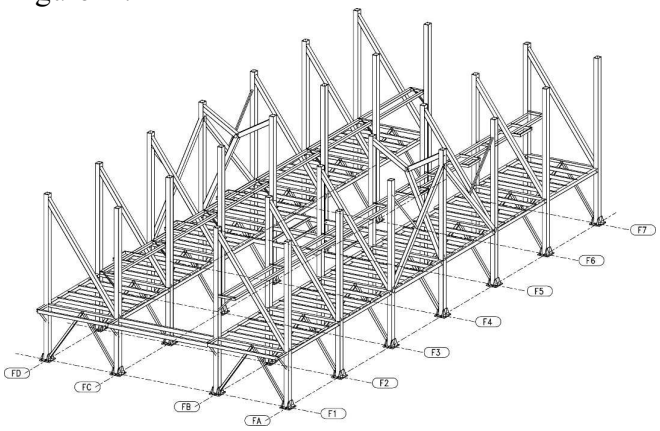

Figure 2. 3D view of the supporting system

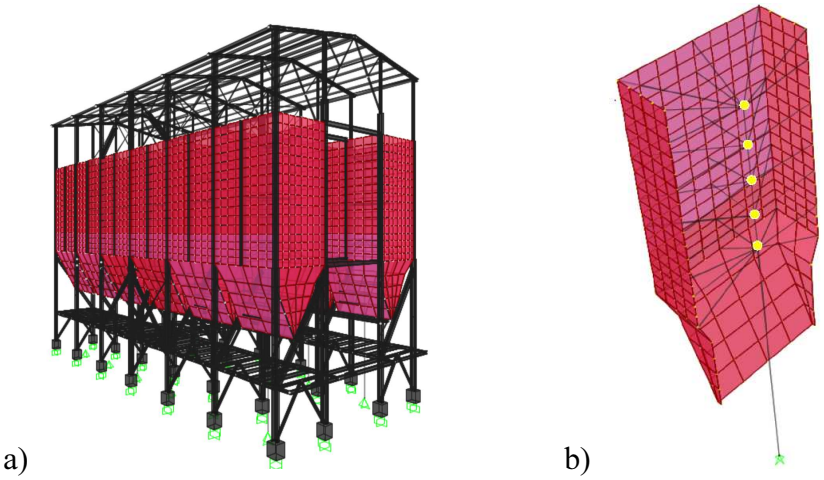
The silos are realized with thin (4 mm) walls stiffened with a close series of horizontal UPN and vertical HEA profiles. The total mass of the silo (23700 kN), considering structural elements and infill material, represent the 86% of the total mass (27650 kN).

The roof is connected directly to the filter walls and its contribution is considered only in terms of vertical load and mass.

2.1 Linear and non linear modelling

To develop a suitable nonlinear model of the building for the execution of Incremental Dynamic Analyses, IDAs, in reasonable amount of time, it is necessary to simplify the structural scheme. In order to have, however, a model able to well represent the structural behavior, it is initially studied a "complete" linear model, see Figure 3a), in which the contribution of practically almost all the structural and non-structural elements is taken into account.



a) b)

Figure 3. "Complete" linear model: a) globall view; b) modelling of the infill-silo interaction.

The dynamic interaction between the silos wall-infill material can sensibly vary the global response of the building. Given the high level of uncertainty associated to the infill material behavior, similar to dust, a refined non-linear interaction model would lead to non-reliable results. For this reason, different infill material modelling solutions are studied and compared and a parametric study is carried out to study the sensitivity of the global behavior to the variation of the characteristics of the schematization assumed.

Three different types of modelling are compared: i) the attribution of the infill material mass directly to the silos walls; ii) the concentration of the infill material total mass of each silo in a single point placed in the baricenter of the silo and connected to the silos walls by linear springs; iii) subdivision of the infill material total mass in 5 points, see Figure 3b), each one of them connected to the silos walls by linear springs. Models i) and ii) highlighted several drawbacks, such as, for the former, the unrealistic high number of the silos walls local vibration modes and the problem of overestimating the rotational inertia, while, for the latter, the high force concentration on the silos wall. The model iii) is then assumed and a parametric analysis varying the spring stiffness is carried out and the results, in terms of period of vibration and participating mass is reported in Figure 4.

It can been noticed that for infill material edometric modulus higher than 25000 kN/m^2, the period and the participating mass associated to the first period can be considered practically constant. Given that the edometric modulus of the dust varies, approximately, between 30000 to 80000 kN/m^2, the response of the model can be assumed to be not influenced by the uncertainties related to the infill material mechanical behavior.

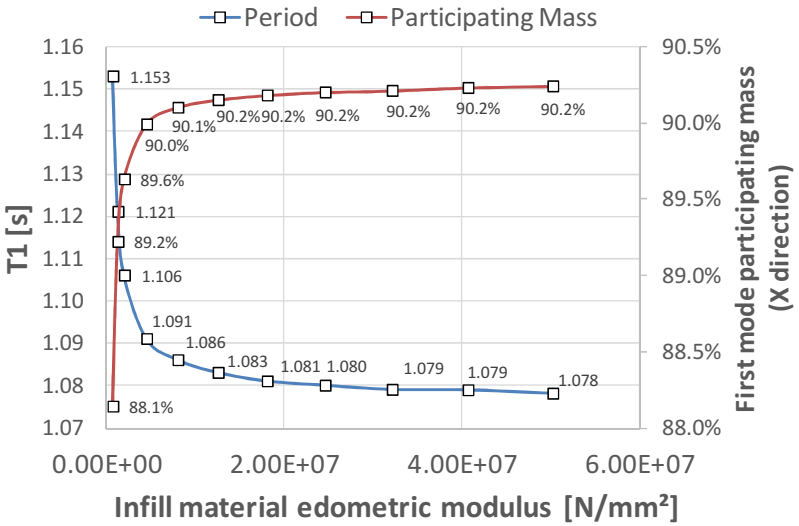


Figure 4. Period of vibration and participanting mass associate to the first vibration period varying the stiffness of the connecting spring in model iii)

The linear model described highlights a structural behavior similar to the one of a single degree of freedom (SDOF), where the great part of the displacement demand is located in the supporting structure. The silos and the roof behave such as a rigid body and the resultant stresses are far below the yielding or buckling threshold. For this reason the structural behavior can be represented by the simplified model shown in Figure 5, where the roof is considered simply as dead load and mass, while the silos are substituted by a trusses system, whose characteristics are evaluated to obtain the same first period and modal shape of the "complete" model.

The simplified model is used to perform the nonlinear IDAs. Each element is modelled using a fiber element and the material is assumed to be elasto-plastic. The global second-order effects are explicitly taken into account, while, in order to consider the post-critic behavior of the bracings in compression, they are modelled introducing the initial imperfection as foreseen by Eurocode 3 [14]. The viscous damping is taken into account introducing an damping ratio associated to the first and second vibrating modes equal to 2% and setting the damping matrix proportional to the mass and initial stiffness matrix.

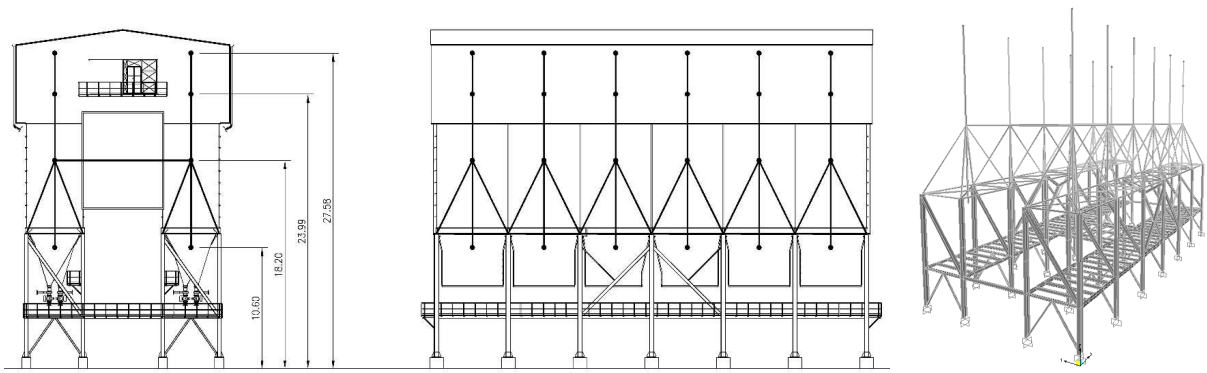

Figure 5. Case study building simplified model

2.2 Limit states and performance parameters

The Ultimate Limit State considered during the structural analysis are resumed, together with the reference standard, in following table .

ULTIMATE LIMIT STATE	ELEMENT	CHECK	STANDARD
Shear resistance	Column	$V_{Ed} / V_{pl,Rd} \leq 0.50$	EN 1998-1:2013 [15]
Plastic rotation capacity	Columns	$\phi < \phi_u$	EN 1998-3:2005
Plastic rotation capacity	Beams	$\phi < \phi_u$	EN 1998-3:2005

Table 1. Main limit state considered

To evaluate the building performance, four different parameters are evaluated during the IDA analysis:

1. maximum displacement. Related to the non structural elements (such as external cladding) damage;
2. maximum acceleration. Related to the acceleration-sensitive systems damage;
3. residual deformation. Related to the structural damage and resilience;
4. seismic energy. The different components of the energy supply important information on the structural damage and on the retrofit choices.

In particular, four type of seismic energy are analyzed: input energy, defined as the energy transmitted by the ground movement to the structure; kinetic energy, related to the building movements; adsorbed (strain + dissipated) energy, related to the damaging of the structure; viscous energy.

2.3 Selection of ground motions

In order to achieve the worst damage scenarios with a robust and reliable procedure, an Uniform Hazard Spectrum -coherent method is adopted for the ground motions. The complete procedure, together with all the background and motivations, is described in the paper presented by Faggella et al. at the 2016 ECCOMAS conference "Performance-based Nonlinear Response History Analysis Framework for the “PROINDUSTRY” Project Case Studies".

A major drawback of using unscaled GMs is that a higher number of records need to be used. At least 7 GMs are needed but, considered their high variation, a higher number is preferred, at least equal to 11. The selected ground motions are listed in Table 2. The IDAs are executed applying simultaneously the three components (2 horizontal and 1 vertical) of each ground motion and using 9 scale factors, SFs, see Figure 6. A total of 198 nonlinear time-history analyses are carried out for the case study (11 GMs x 9 SFs x 2 directional combinations).

2.4 Seismic vulnerability of the case study current state

The seismic vulnerability of the case study is studied through the IDAs and represented through the IDA curves, in terms of maximum displacement, maximum acceleration, residual displacement and seismic energy (elastically stored or dissipated by the structure). All the parameters are registered at three different levels of the structure, see Figure 7.

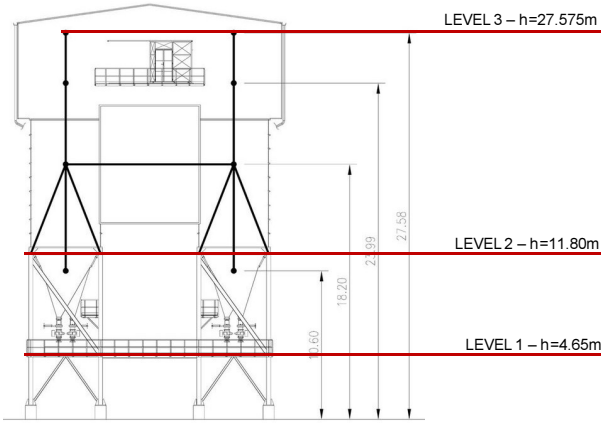

Figure 7. Individuation of recorded levels

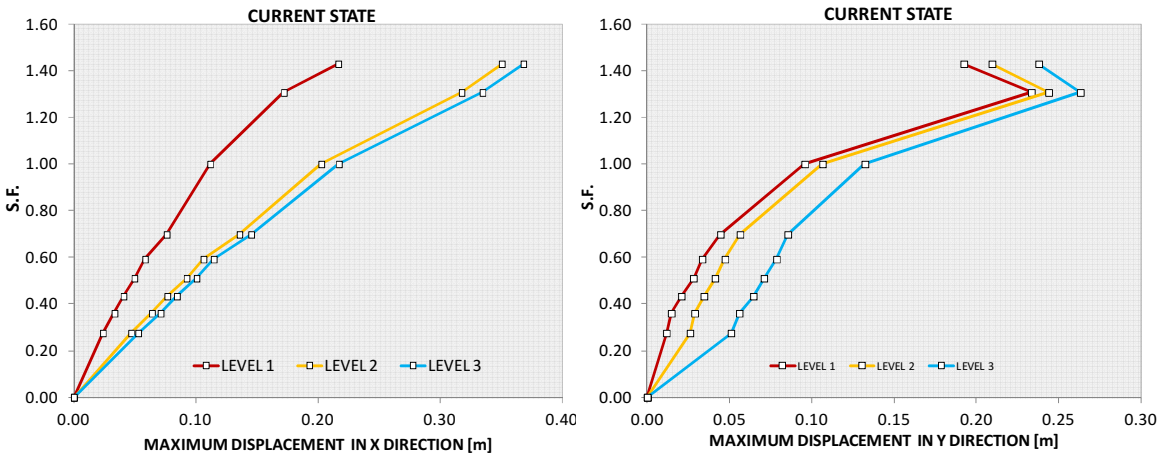
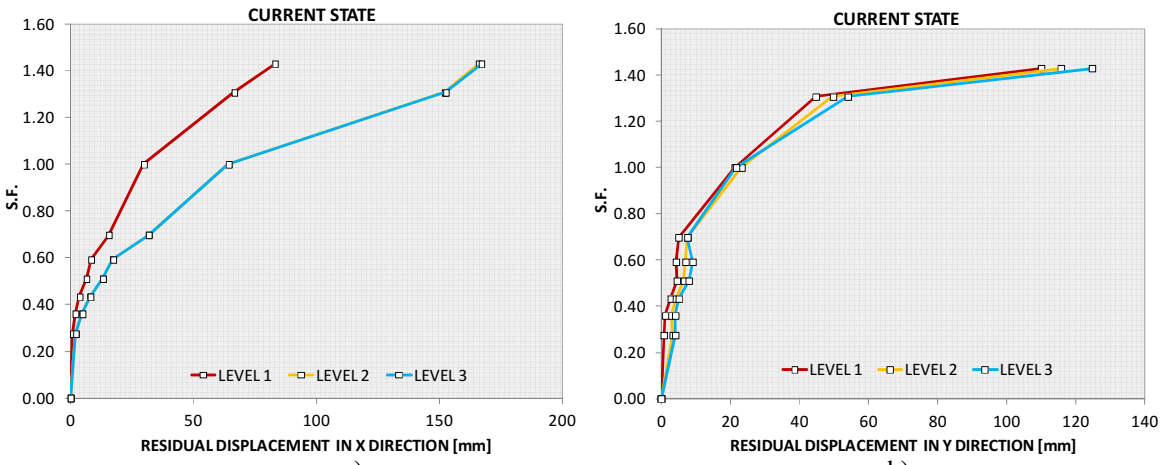
In Figure 8 and Figure 9, the IDA curves more representative of the strucruarl behavior are shown, while in Figure 10 the maximum displacements versus the maximum shear force plotted.



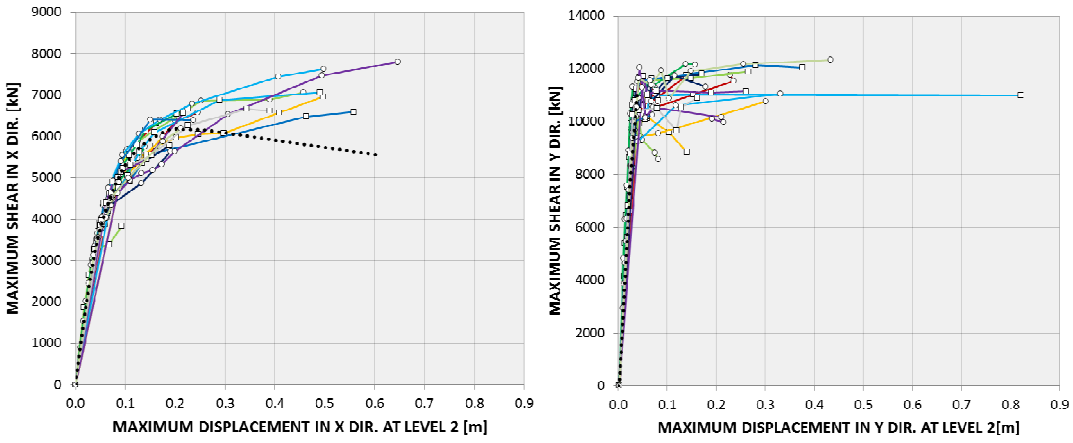
a) b)

Figure 8. Maximum displacements (mean values) at different level in the a) X and b) Y directions



a) b)

Figure 9. Residual displacements (mean values) at different level in the a) X and b) Y directions



a) b)

Figure 10. Maximum base shear vs maximum displacement at level 2 graph in the a) X direction and b) Y direction

From the analysis of Figure 8 and Figure 9 it can be seen that, in the X direction the displacement demand is equally distributed between the ground and first floor. This is mainly due to the low number of bracing in the first floor. In the Y direction, the displacement demand is concentrated at the ground floor, highlighting an early plasticization of the inverted V bracings with respect to the first floor diagonal bracings. In both directions, important residual displacements are registered at the end of each time-history analysis. The presence of such residual displacements lower considerably the resilience of the building, given the great difficulties in repairing a deformed and unstable structure.

Interesting information on the building behavior, especially in view of the retrofitting study and optimization, are supplied by the analysis of the input seismic energy transmitted by the earthquake to the structure and the stored and/or dissipated one. In Figure 11 an example of the energy time-histories recorded for the ground motion IN113A (the final A means that the main horizontal component is applied in the X direction) are reported for two different scale factors. It can be observed that, for low SCs, the energy dissipation takes place mainly for viscous damping, while, increasing the seismic action, the energy adsorbed by the structure, strictly related to the structural damage, represent the main component of the input energy.

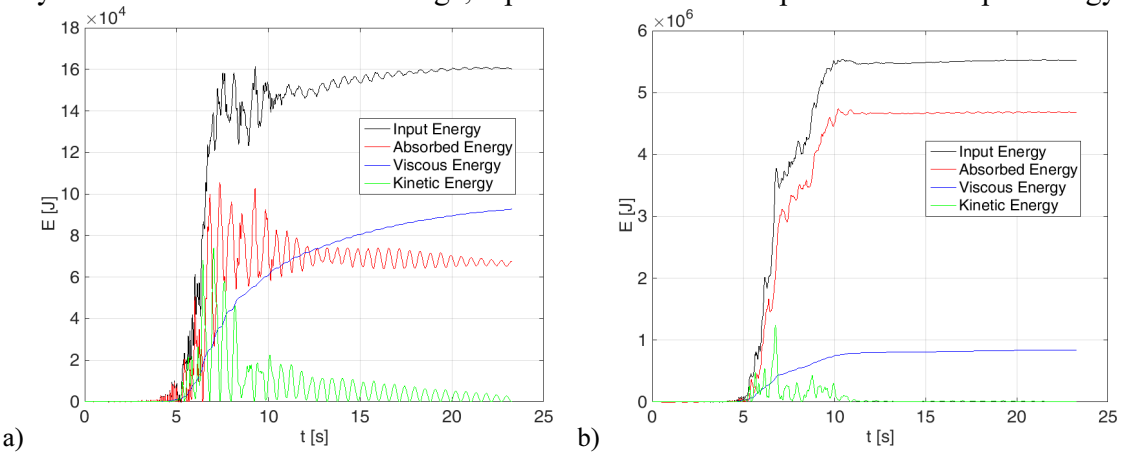


Figure 11. Energy time-histories for the IN113A GM recording: a) SF = 0.275; b) SF= 1.430.

Interesting results can be obtained comparing the ratio between the adsorbed or the viscous energy and the input one for all the GMs and SFs considered, as shown in Figure 12. It can be noticed, in fact, that for all the GMs the ratio with the input energy tends to a certain value, respectively equal to 0.83 for the adsorbed and 0.17 for the viscous energy. This means that, for SFs higher than 0.592 the structure develops the complete collapse mechanism.

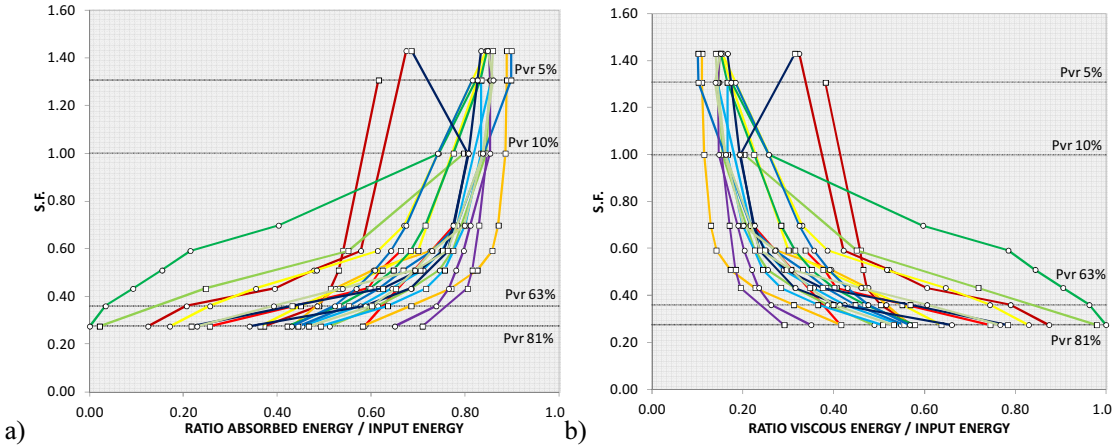

Figure 12. Ratios between: a) the adsorbed and input energies; b) viscous and input energies

3 SEISMIC RETROFIT

The IDAs on the current state evidenced several structural problems, such as:

- the building is characterized by a low stiffness in the X direction, both at ground and first floor. The seismic energy dissipation in this direction is mainly obtained through the formation of plastic hinges in the beams and columns;
- in the Y direction, the initial stiffness is sufficient to avoid excessive displacements, but the high slenderness of the bracings implies a insufficiently ductile dissipating mechanism;
- the eccentricity between the bracings and the column in the X direction causes excessive shear forces in the column;
- the structure is characterized by important residual displacements in both directions at the end of the earthquakes (mean values greater than 100 mm for the higher scale factor considered).

On the base of the aforementioned results, a seismic retrofit intervention, using the Steel Self-Centering Device described in [13] is proposed. In the following, after a short description of the device, the pre-sizing of the retrofit is described and its effectiveness is assessed through IDAs. Finally, the influence of the re-centering capability of the SSCD inserted within the structure is investigated trough a parametric analysis.

3.1 The steel self-centering device (SSCD)

The SSCD, a complete description of which is available in [13], is made up of three groups of elements, each with specific functions: the Skeleton, the Dissipative Elements and the Pretension Elements. The Skeleton serves to transmit and distribute any external forces between the Dissipative Elements and the Pretension Elements. Figure 13 shows the main Skeleton elements (External Carter, Internal Sliding Frame and Endplates), the Dissipative Elements and the Pretension Elements. The Internal Sliding Frame is positioned within the External Carter.

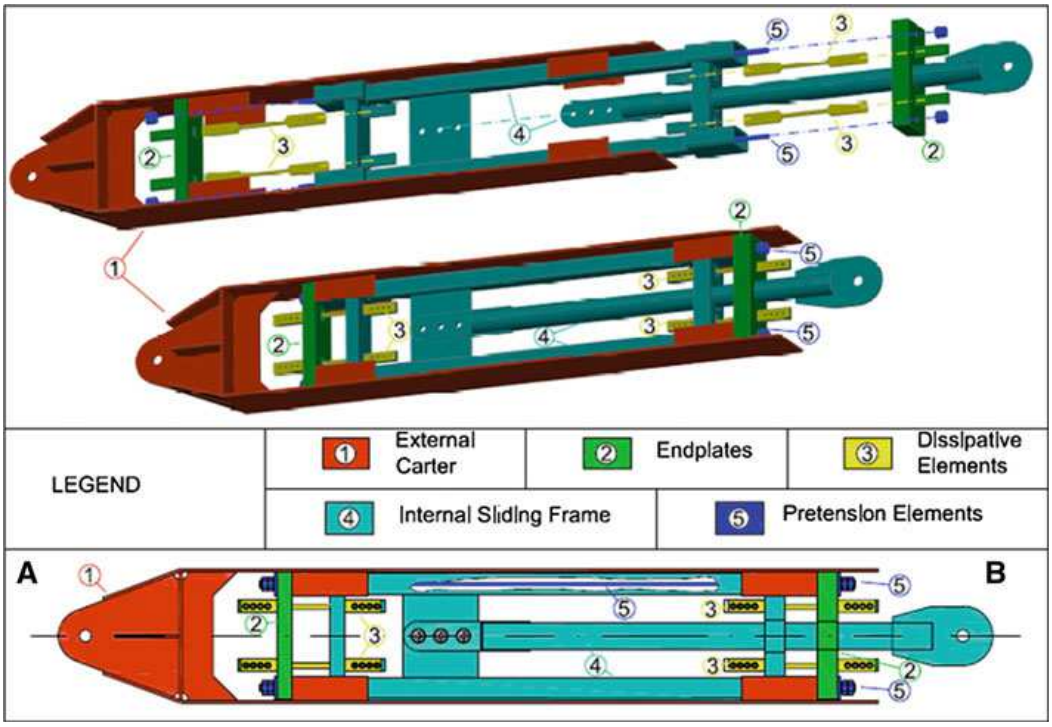

Figure 13. Main elements of the SSCD [13]

The Carter has guide elements that allow the Internal Sliding Frame to move only in the axial direction and, at the same time, serve as stops for the Endplates in the longitudinal direction. The endplates are located in correspondence to the ends of the Internal Sliding Frame. The Dissipative Elements, located within the skeleton, are made up of dog bone shaped steel elements linked to the Internal Carter and the Endplates. They are equipped with a lateral buckling restraining system. The Pretension Elements, made with Prestressing Cables, are located within the Skeleton and linked at both their extremities to the Endplates.

The elements are positioned and connected to each other in order to ensure the same global behavior of the SSCD device under both tension and compression external forces.

Thus, the cyclic behavior of the SSCD is characterized by a flag-shaped hysteretic curve with a residual displacement of zero.

The experimental results carried out in [13] showed the very good capacity of the system in minimizing the residual deformations when the external force drops to zero, see Figure 14.

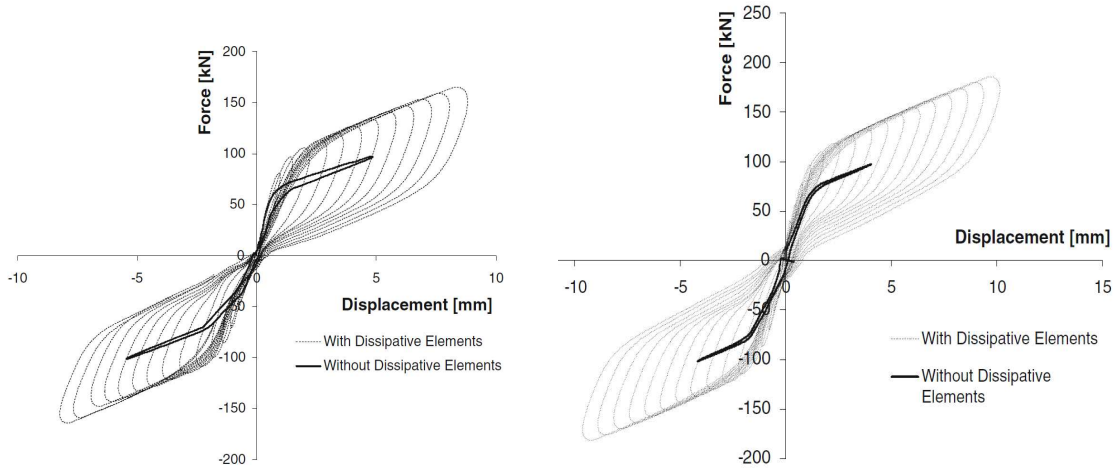

Figure 14. Force-displacement curve of the SSCD with dissipative elements, a) test 1 and b) test 2 [13]

Depending mainly on the value of the ratio between the initial pretension force and the yield strength of the Dissipative Elements, the hysteretic curve of the SSCD may present different shapes, each characterized by different values of the dissipated energy, residual displacement and residual re-centering force, as shown in Figure 15.

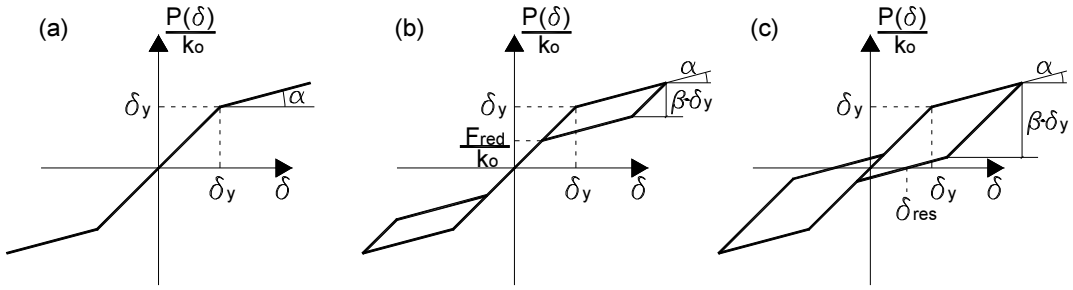

Figure 15. Idealized flag-shaped hysteretic curve normalized by the initial stiffness ko: a) $\beta = 0$, b) $0 < \beta < 1$ and c) $\beta > 1$

The shape of the hysteretic curve can be represented determined by two parameters, α and β, where α is the ratio between the hardening and the initial stiffness, while β reflects the energy dissipation and the system's re-centering capacity [9], which, as mentioned, can be assumed equal to the ratio between the yield strength of the Dissipative Elements and the initial pretension force. A hysteretic curve with $\beta = 0$ can be obtained by using the SSCD without

any Dissipative Element, in which case the device exhibits nonlinear elastic behavior with great re-centering capacity, but no energy dissipation. On the other hand, values of $\beta > 1$ lead to residual displacements (when the external force drops to zero) but also to an higher energy dissipation.

3.2 Pre-dimensioning of the SSCD bracings

The SSCD position is assumed limiting, as much as possible, the interferences with the functionality of the building. The SSCD are so introduced, substituting, in the Y direction and at the first floor of the X direction, the existing bracings. To protect also the ground floor elements in the X direction, supplemental SSCD bracings are introduced as schematically shown in Figure 16.

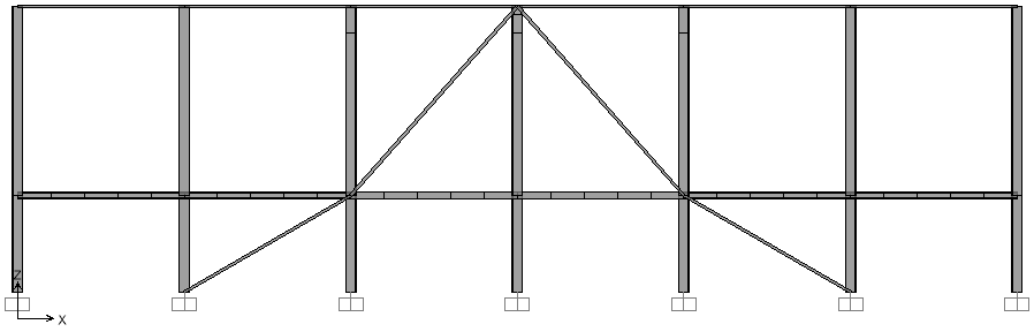

Figure 16. SSCD bracings disposition in the X direction

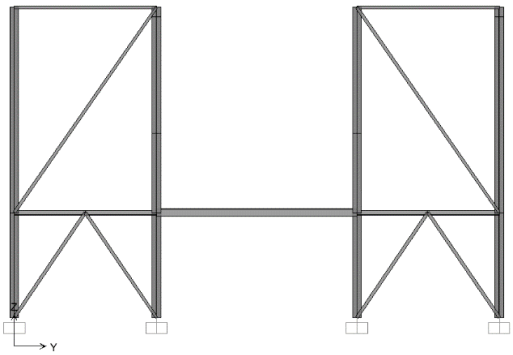

Figure 17. Figure 16. SSCD bracings disposition in the Y direction

The retrofit pre-design is carried out evaluating the characteristics of the SSCD bracings to limit the gravity structure (beams and columns) damage as much as possible. For this reason, the yielding force of the SSCDs are evaluated taking into account the elements resistance to which they are connected. The initial stiffness is estimated imposing a maximum displacement of the gravity structure equal to the one corresponding to the 0.2% of the residual displacement, see Figure 18. The mechanical characteristics of the resulting SSCD are resumed in Table 3.

Level - direction	Number of SSCD	k_o [kN/mm]	F_y [kN]	α	β
Ground floor - X	8	72	529	0.26	0.85
First floor - X	8	88	848	0.26	0.85
Ground floor - Y	28	112	332	0.16	0.85
First floor - Y	14	77	556	0.20	0.85

Table 3. Mechanical characteristics of the SSCDs

Figure 18. Evaluation of the gravity structure displacement corresponding to the 0.2% of residual displacement in the X direction

3.3 IDA results for the retrofitted case

With reference to the levels definition of Figure 7, in the following are reported the main results, in terms of IDA curves.

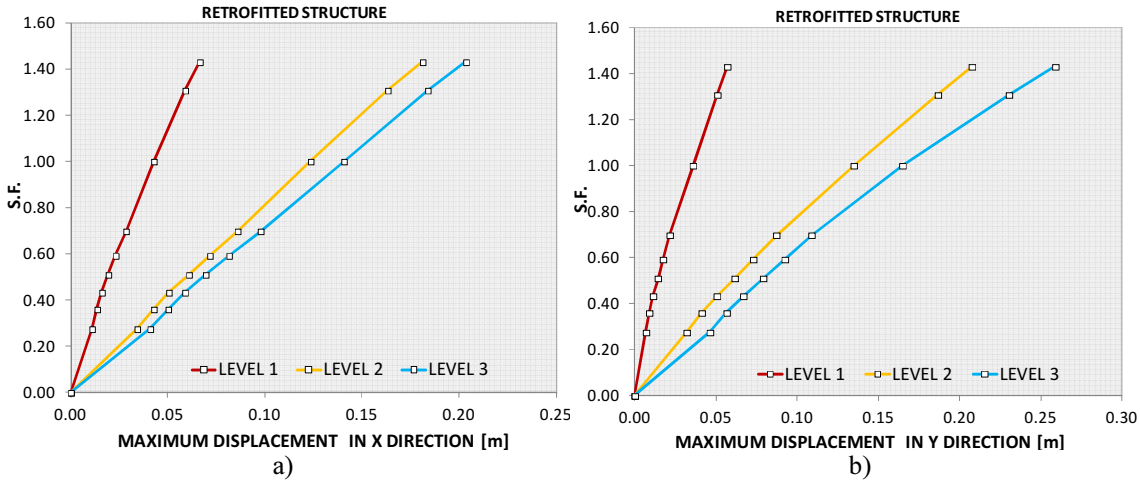

Figure 19. Maximum displacements (mean values) at different level in the a) X and b) Y directions

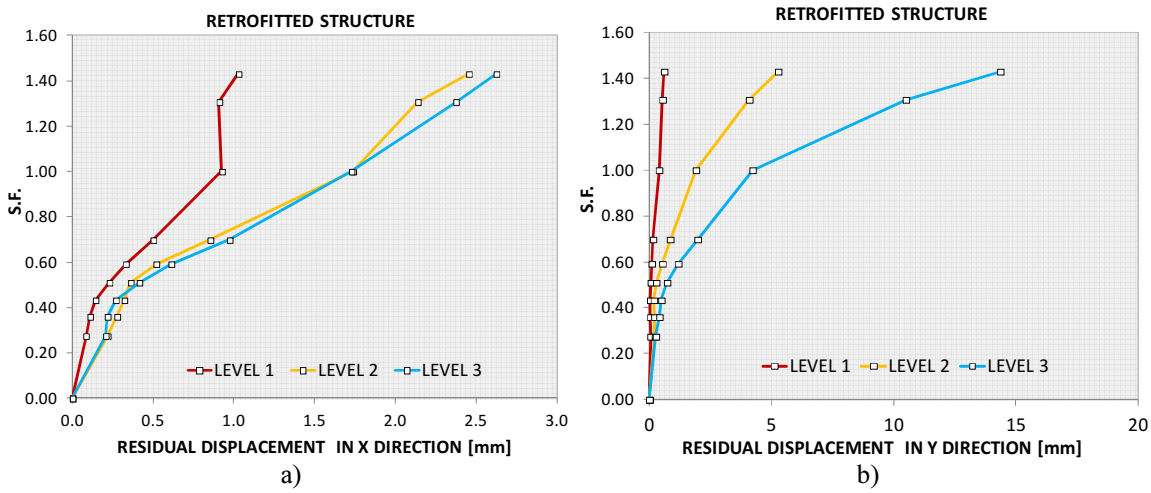

Figure 20. Residual displacements (mean values) at different level in the a) X and b) Y directions

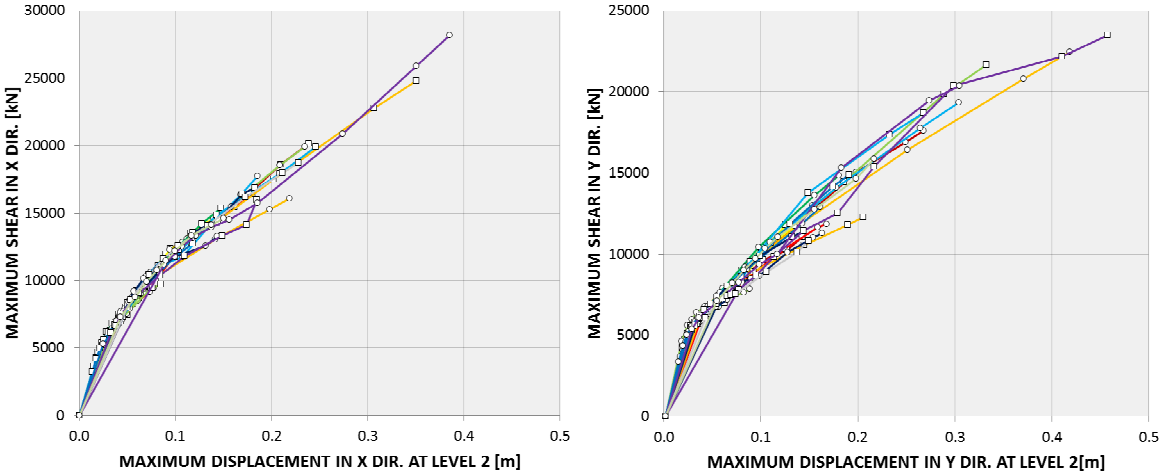

Figure 21. Maximum base shear vs maximum displacement at level 2 graph in the a) X direction and b) Y direction

From the analysis of Figure 19 it can be seen that, in both directions, the displacement demand is now equally distributed between the first and second floor. Figure 20 testifies the optimum re-centering capability of the retrofitting solutions: the residual displacements are lower than 3 mm in the X direction and 15 mm in the Y one. In Figure 22 the displacement time-histories for the Ground motion IN445A, SF=1.430, in both the main directions highlights, together with the global hysteretic curves, the differences in terms of maximum and residual displacements in the case of un-retrofitted and retrofitted structure.

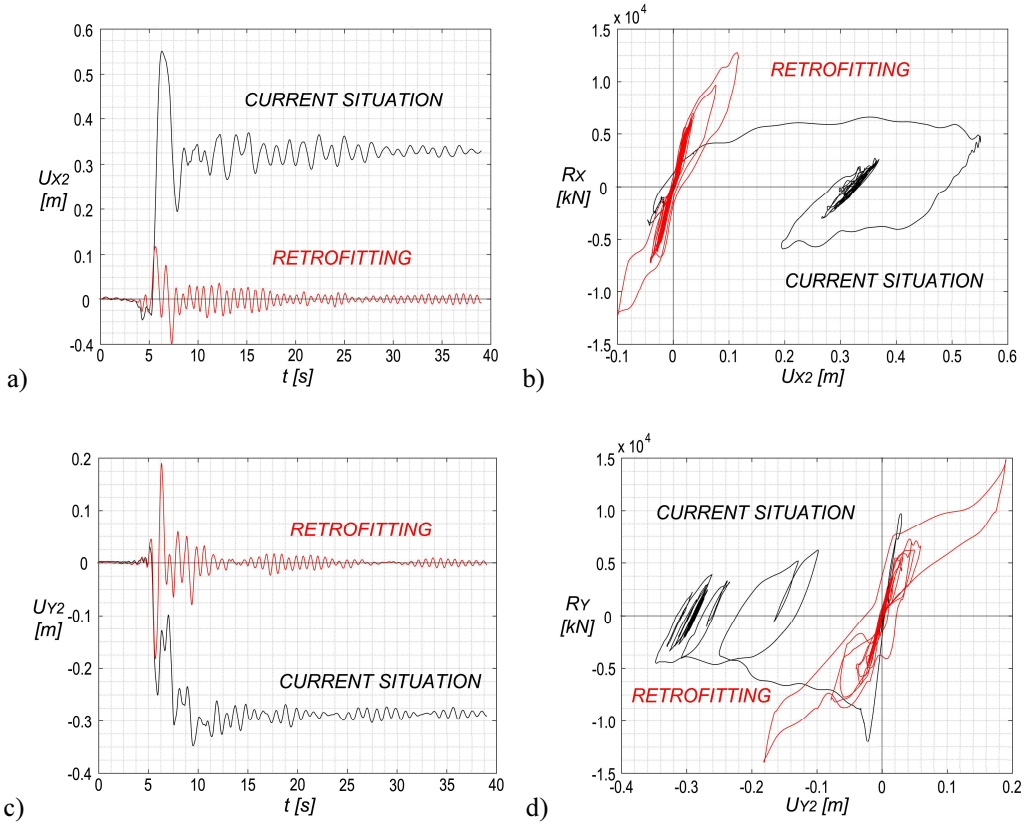

Figure 22. Ground motion IN445A, SF=1.430: level 2 mean displacement time history in a) X and c) Y directions; level 2 mean displacement vs total base shear in b) X and d) direction.

Figure 23 shows, for clarification purpose, the energy time-histories for the IN113A GM for the minimum and maximum scale factor adopted, respectively equal to 0.275 and 1.430. For low value of the seismic action, the gravity structure remains in the elastic field and the energy adsorbed by it is practically equal to zero and all the input energy is dissipated by viscous phenomena, contrarily to the case of the un-retrofitted structure, see Figure 11. When the seismic action and, consequently, the input energy increase, the ratio of energy dissipated by viscous phenomena decreases and the input energy is mainly dissipated by the SSCDs. A low ratio (about 1/5 with respect to the un-retrofitted case) is absorbed by the gravity frame, evidencing so a good level of structural protection.

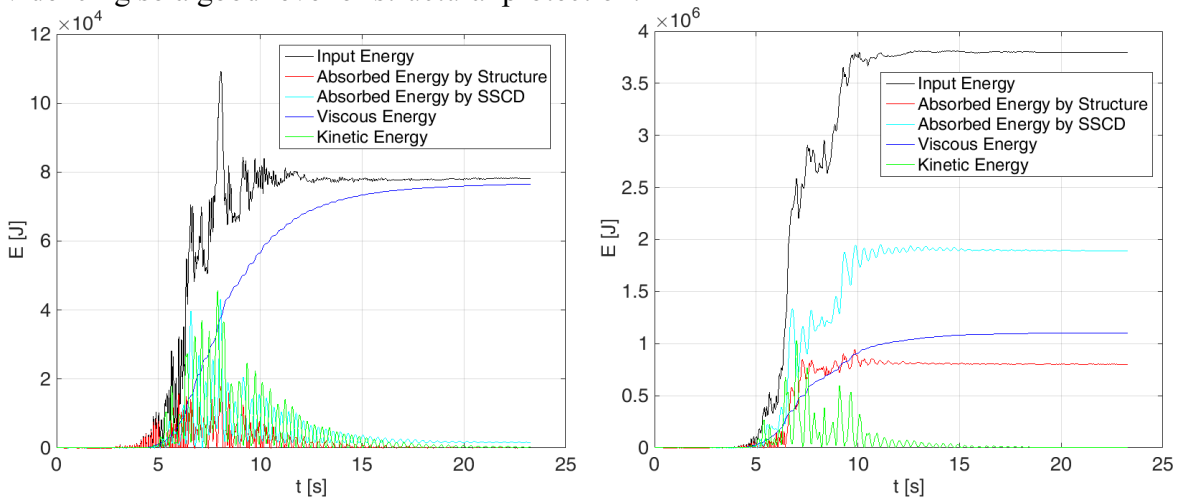

Figure 23. Energy time-histories for the IN113A GM recording: a) SF = 0.275 ; b) SF= 1.430.

The effectiveness of the retrofit can be appreciated analyzing Figure 24 where the energies adsorbed by the gravity structure, representative of the structural damage, and the one dissipated by the SSCDs, both normalized by the input energy, are represented. The structural protection is optimized for values equal to about 0.6, while, for higher values, also the gravity structure dissipates energy, accumulating so damages.

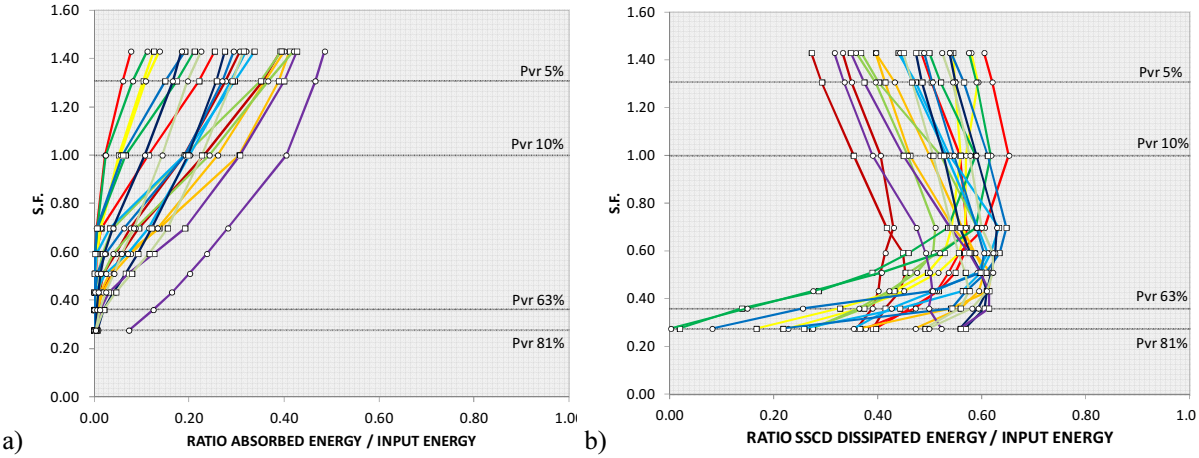

Figure 24. Ratios between: a) the energy adsorbed by the gravity structure and the input one; b) energy dissipated by the SSCDs and input one

4 CONCLUSIONS

In the present paper the seismic retrofit of an industrial structure through an innovative self-centering hysteretic dampers is proposed. The need of performing several Incremental Dynamic Analyses required a preliminary simplification phase of the nonlinear model. It resulted that, even for the linear model, the uncertainties related to the missing of a precise knowledge of the infill material mechanical characteristics, does not influence sensibly the dynamic behavior of the whole model. Moreover, for the specific case study analyzed, where the main structural problems are located in the supporting structure, the modelling of the supported silos as elements with equivalent stiffness and mass, provides results, in terms of dynamic responses, very close to one supplied by a refined model.

The execution of IDAs on the nonlinear model of the building in the current state, highlighted several structural problems, even for low value of the seismic action, especially in terms of excessive maximum displacements demand and of residual displacements.

To solve these problems, a retrofit solution using an innovative Steel Self-Centering Device (SSCD) is proposed. The execution of IDAs also in the retrofitted state, highlighted that:

- the dampers minimize, in a very effective way, both the maximum and residual displacements of the structure;
- the gravity structure is completely protected for low-to-mid value of the seismic action, as highlighted by the analysis of the seismic energy components;
- the proposed retrofit solution is optimized for a scale factor, associated to the design spectrum adopted, equal to 0.60. For higher values of scale factors, the building is however able to sustain the seismic action, but some damage is accumulated also in the gravity structure.

Supplemental studies are currently ongoing to evaluate the sensitivity of the building response to the SSCD mechanical characteristics and to compare the efficacy of the innovative damper adopted with respect to the one of a "classical" solution, such as a buckling restrained brace (BRB), not characterized by the presence of a re-centering force, but with an increased energy dissipation capacity [16] [17].

Keywords: Industrial Structures, Silo Structures, Seismic Retrofitting, Seismic Protection Devices, Model Simplification, Incremental Dynamic Analyses

Abstract. *This paper deals with a real-world silo structure and the assessment of its seismic performance and possible retrofitting measures by using seismic protection devices. Firstly, the silo structure is shortly described followed by a simplified numerical modelling approach with the aim to save computational effort as much as possible but still achieve a reliable response of demands and failure modes. A comparison between the complex and simplified model is done, showing a very good match in terms of its dynamic properties, which are Eigenfrequencies, modal shapes and effective modal masses. With this simplified model incremental dynamic analyses are conducted to assess the current performance of the structure as-built. Strengths and weaknesses are highlighted by the simulation outcomes. Following, two possible retrofitting strategies using torsion-based hysteretic dampers are discussed. Hereby it is shown, how the seismic device can be modelled in any finite element software by using rheological models. In one strategy of seismic retrofit an innovative torsional device is inserted at single bays of the structural frame. In the second strategy the steel torsional hysteretic damper is applied at the base of the steel columns, such that the structure is separated from the ground. The first retrofit approach proves to be effective in prohibiting a severe sides-way collapse which occurred for some earthquakes. The second shows to be greatly effective in preventing failure and also decreases deformation demands on the structure efficiently.*

1 INTRODUCTION

Seismic events may have disastrous effects on industrial sites; for example the Duzce earthquake in Turkey 1999, the L'Aquilla earthquake 2009 in Italy or the more recent Tohoku earthquake in Japan 2011 caused huge financial losses, as they all affected important industrial areas. One reason for the high losses are the high financial investment costs gathered on industrial sites which are at risk due to direct damage of industrial components and facilities. However, also more frequent smaller seismic events can lead to impairment of the functionality of key components and thus cause costly business interruptions. A further special characteristic of industrial facilities is the usual high risk potential of environmental damage as well as potentially threats to health and life of employees. For these reasons industrial structures are ideally suited for seismic design and retrofit by using special seismic protection systems.

The European project "PROINDUSTRY – Seismic PROtection of INDUSTRial plants by enhanced steel based sYstems" aims at developing such enhanced seismic protection devices applicable to new and already existing industrial structures. One of the several case studies investigated in the scope of the project is a large silo structure located in a steel plant. This silo is a very important member of the supply chain and its loss of functionality may lead to business disruption of the whole plant.

In this paper this realistic silo structure is firstly investigated as-built and further on different seismic retrofit strategies are applied. To assess on the effectiveness of the seismic retrofitting measure incremental dynamic analyses are the most detailed tools available. Due to the scatter in the characteristics of natural earthquakes a big amount of analyses needs to be conducted to obtain reliable results. As especially industrial facilities are often large and of complex nature, computational effort might be unmanageable. Therefore, usually a simplified model of the complex structure is sought after, which preserves characteristic dynamic behavior by being feasible to handle. Moreover, in order to obtain a reliable structural response not only the structure itself needs to be modelled realistically, also the applied seismic device needs to be represented appropriately. If the used finite element software does not provide special elements to model the behavior, which is often the case for new innovative seismic devices, it will be needed to use more or less complex rheological models or to implement ones own algorithm in the analysis core of the used software.

After a short description of the case study, a simplified modelling approach for the complex structure as well as the seismic device is presented. With these models first the as-built seismic performance is assessed and secondly two retrofitting strategies are investigated and its outcomes are compared to the initial stage.

2 SILO STRUCTURE CASE STUDY

2.1 Description of the case study

The case study investigated herein is an elevated silo structure with several rectangular silos constructed in the early 70s. The silo is part of a huge steel plant and stores iron ore, limestone and sinter. Thus, the structure has a key role in the storage and supply chain of the whole industrial facility. When the silo is out of function, this will lead to a costly downtime of several other operations within the industrial site. An assessment of the seismic performance and a potential seismic upgrade is therefore highly advantageous.

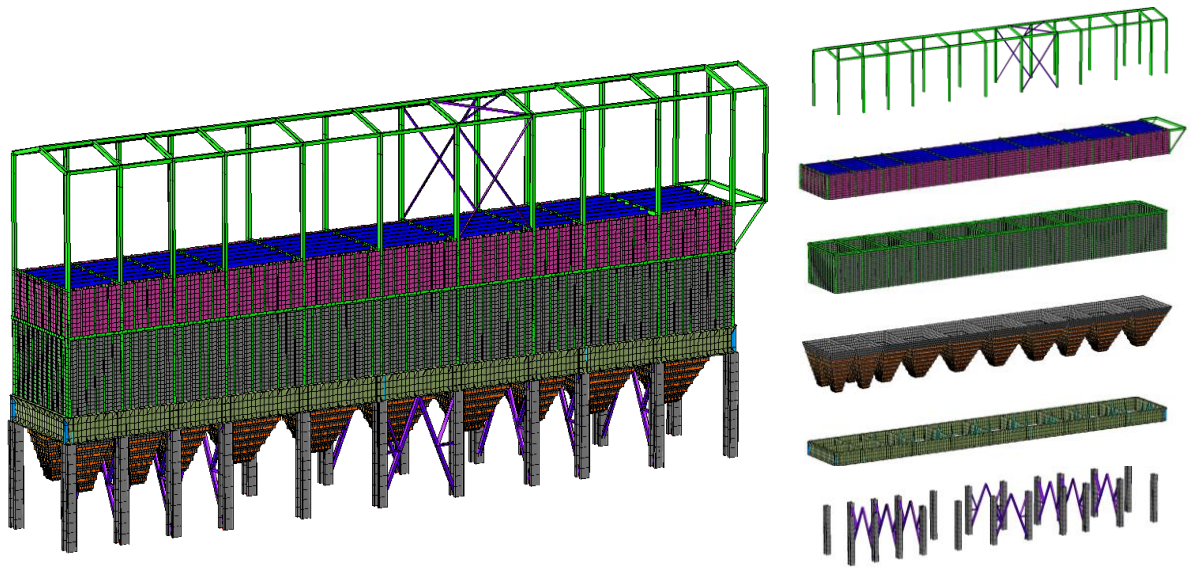

Figure 1: Silo steel structure. Complete model (left) and single subassemblies of silo structure (right).

The building has dimensions of W x H x D equal to 78 x 40 x 11 m. The structural layout and main characteristics can be seen in Figure 1. The most significant single subassemblies of the structure are shown on the right of Figure 1. The top is made of a roof beam structure, which is based on vertically stiffened shells and horizontal beams. The level below is formed by the silo shaft composed of shells with vertical stiffeners and an upper ring beam. Adjoining are the silo hopper shells stiffened by horizontal beams. Below is the hopper skirt support, which is also strengthened with vertical stiffener plates. Finally, at the lowest level the steel supporting structure is visible, which is made of heavy built-up columns and braced frames, whereby inverted V-bracings are used. It can be seen that 6 braces are built in the short Y-direction which will be named transversal direction in the following, and 2 braces in the long X-direction, labeled as longitudinal direction. Probably, the unbalanced number of braces in the two directions is attributed to the fact that wind forces were the essential considerations for the design of the bracing system, thus more braces are needed in transversal direction due to the big area where wind forces can act on. The calculated mass of stored material equals approximately 25,000 t and the self-weight of the steel structure equals to 2,400 t. The structure is made of S275 structural steel.

2.2 Description of the simplified model

The complete finite element model shown in Figure 1 is very complex and has a large number of degrees of freedom. The total number of dynamic simulations equals to 198, which results from two sets of ground motions (low-to-medium and high seismicity) with each eleven ground motion time histories times nine scaling factors. Taking into account that both the original and the retrofitted have to be simulated the number already rises to 396 dynamic time history simulations. Moreover this number is the absolute minimum. It does not consider repeated simulations due to different retrofitting strategies and varying parameters of the used seismic protection device and does not take into account several runs due to debugging . Thus, in total several hundred analyses will be needed to be conducted. Not only the computational time, but also the limited storage for simulation output may show up to be problematic. Therefore, due

to the huge amount of dynamic simulations which need to be conducted during the PROINDUSTRY project a computationally more efficient model was sought after.

The approach in simplifying the numerical model was to concentrate on the supporting structure and neglect the silo structure. This assumption was based on several reasons: Firstly, the silo shells are quite thick and massively stiffened, such that global failure of the structure is assumed to take place in the steel supporting structure rather than in the steel silos. Secondly, the dynamic modelling of the bulk material inside the silo would be needed to obtain reliably local failure of the silo shell. However, complex interaction models would be needed which further need several input parameters afflicted with a high level of uncertainties. Thus, on the one hand the reliability of the sophisticated approach would be still questionable and on the other hand the complexity excludes practically the simulation of several hundreds of analyses.

However, with the simplified approach just demands on the supporting structure and the mass points representing the silos are determined, without giving information about demands on the silo shells. However, peak forces and differential displacements obtained by the simplified model might be statically applied to the bottom or center of gravity of the silos bins. In a more complex approach, for bypassing this lack of information acceleration time history of the supporting structure may be applied to the bottom of the silo structure in a separate analysis, i.e. a cascaded approach similar to the floor response spectrum method used for SDOF systems. In this case the most detrimental excitation cases could be applied, to avoid extensive simulations but still to obtain reliable performance of the superstructure.

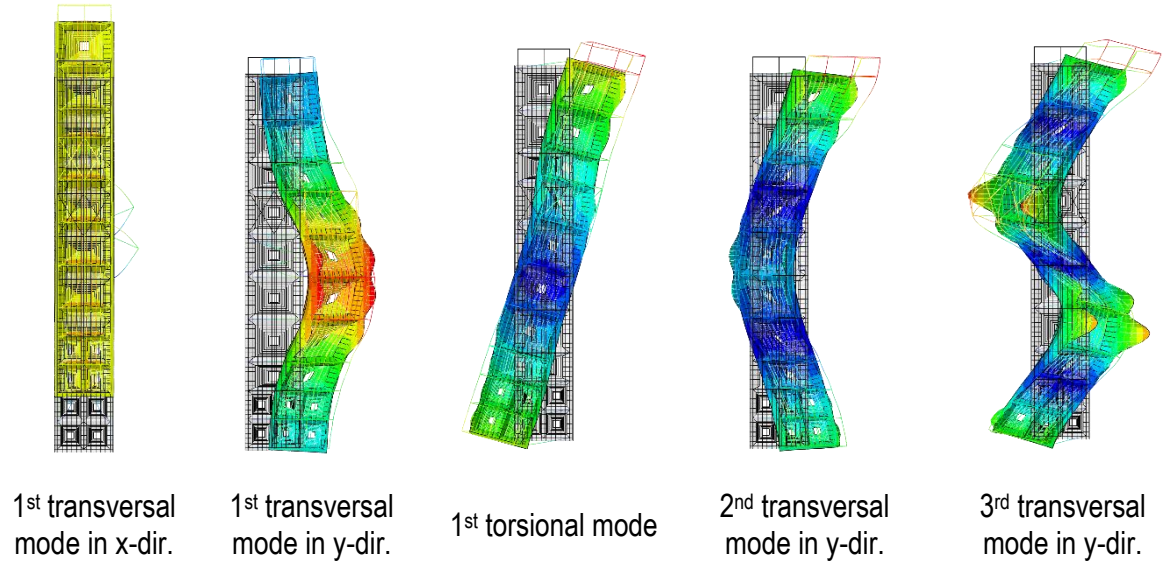

Figure 2: First five global mode shapes of complex structure.

Summarizing a simplified model is sought after, where the supporting structure is modelled explicitly by beam elements and the superstructure is taken into account by equivalent mass and stiffness properties applied to the supporting structure. Considering the Eigenmodes of the complex model shown in Figure 2, it is obvious that the superstructure cannot be modelled as rigid. Thus, a simplified model needs to capture the flexible behavior of the superstructure without explicitly modelling it. The flexibility needs to be modelled at the connection of the columns to the silos, representing the joint details shown in Figure 4 left. Finally, the simplified model shown in Figure 3 has been found to be appropriate. The silos are represented by mass points, which are located at the center of gravity of the full silo bins. A configuration of all silo bins totally filled has been investigated in this research work, which is in general the most critical

situation. Torsional response due to extreme misbalanced filling configurations might be also critical, however this issue was not investigated further herein. The silo mass points are connected to each other by several constraints. The cross sections are modelled as fibre elements, where the stress strain law is intergrated at every interpolation point. Conservatively, an almost elastic – ideal plastic stress strain curve with a yield point of 27.5 kN/cm² has been assumed. The connection of the silo mass assembly with the column tops was the key point and is discussed in the following.

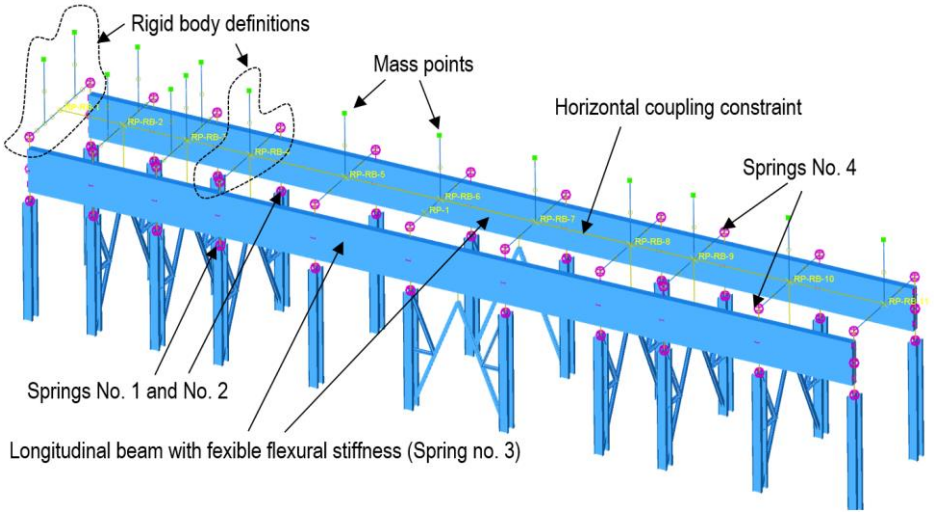

Figure 3: Simplified model with explicitly modelled supporting structure made of columns and frame braces with equivalent springs and couplings in order to take the flexible superstructure into account.

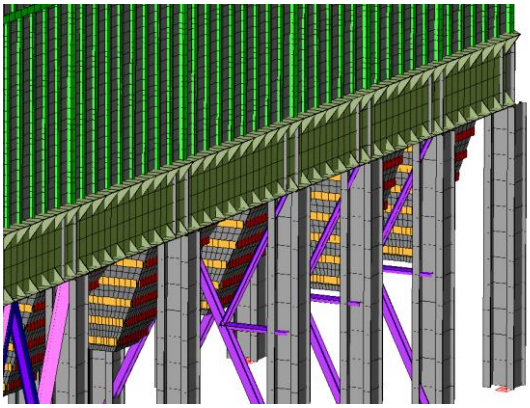

Figure 4: Connection detail between supporting and superstructure at columns.

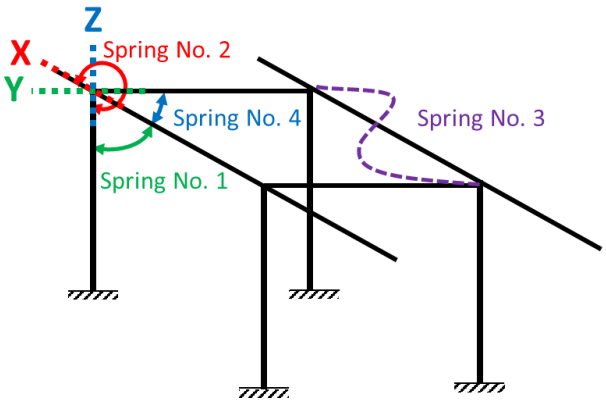

Figure 5: Schematical drawing of spring subassembly.

In order to obtain a reliable response of the simplified model, in total four spring or flexural stiffness properties respectively have been applied to the model. A schematical drawing of these springs can be found in Figure 5. A short description of each spring characteristic is given in the following Table 1.

The spring parameters were calibrated by a trial-and-error procedure until three aspects in the simplified model matched the complex model's ones for the relevant modes:

- Eigenfrequencies
- Modal shapes
- Effective modal masses

Spring No. 1

- *Rotational spring about global Y-axis*
- *Connecting column top nodes and node of longitudinal beam*
- *Dominant spring for fundamental mode, not affecting higher relevant modes*

Spring No. 2

- *Rotational spring about global X-axis*
- *Connecting column top nodes and node of longitudinal beam*
- *Influencing higher relevant modes*

Spring No. 3

- *Rather a smeared stiffness property than a spring*
- *Flexural stiffness about local z-Axis of longitudinal beams (i.e. also global Z-Axis)*
- *Influencing higher modes, is needed to achieve transversal flexible behavior*

Spring No. 4

- *Rotational spring about global Z-axis*
- *Connecting longitudinal beam and transversal rigid T-type beam nodes. Influencing higher modes, is needed for the transversal flexible behavior to distribute transversal deflection from the higher displacement value at the middle to both ends in the longitudinal dimension, or in other words to form a more smooth transition from the middle bulge to the outer frames (see e.g. Figure 2: 1st transversal mode in y-dir.)*

Table 1: Spring characteristics used in simplified beam model.

The final spring values which yielded the best match of the dynamic properties are given in Table 2. Whereby the rotational springs No. 1, 2 and 4 can be specified directly, the flexural stiffness of the longitudinal beams (spring No. 3) is achieved by defining a cross section with dimensions of 70 x 400 cm and an elastic modulus of 21000 kN/cm².

Spring No.	Label	Value	Units
1	$K_{1,\phi}$	610 000	kNm/rad
2	$K_{2,\phi}$	5 500	kNm/rad
3	$K_{3,EI}$	24 010 000	kNm²
4	$K_{4,\phi}$	10 000 000	kNm/rad

Table 2: Spring parameters used for the simplified model.

In the following the achieved match of dynamic properties between the simplified beam model and the full structure model is shown. Modal frequencies of the first five modes are shown in Table 3. Effective modal masses in both horiziontal directions are listed in Table 4. The total mass of the system is 27 400 t. Corresponding modal shapes of the simplified and the full complex model are shown in Figure 6 to Figure 10 for comparison. It can be stated that for the most relevant modes no. 1, 2 and 4, the dynamic properties of the complex model are well represented with the simplified beam model.

2.3 Seismic input

As input for the Incremental Dynamic Analyses recorded ground motion time histories have been used. A detailed description on the selection criteria and characteristics of the accelerograms can be found in [1]. Two sets with each eleven ground motions have been assembled: One set representative for low-medium seismicity regions and one representative for high seismicity regions (see Table 5 and 6 respectively). For the matching of the target spectrum the geometrical mean of both horizontal components has been used. Figure 1 and Figure 12 show the individual spectra of the selected accelerograms along with the mean and target spectrum. All three components – two horizontal and one vertical – were taken from the same recording. Also the vertical component has been applied in the simulations, because it might be critical due to the very high gravity loads present in the silo structures.

For the incremental dynamic analyses in total nine scale factors – different ones for the low-medium seismicity and high seismicity ground motion sets – have been used. The scale factors were chosen such that different return periods have been covered, starting from rather frequent earthquakes (return period of 60 years) to extreme rare earthquakes (return period of 2475 years).

3 SEISMIC PERFORMANCE OF AS-BUILT STRUCTURE

First the as-built structure has been subjected to all earthquake time histories and scale factors. The most important outcomes are discussed in the following sections separated for the low-medium and the high seismicity ground motion sets. In general all simulations have been conducted geometrically fully nonlinear (large displacement theory).

3.1 Low-medium seismicity ground motion set

The incremental dynamic analyses with the low-medium seismicity accelerograms showed no larger convergence problems. Figure 14 shows the displacement at the top of the supporting structure in longitudinal and transversal direction as function of peak ground acceleration PGA. At the lowest scale factors the structure behaved almost elastic. For lower scale factors braces buckled in compression and yielded in tension. For the highest scale factors strong yielding and buckling occurred in almost all braces. Also all columns yielded at their base. However, no failure of the structure occurred for all of the earthquakes even at the highest scale factor.

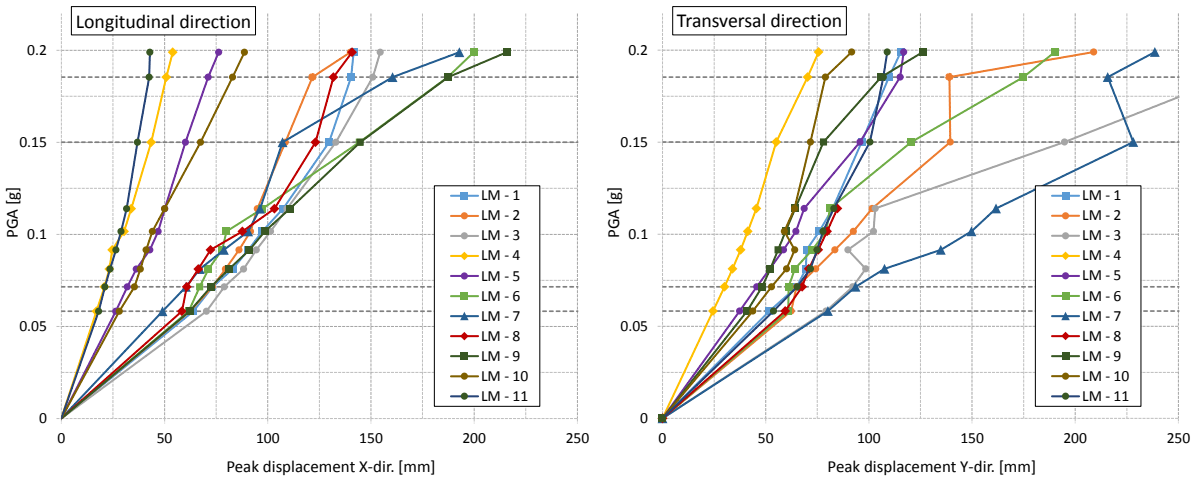

Figure 13: Low-medium seismicity IDA curves in longitudinal X- (left) and transversal Y-direction (right)

3.2 High seismicity ground motion set

As expected the high seismicity ground motion set provided much higher demands on the structure. Strong yielding patterns (yielding and buckling of braced frames, yielding of columns at base and top) occurred already for low scale factors. Figure 14 shows the corresponding IDA curves. At higher scale factors convergence difficulties occurred, thus, the IDA curves are not complete, as just fully completed simulations are shown in the diagram. The premature abortion of simulations mainly arrived due to collapse of the structure or excessive deformations of braces. The performance of the structure for each earthquake is summarized in Table 7.

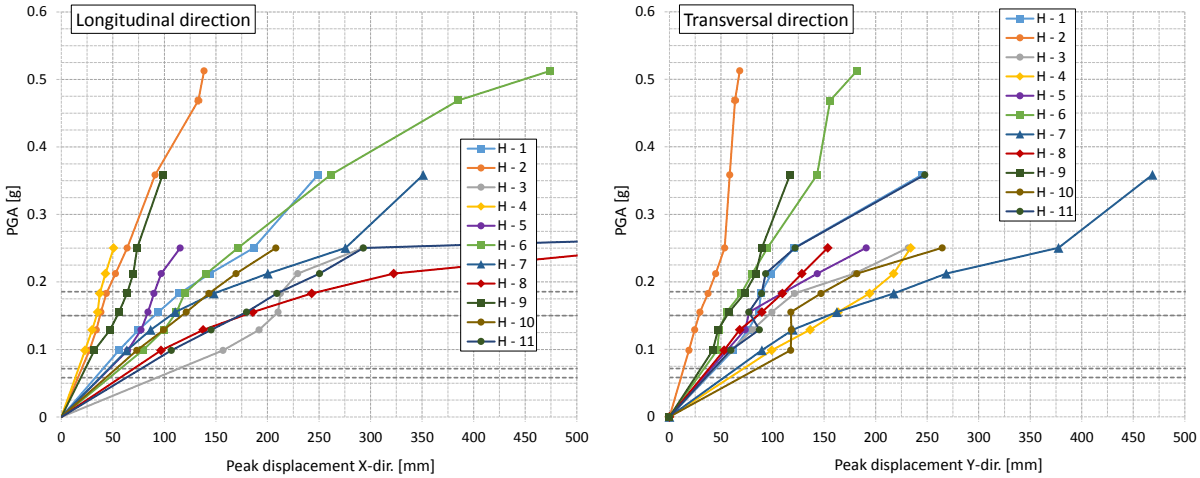

Figure 14: High seismicity IDA curves in longitudinal X- (left) and transversal Y-direction (right).

Ground motion	Comment
H – 1	Excessive deformation of one brace causes convergence problems
H – 2	Full range of scale factors finished
H – 3	Global sidesway collapse in longitudinal direction
H – 4	Five braces exhibit excessive deformations leading to abortion of the simulation
H – 5	Excessive deformation of one brace causes convergence problems
H – 6	Full range of scale factors finished
H – 7	Three braces deform extensively and cause abortion of the simulation
H – 8	Global sidesway collapse in longitudinal direction
H – 9	Five braces exhibit excessive deformations leading to abortion of the simulation
H – 10	Three braces deform extensively and cause abortion of the simulation
H – 11	Global sidesway collapse in longitudinal direction

Table 7: Comments on performance of IDA simulations.

Three of eleven earthquakes triggered a clear sides-way collapse in longitudinal direction. This highlights one of the weakness of the structural layout. Whereby in the transversal direction the structure is stiffened by in total 6 braced frames just two braced frames exist in the longitudinal direction. Obviously wind forces have governed the brace layout, where due to a much larger influence area the resulting lateral force is high in transversal direction and is relatively low in longitudinal direction. The evolution of the typical sides-way collapse is illustrated in Figure 15. Yielding at the bottom of columns is followed by yielding and buckling of the two frame braces and yielding of column tops and finally the structure collapses due to P-Delta-effects. In six of the eleven earthquakes the simulation aborted prematurely either due to torsional buckling of the columns, which was triggered by out of plane displacements of the bracing frames, or due to or excessive deformations of the braces. See Figure 16 for an impression. Two of the eleven earthquakes finished without signs of global collapse.

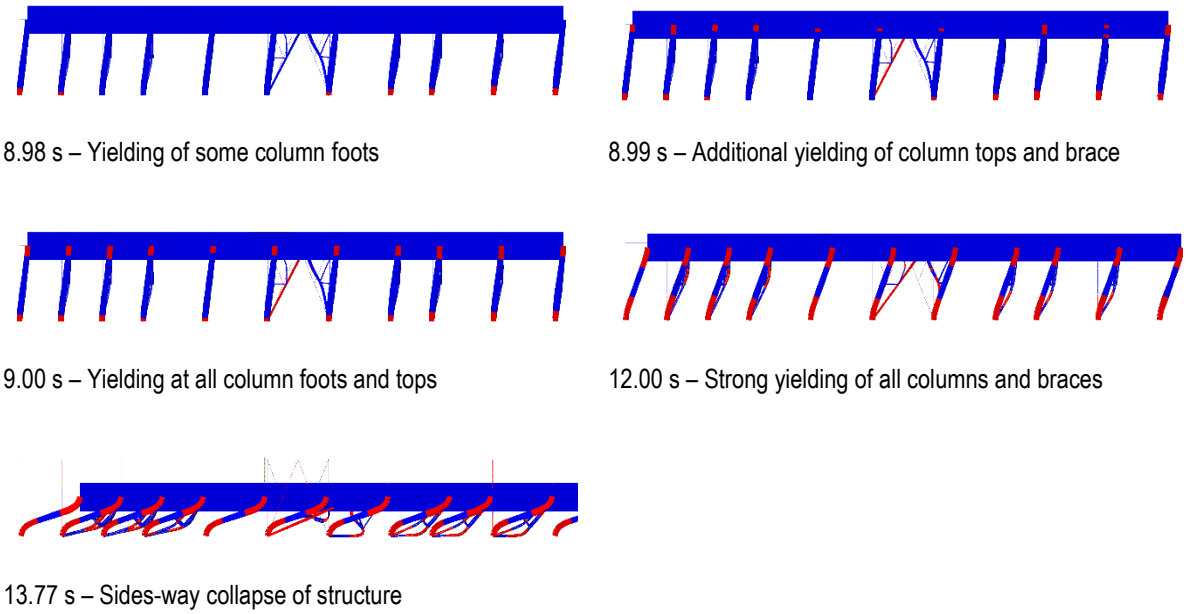

Figure 15: Chronological evolution of sides-way collapse which occurred for earthquakes no. 3, 8 and 11, deformation scale factor 1.

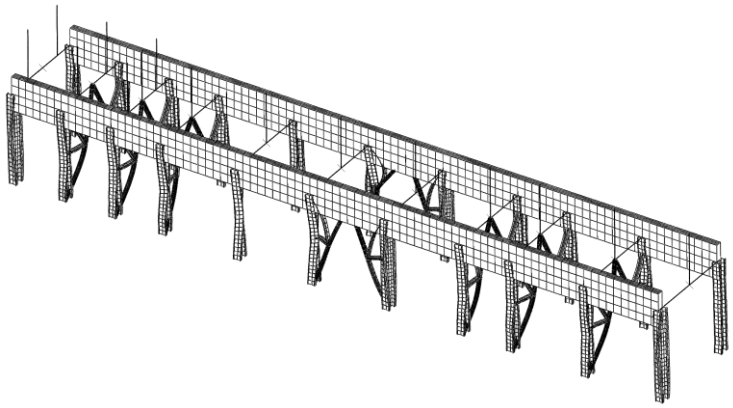

Figure 16: Failure mode torsional buckling of columns triggered by out of plane displacement of brace layer, deformation scale factor 1.

4 SEISMIC RETROFITTING STRATEGIES

The principle of torsional yielding of steel rods shall be used in the phenomenologically modelled applied seismic devices. Such devices exist for example as Multi-Directional Hysteretic Devices explained in [2]. After a short introduction into the hysteretic behavior of such devices two generic retrofitting strategies will be investigated: As first retrofitting strategy a torsional damping device is applied inside the braced frames and as second strategy it is used as base isolation layer inserted between ground and structure at each column base.

4.1 Torsional energy dissipation devices

The seismic device hysteresis loop is shown in Figure 17. The most important aspects are the beneficial stiffening effect for higher displacements and the isotropic hardening of the yield surface. The stiffening effect is accomplished by the kinematics of the system. Two numerical

models have been tested to simulate the hysteresis loop of the seismic device, which are schematically sketched in Figure 18. Basically a plastic spring is put in parallel with either contact elements which are themselves put in series with additional elastic springs or just one multilinear elastic spring. The plastic spring accounts for the yielding and the isotropic hardening effect, which is accomplished by choosing appropriate isotropic hardening parameters. The stiffening effect is modelled by the contact element and elastic spring series or the multilinear elastic spring. The more contact spring combinations or data points for the multilinear spring are used, the more smooth the post yielding curve will look like. Both systems are able to reproduce the same hysteresis curve shown in Figure 17. The fit between test and simulation seems to be acceptable taking into account the simplified modelling approach. Although both modelling approaches yield the same results, the second one proves to be more robust and computational efficient, mainly due to the lack of highly discontinuous contact elements. In general, no convergence issues could be observed for the second approach and runtime of simulations compared to the unretrofitted simulations just slightly increased.

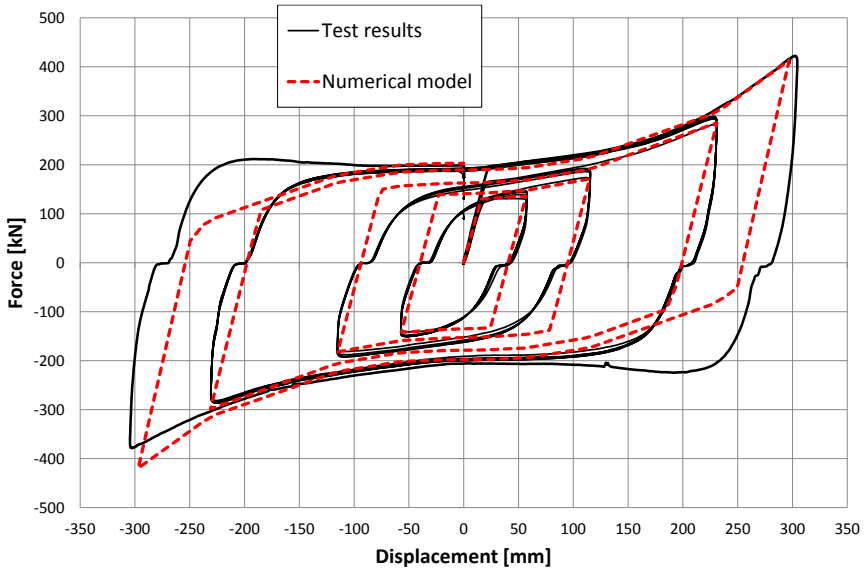

Figure 17: Typical force displacement hysteresis for torsional devices obtained by experimental tests (prototype with one default yielding core) [provided by MAURER SÖHNE] and results of numerical representation.

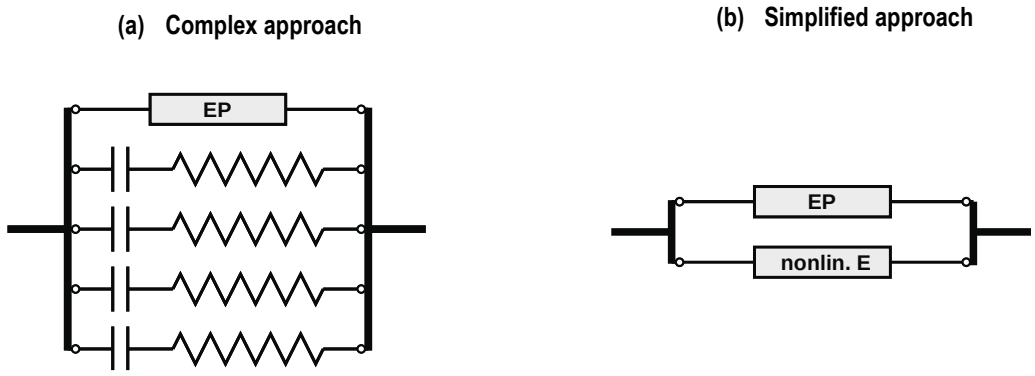

Figure 18: Rheological models to simulate the hysteresis of the torsional seismic device: approach with contact elements (a) and approach with multilinear elastic spring (b).

4.2 Retrofitting approach I: Energy dissipation in braced frames

The torsional hysteretic device inserted between an added V-brace and the bottom of the superstructure has been modelled phenomenologically by inserting the rheological model discussed aboved at this spot. Figure 19 ashows a schematical sketch of this approach. The diagonals in the V-brace need to act both in tension as well as in compression. In order to prevent buckling the braces need to be sufficiently squat. In the simulations the flexibility of the V-brace was assumed to be negligible compared to the flexibility of the device and thus was modelled as rigid.

The analysis conducted is considered as demand identification, i.e. how much torsional rods of the characteristic shown in Figure 17 are needed to improve the structural response significantly. The main purpose was to prevent the global sides-way collapse which happened in three of eleven earthquakes for the original structure. By an iterative procedure it was find out that in total 48 of torsional yield cores used for the whole structure would achieve this aim. Using thicker yielding cores the total amount would decrease accordingly. Number of cores per bay and number of bays need to be adapted to constructive and practicability boundary conditions. For example Figure 19 shows a device equipped with four yielding cores.

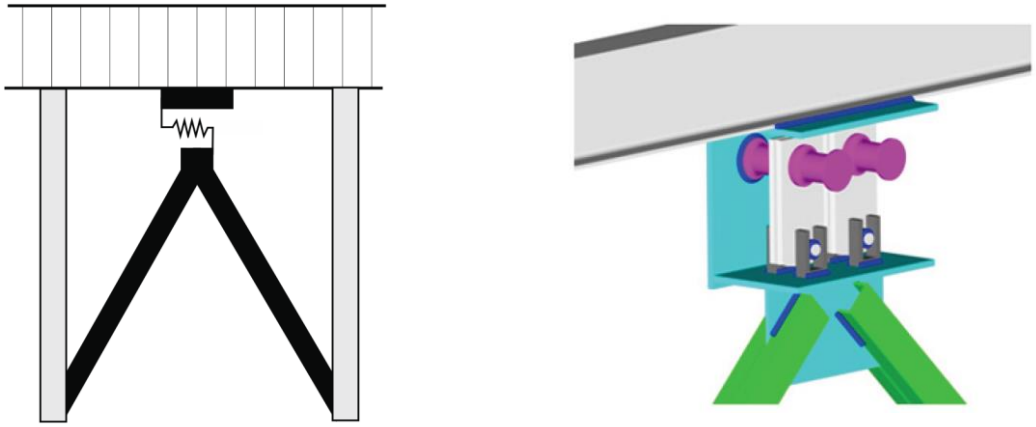

Figure 19: Schematical drawing of applied torsional hysteretic device into frame bay (left) and detail of prototype torsional device equipped with four yielding cores (right, [3]).

The applied retrofitting strategy adds additional amount of damping to the structure but also increases the stiffness of the longitudinal sway mode. Thus, this mode shifts to a higher acceleration value in the response spectrum which might cause an increase in demands. The modal periods of the structure after application of one of the discussed retrofitting strategies are listed in Table 8 while the mode numbering is in accordance to the mode shapes shown in Figure 6 to Figure 10.

	Modal period T [s]		
	As-built	Retrofit I	Retrofit II
Mode 1	1.69	1.18 (*70%*)	2.50 (*150%*)
Mode 2	1.24	1.24 (*100%*)	2.09 (*169%*)
Mode 3	0.90	0.89 (*100%*)	1.71 (*190%*)
Mode 4	0.72	0.72 (*100%*)	0.89 (*124%*)
Mode 5	0.59	0.59 (*100%*)	0.65 (*110%*)

Table 8: Modal periods after application of retrofitting.

A comparison between the as-built structural performance and the retrofitted structure shows that with the determined amount of steel cores the failure mode of sides-way collapse could be completely excluded. Figure 20 shows the corresponding IDA curves. Whereby for the H – 8 peak displacement are still high – but without collapse taking place – the peak displacement for the other two earthquakes H – 3 and H – 11 are siginificantly reduced. Figure 21 shows a comparison for the no failure earthquakes. In general peak displacements are in most cases equal or lower, especially at the highest peak ground acceleration yielding a reduction of at least 20% can be obtained. The same holds true for the other earthquakes. Due to the period shift in some cases peak displacements may also be higher. The ratio of peak displacements of as-built to retrofitted behaviour is shown in Figure 22. Otherwise than the sides-way collapse failure mode, the other premature abortion reasons due to excessive brace deformations still occur. The behavior in transversal direction was essential the same, because the braced bays act in general just in longitudinal direction.

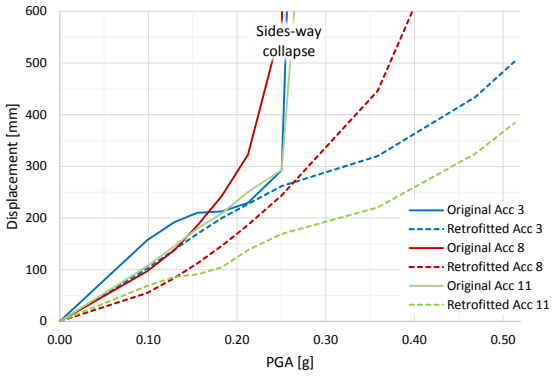

Figure 20: Comparison between as-built and retrofitted structure performance for sides-way collapse triggering earthquakes.

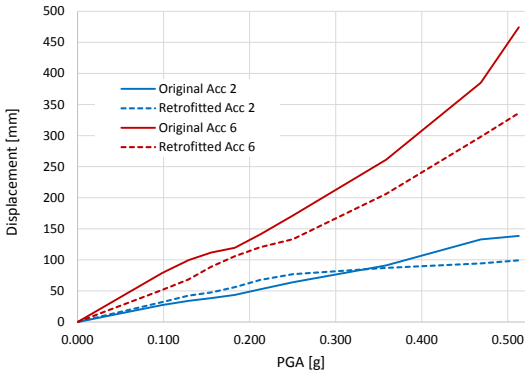

Figure 21: Comparison between as-built and retrofitted structure performance for no global failure earthquakes.

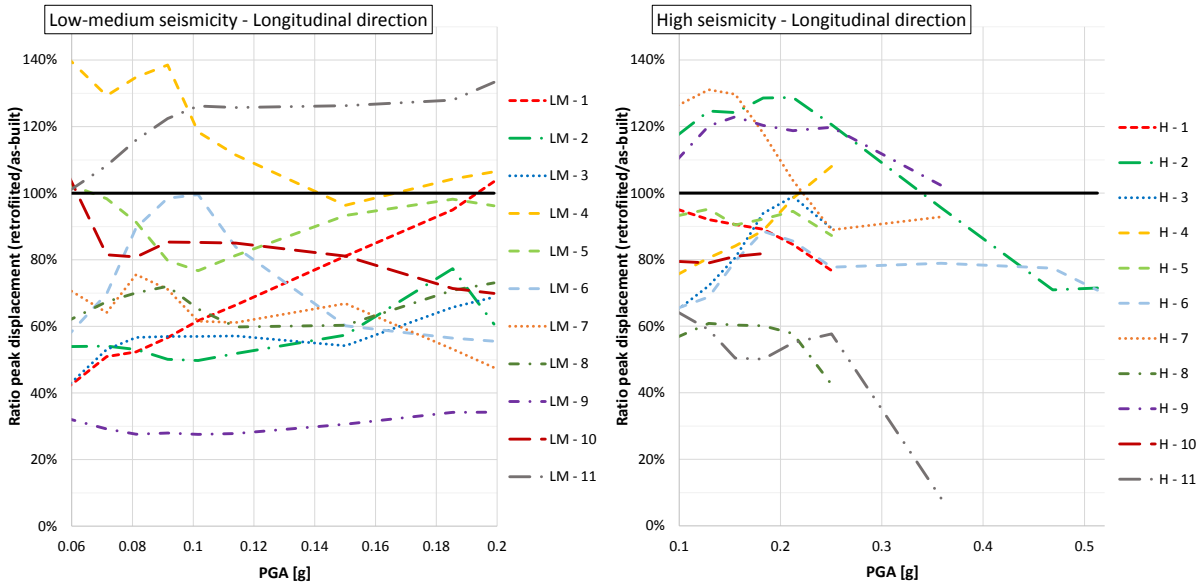

Figure 22: Ratio of as-built structure peak displacements in longitudinal X-direction to that ones of retrofitted structure for low to medium (left) and high (right) seismicity ground motion sets.

4.3 Retrofitting Approach II: Base isolation with torsional hysteretic dampers

For the base isolation retrofitting strategy every column base has been separated from ground in both horizontal directions and the numerical model of the seismic device has been applied in both orthogonal directions. The hysteretic curve looks similar as that one shown in Figure 17 with the modification that the initial stiffness has been tuned in such a way to yield an increase in the period in longitudinal direction of 50%, which yields a fundamental period of 2.5 seconds. The impact on the other modes is listed in Table 8.

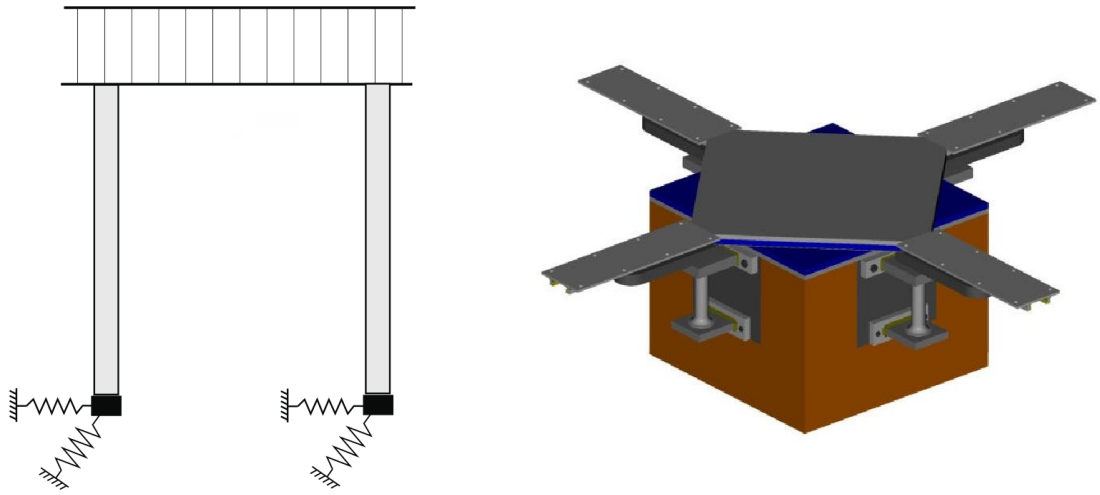

Figure 23: Schematical drawing of applied torsional hysteretic device as base isolation (left) and detail of multi-directional torsional hysteretic device (right, according to [4])

The retrofitted structure performed very well, as also for the high seismicity conditions no structural failure occurred. Figure 24 shows the relation between the peak displacements in the structure for both low to medium seismicity and high seismicity ground motions in longitudinal and transversal direction. For the retrofitted structure these are the displacements related to the top of the seismic device, which itself has to perform additional displacements. At higher peak ground accelerations for some high seismicity earthquakes the ratio was set to zero, in these cases when the as-built structure did not converge due to failure or excessive deformations. Otherwise the ratio is computed just for fully completed simulations. As can be seen for all of the ground motions deformation demand in the structure is efficiently decreased, for some even to 20% of its initial values.

The relative displacements inside the seismic device have been evaluated and are listed in Table 9. Demands have to be lower than capacity of the seismic device, otherwise the obtained results are not achievable in reality. For all of the low to medium seismicity earthquakes the displacements are well within the range of feasible displacements as can be compared to Figure 17. For some of the higher seismicity ground motions the demand on the seismic device is quite high for peak ground accelerations in the range of 0.25g to 0.5g. However, up to a peak ground acceleration of 0.2 g also for all of the high seismicity ground motions the peak relative displacement is below 400 mm, which is a well achievable capacity for this type of device.

5 CONCLUSIONS

This paper has shown how a complex finite element model may be transferred into a simplified model to save computational effort and storage need by maintaining its most important dynamic properties. Such simplifications are needed to be able to handle the huge amount of seismic analyses which need to be conducted for the purpose of Incremental Dynamic Analyses.

With this simplified model Incremental Dynamic Analyses have been conducted to assess on the current performance. Further on, two retrofitting strategies have been applied in a generic way: Additional stiffness and energy dissipation with additional bracings equipped with seismic devices and a base isolation layer between column footings and ground. The simple modelling of the characteristic hysteresis by help of a rheological model has been discussed. While the first retrofitting strategy showed to be effective in preventing the global sides-way collapse failure mode, the second one moreover could drastically reduce displacement demands in all the earthquakes.

In these analyses the seismic devices have been applied in a generic way. In future the modelling strategies and used parameters for the seismic device will be investigated more deeply regarding practicability and economic issues. Moreover, further limit states have to be incorporated as solely the displacement or occurrence of global failure. The demand on the seismic device has to be compared in detail with its realistic capacity.

6 ACKNOWLEDGMENTS

The research leading to these results has received funding from the European Union's Research Fund for Coal and Steel (RFCS) research programme under grant agreement n° RFSR-CT-2013-00019, project "PROINDUSTRY – Seismic PROtection of INDUSTRial plants by enhanced steel based sYstems".

The test results of the prototype of the torsional seismic device have been provided by Maurer Söhne Engineering GmbH & Co. KG, which is greatly acknowledged.

Keywords: Silos, seismic retrofit, seismic isolation, curved surface sliders

Abstract. *Silos are industrial facilities used for storing a huge range of different materials. In the last decades, many silos were damaged by natural events, among which the seismic events are the most significant. Indeed many plants are located in territories in which seismic risk is not negligible. Furthermore, most of these plants have been designed, and built before the latest updates of the seismic design codes took place, and most of them are prone to earthquakes. In this study, seismic behaviour of an existing industrial steel silo system in Italy has been investigated, and a retrofit solution has been proposed making use of seismic isolation technology. Curved surface single sliding pendulums have been designed as a base isolation retrofitting solution. Incremental dynamic analysis method has been used in order to evaluate the seismic performance of both the non-isolated and isolated cases. Structural benefits of the seismic isolation retrofitting solution has been quantified in terms of inelastic deformations, base shear, floor drifts, isolator displacements, and residual drifts, and comparisons between the original and retofitted solutions are presented. The impact of vertical ground accelerations on the global behaivour of seismic isolated silos has been highlighted, which showed that a fully elastic superstructure behaviour can be achieved only when the vertical component of earthquake is not significant. Uplift has been investigated and stated as a limiting parameter for the design of seismically isolated silos. The study has been realized thanks to EU-RFCS research fund for PROINDUSTRY project [1].*

1 SILOS CASE STUDY

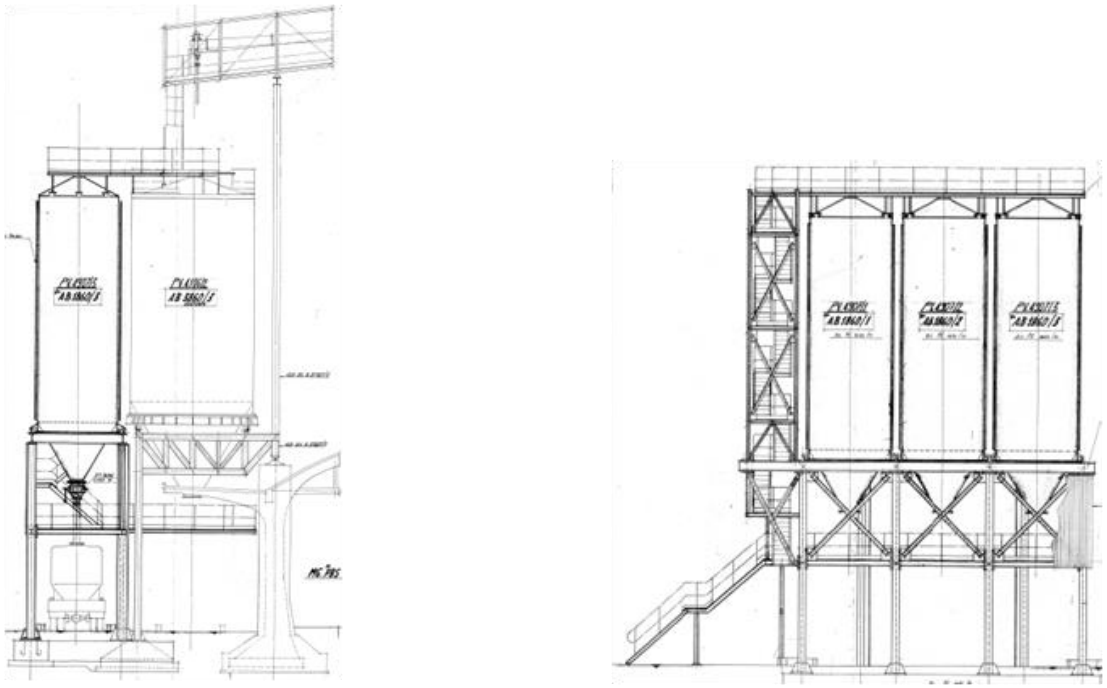
The case study is composed of three silos, elevated on a steel structure, constructed next to another 2 elevated silos. It's a silo system from SOLVAY Italy (Figure 1).

Figure 1 Case study

Main characteristics of the system are the following:

Internal radius of silos:	1.75 m
Total height of silos:	13.356 m
Thickness of silo body:	Changes along height from 12 to 8 mm.
Steel:	Fe360b
Silo content:	Sodium percarbonate
E =	210000 MPa
ν =	0,3
ϒsteel =	7850 kg/m3
ϒcontent =	1200 kg/m3 (sodium percarbonate)

Layout of the system can be seen in Figure 2. The stairs and connection structure between three silos are neglected for simplicity, since the rigidity and the mass of the silos probably will lead the global behaviour, without an important effect of the connecting structures and stairs.



a. Transversal view b. Longitudinal view

Figure 2 System layout

The silos are connected to the support structure by means of stiffener plates (Figure 3). 24 stiffener plates are welded to the silo wall, equally spaced around its perimeter. These stiffener plates are then welded to the ring beam with 150x30 mm cross section. The ring beam is bolted to the support structure beams.

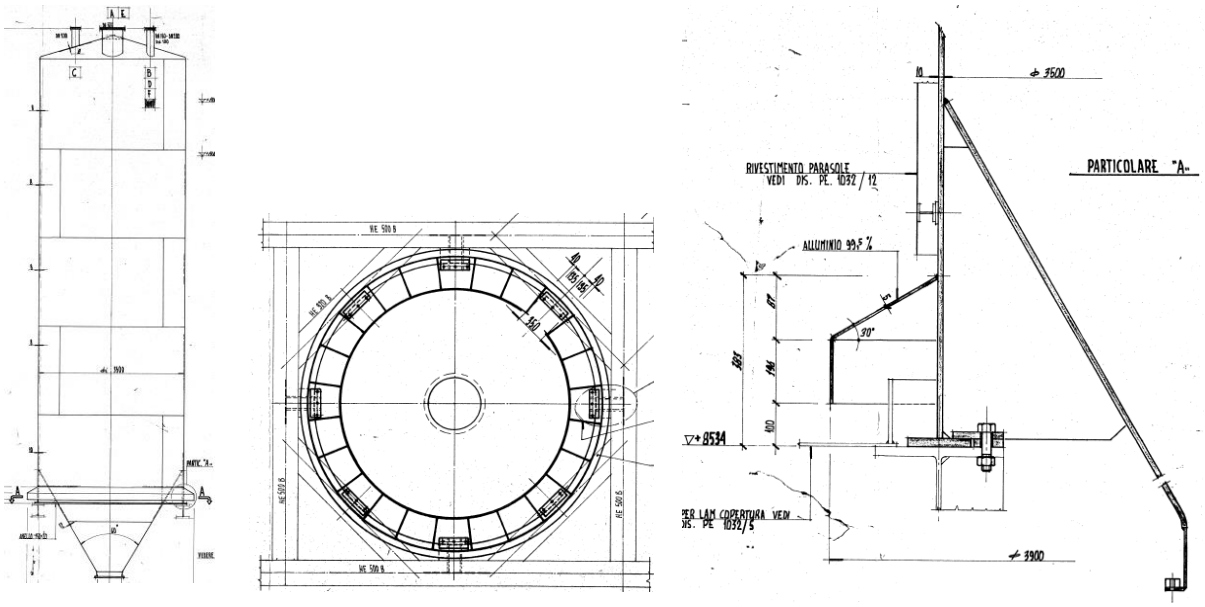


Figure 3 Ring beam-silo connection detail

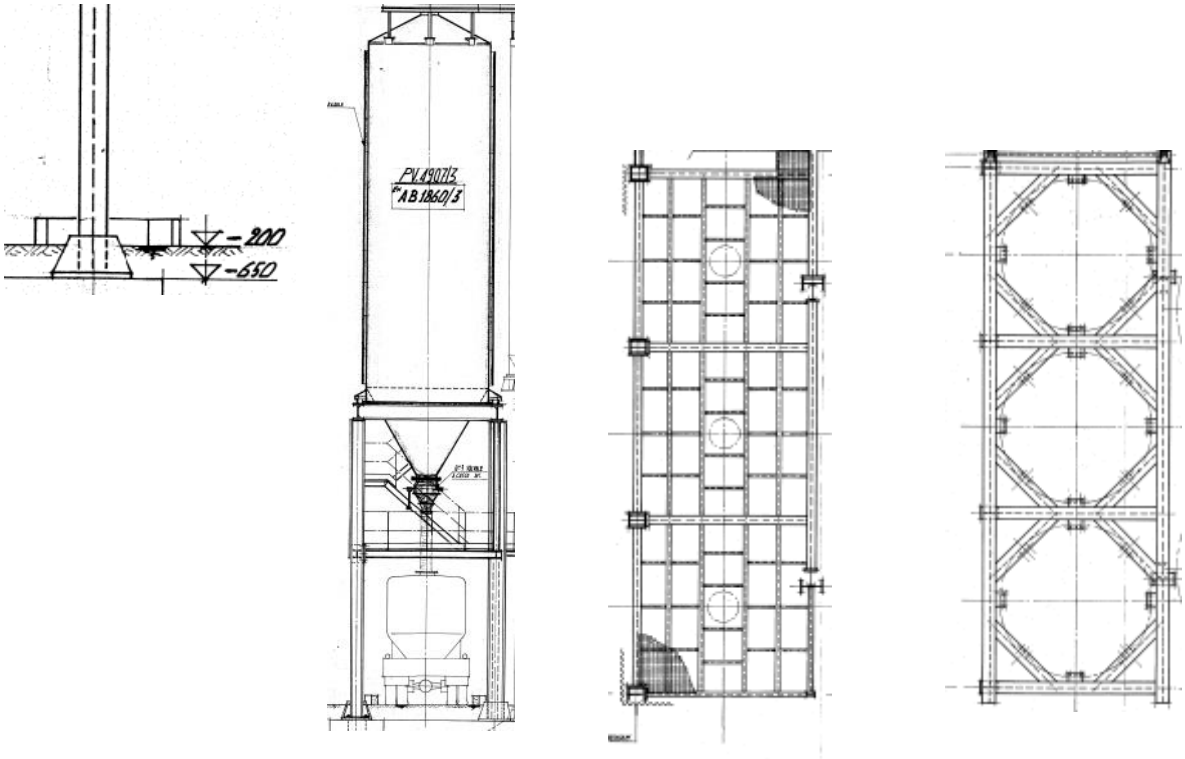
Three main levels are considered in the numerical model:

Level +0 mm: The columns are fixed at this level, which corresponds to "-650.00 mm" level of the drawings (Figure 4.a)

Level +4850 mm: First beam level (Figure 4.c)

Level +8934 mm: Second beam level (Figure 4.d)

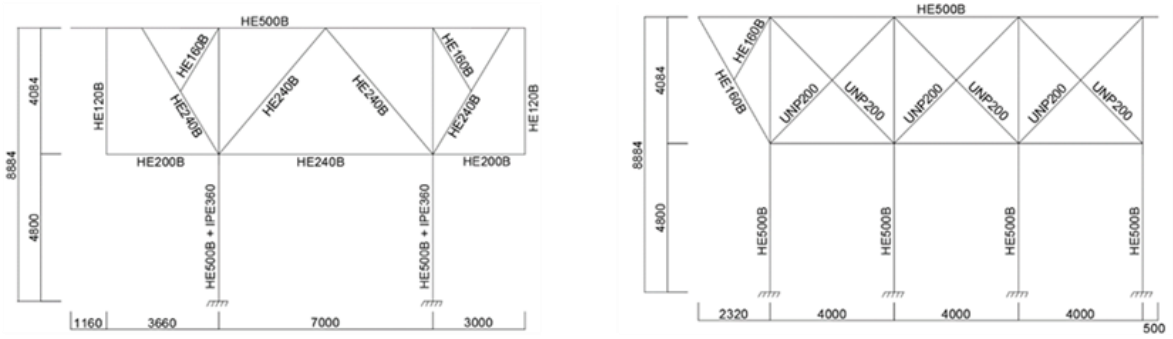
Level +20580 mm: Top point of silos (Figure 4.b)



a. Ground level b. Section view c. +4850 mm plan view d. +8934 mm plan view

Figure 4 Different levels of the system

The supporting structure is an asymmetric steel frame braced only in longitudinal direction, with different bracing layouts in two sides (Figure 5).



a. V-braced side b. X-braced side

Figure 5 Two sides of the structure

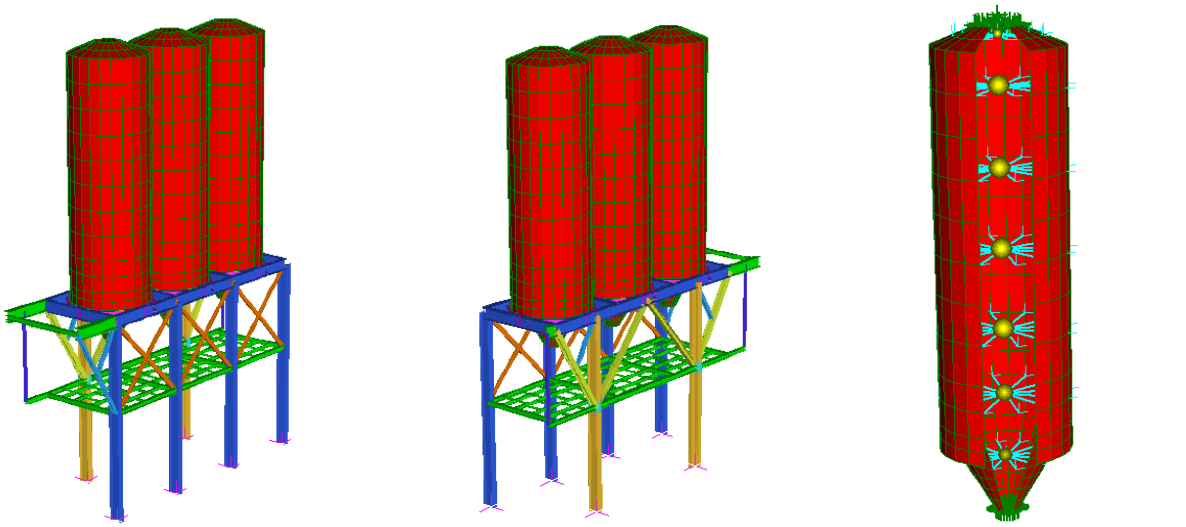
2 NUMERICAL MODEL

Numerical model is composed of silo bodies made of shell elements, steel structure made of beam elements formulated by fiber-based distributed plasticity approach [2], steel plate elements and rigid links that connect silo bodies and steel structure. Bracing elements are given initial imperfections according to EC3, as shown in Table 1.

S235 Steel	e_0 [mm]
HE240B [m]	35,9
HE160B [m]	15,9
HE240B [m]	16,0
UPN200 [m]	19,1

Table 1 Initial imperfections for bracing elements

The supporting structure has different bracing configurations in two sides of the frame (Figure 6.a.b). Lumped dynamic masses simulate the silo content, distributed at 7 levels inside silo, connected to silo walls by rigid links (Figure 6.c).



a. Model view 1 (X-braced side) b. Model view 2 (V-braced side) c. Lumped masses

Figure 6 Numerical model

The connection between HE500B longitudinal beams and silo are simulated with rigid links in the model. The connection between silo and ring beam is composed of 24 steel plates, which are simulated with shell elements in the model.

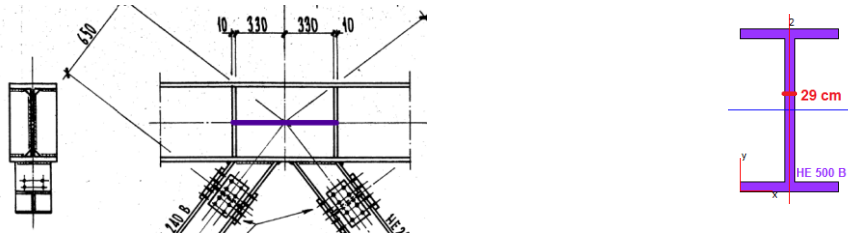


Figure 7 Reinforcement of the joints

As shown in Figure 7, the reinforcements of nodes are simulated by an ideal section with a doubled thickness of the core between the two reinforcement plates: stiffening the joint in this way, its behaviour is almost the same that the real one with the stiffening due only to the two reinforcement plates. The main areas where the joints are stiffened are contact points between the silos and the frame, and the joint between the two composite columns HE500B+IPE360 and the beams at the first floor.

Total mass of the system is 453,9 tons with following components:

Silo content: 391,1 tons

Silo body steel weight: 31,37 tons

Structural steel: 31,43 tons

Stress-strain relationship of the steel material has been defined with the following parameters:

Yield strength fy = 235 MPa
Ultimate strength fu = 360 MPa
Kinematic strain hardening: 1 %
Ultimate strain = 0.06

In Table 2 Modal analysis results, modal analysis results are reported. Mode shapes are shown in Figure 8 Mode shapes.

	Period	Mass participation
1st global mode in y direction (transversal)	1.2 sec	97.96%
2nd global mode in x direction (longitudinal)	1.05 sec	90.177%
3rd global mode in z direction (vertical)	0.13 sec	95.541%
1st global torsional mode	0.84 sec	9.4%

Table 2 Modal analysis results

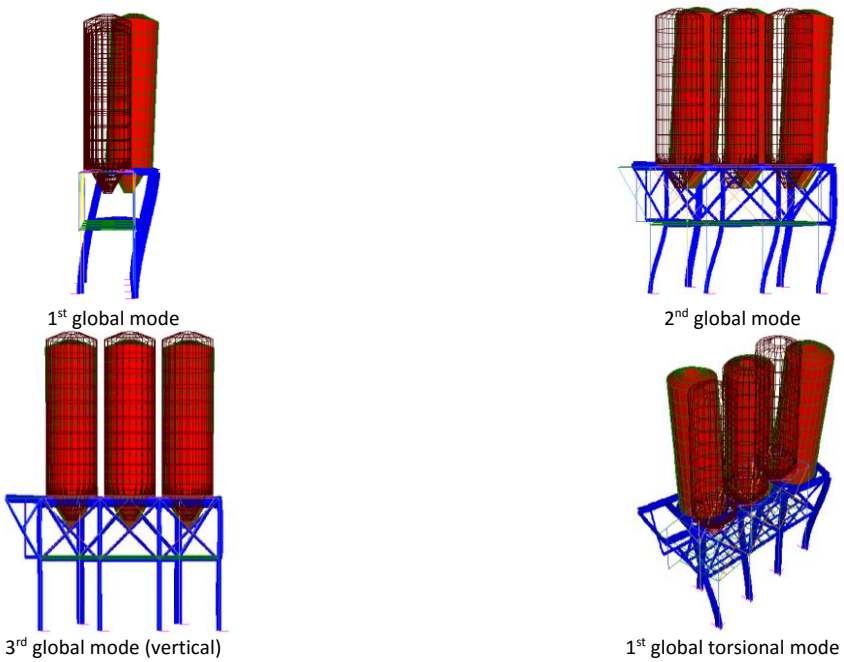

Figure 8 Mode shapes

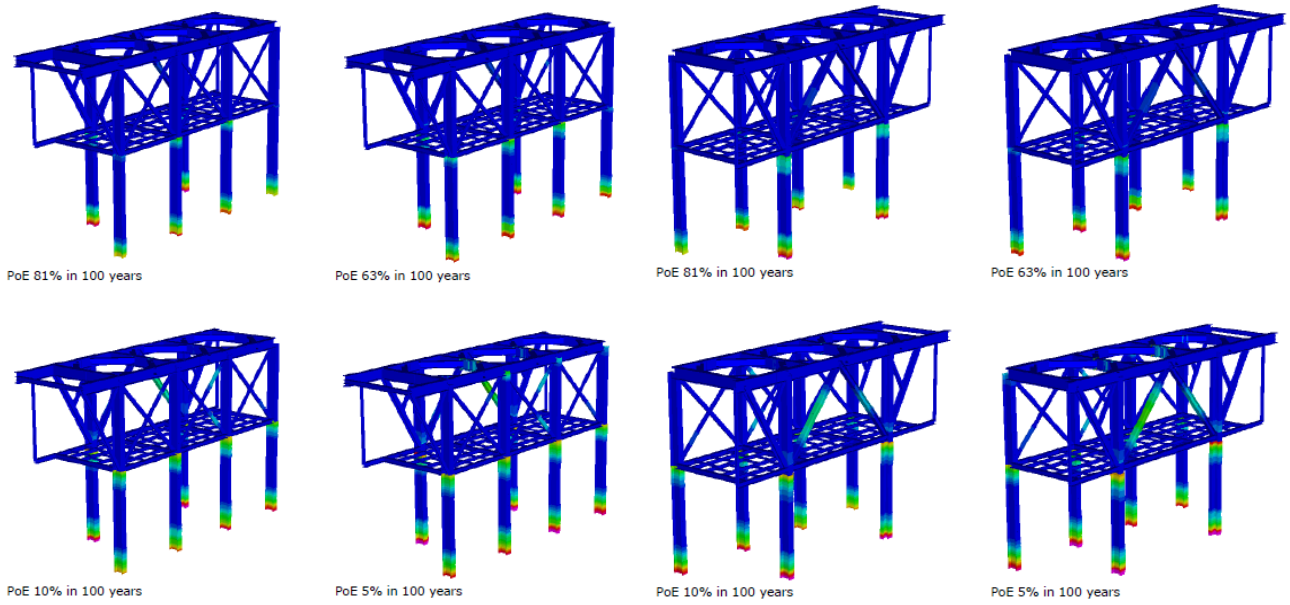
3 FAILURE MECHANISMS OBSERVED IN THE ORIGINAL STRUCTURE

Results of Incremental Dynamic Analysis performed on the original structure have been presented in deliverable 2.3. In this report, only failure mechanisms of the original structure are presented, in order to provide the degree of improvement by means of seismic isolation devices.

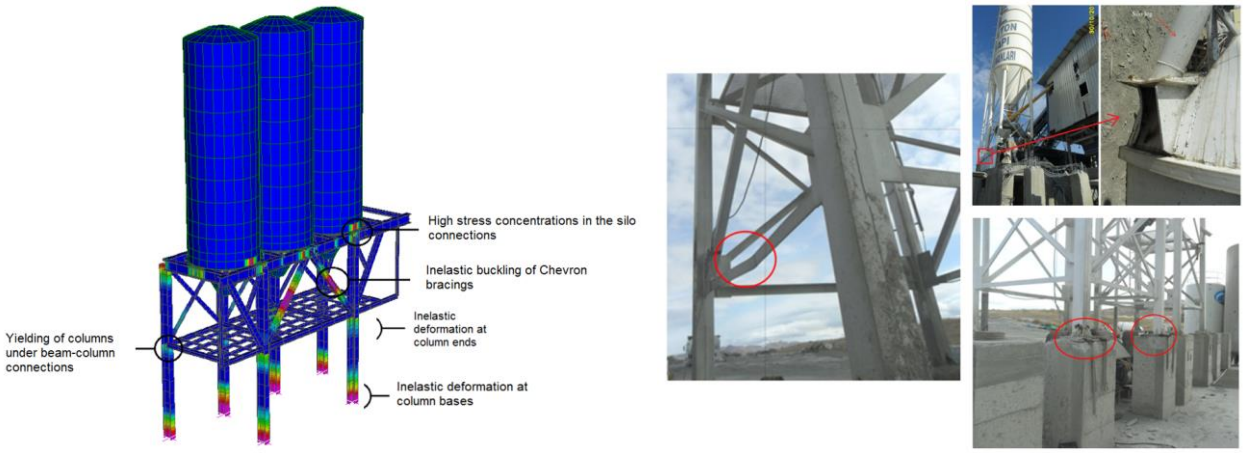
In the original structure, yield takes places at column bases even in the analysis with low scale factors. Increasing the intensity, the plastic behaviour is redistributed to the column ends, bracings, and connections between silo and supporting structure (Figure 9).



a. X-braced side b. V-braced side

Figure 9 Failure mechanisms of the original structure

Figure 10 shows that the numerically obtained failure mechanisms represent common structural damages that can be observed after strong earthquakes, such as Van Earthquake. Therefore, the seismic retrofitting solution should address these criticalities.



a. Failure mechanisms obtained from numerical analysis b. Damages observed on the support structure of elevated silos after Van Earthquake (2011)

Figure 10 Structural damages observed in Van Earthquake and numerically obtained failure mechanisms [3]

4 DESIGN OF SEISMIC ISOLATION SOLUTION

To retrofit the structure, a single sliding pendulum isolator has been designed in cooperation with project partner MAURER [4]. A static diagram of the forces acting in a sliding pendulum isolator used for the retrofitting is shown in Figure 11, while the force - displacement relationship is displayed in Figure 12.

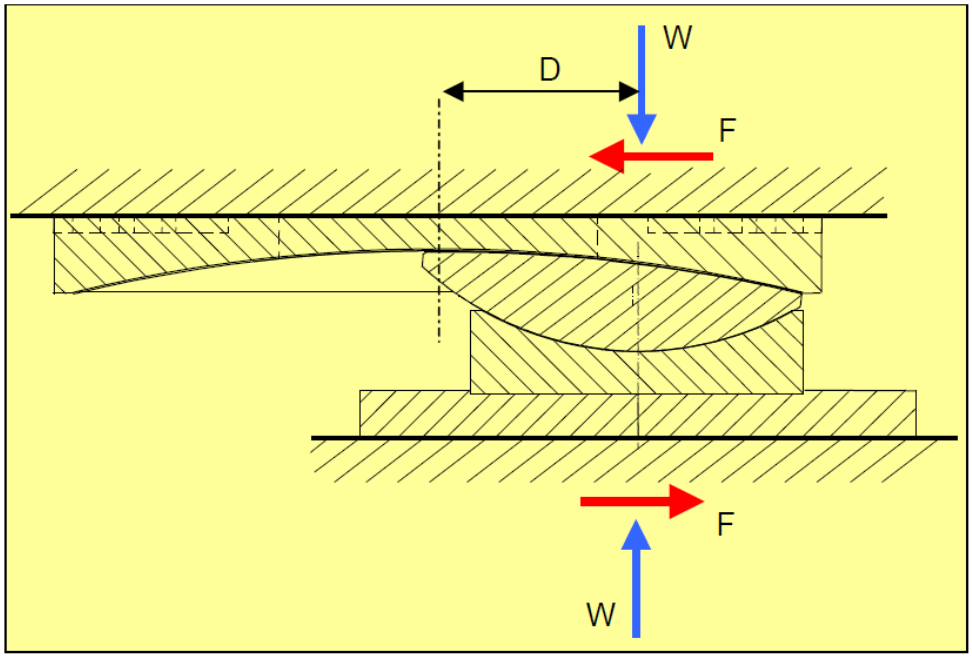


Figure 11 Forces acting in a sliding pendulum isolator

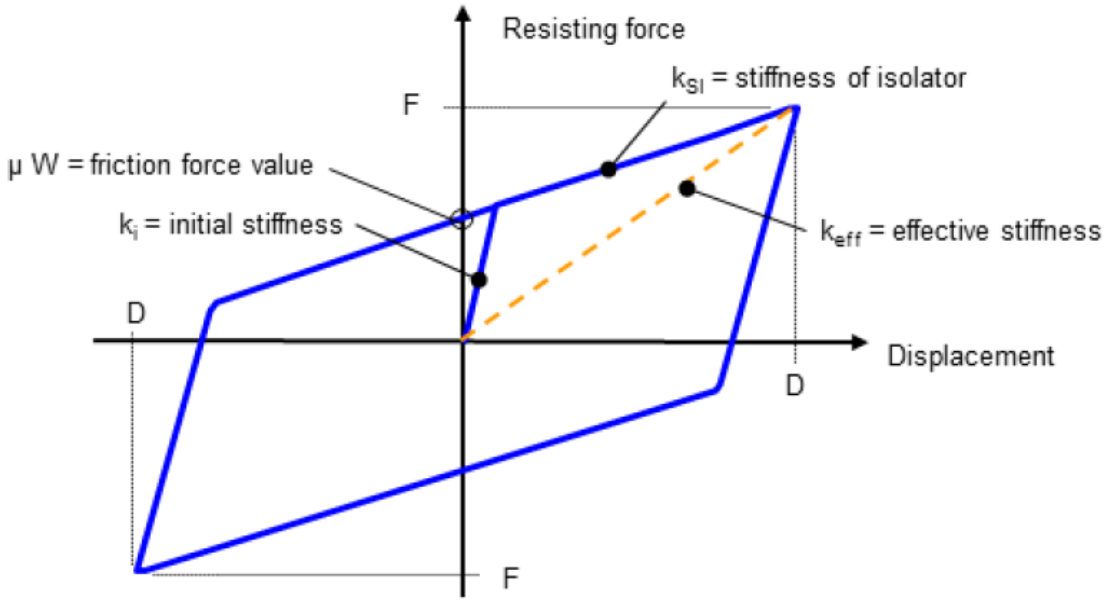

Figure 12 Force - displacement relationship in a sliding pendulum isolator

The equations governing the behaviour of a single isolators are the following:

Response period of the Isolator $$T = 2 \cdot \pi \cdot \sqrt{\frac{R}{g}} \cong 2 \cdot \sqrt{R}$$

Horizontal resisting force $$F = \frac{W}{R} \cdot d + \mu \cdot W \cdot sgn(d)$$

Horizontal stiffness due to the vertical load $$K_H = \frac{W}{R}$$

Effective stiffness $$K_{eff} = \frac{W}{R} + \frac{\mu \cdot W}{D}$$

Effective response period $$T_{eff} = 2 \cdot \pi \cdot \sqrt{\frac{R}{K_{eff} \cdot g}}$$

Damping due to friction $$\beta_{eff} = \frac{2}{\pi} \cdot \frac{\mu}{\frac{D}{R} + \mu}$$

Vertical displacement $$\delta_V \cong \frac{1}{2} \frac{D}{R^2}$$

Re-centering criterion $$\frac{D}{R} > \mu$$

Where W is the vertical load acting on the isolator agent, μ is the dynamic friction factor, d is the horizontal displacement, D is the horizontal speed and R is the radius of curvature. Note that the horizontal stiffness is linked to the load acting on the isolators: in an optimal design should therefore a different isolator should be adopted for each design vertical load.

In particular an isolator can be modelled by placing in parallel the two following elements, as shown in Figure 13.

1) Point Contact element: by means of an element of this type it is possible to define the friction factor and the vertical stiffness of the isolator. You can also define the yield surface of the isolator (rectangular or elliptical) and the friction model (elastic or plastic). Using an elliptical surface we ensure that the point at which the isolator begins to flow is the same in all directions, while the plastic friction model governs the hysteretic behaviour of the isolator.

2) Connection element: using an element of this type the stiffness of the isolator to sliding in horizontal directions can be defined.

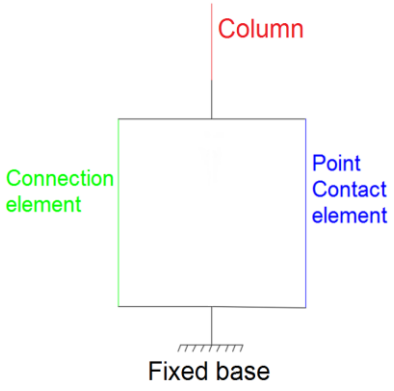

Figure 13 Modelling of the isolator in Straus7

It should be noticed that in Strand7 the length of the two elements of the isolator is not influencing the isolator behaviour, which is completely defined by the intrinsic properties of the

two elements. Assuming a fictitious length of the isolators equal to 500 mm, to each column of the previously modelled structure are added a Point Contact and a Connection element. The modelled isolators are shown by Strand7 as lines, whose lower point is stuck to the ground and whose upper end is connected to the column, as shown in Figure 14.

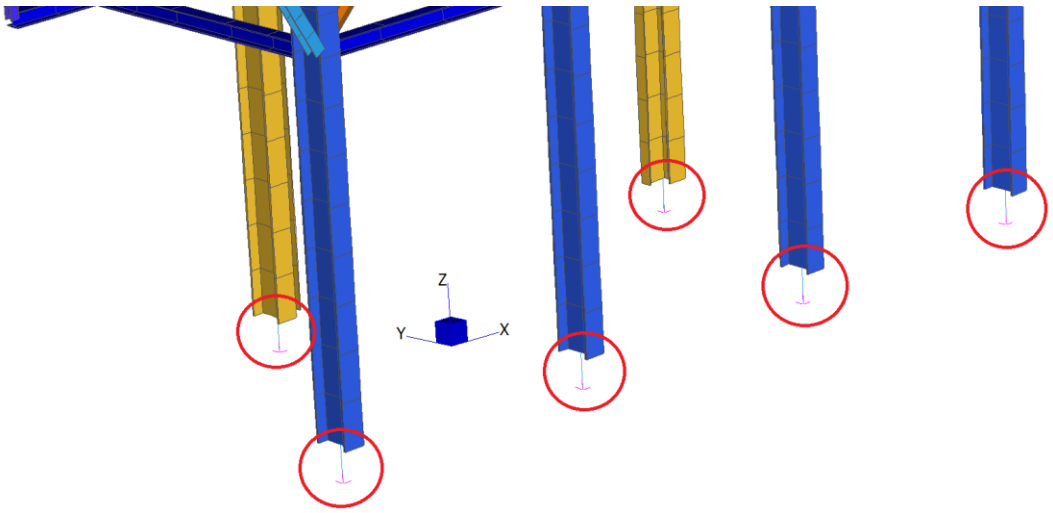

Figure 14 modelling the isolators in Straus7

To verify the correctness of the isolation system modelling, a non-linear static analysis was carried out, gradually applying a hypothetical design displacement of ± 300mm to the isolators as shown in Figure 15. A period of 4 seconds hence a sliding stiffness k_s equal to 0.187 kN / mm) and 4 % friction factor was assumed for all the isolators.

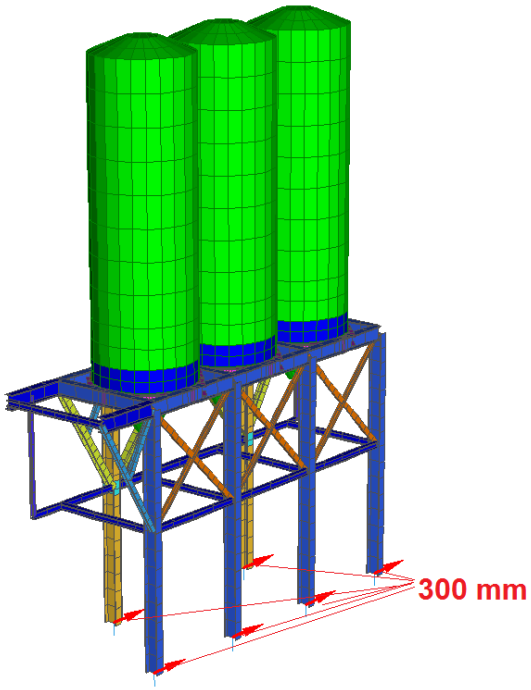

Figure 15 Displacements imposed to the isolators

With reference to the nodes numbering shown in Figure 3.50, let's consider, for example, the isolator in the node 5, on which acts a vertical load of 777.8 kN. The force-displacement response of the isolator in the node 5, obtained by the nonlinear static analysis is shown in Figure 16, where the displacements are dimensionless for a better understanding.

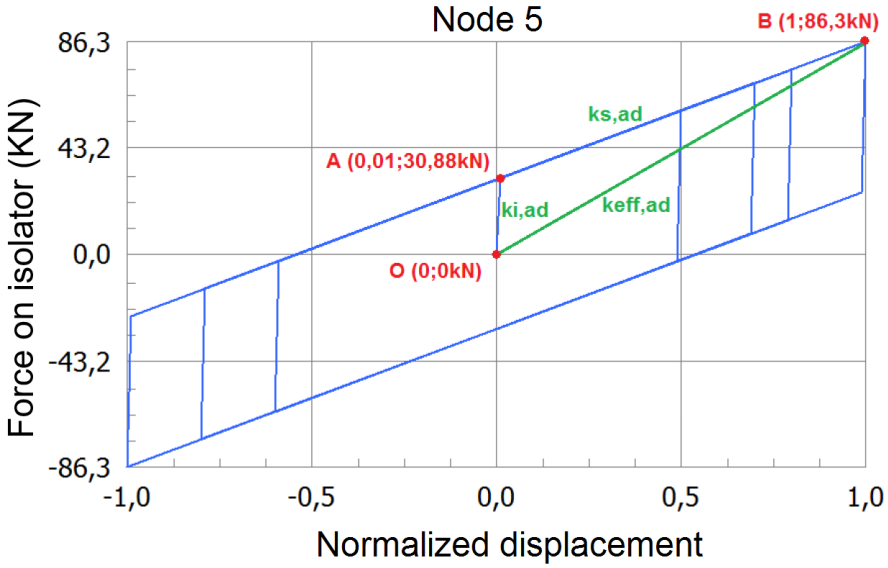

Figure 16 Constitutive law of the isolator in node 5 in terms force-displacement (period 4 seconds and friction factor 4%)

From the constitutive law obtained by the nonlinear static analysis, the initial stiffness k_i and the sliding stiffness k_s of the isolator are:

$$k_{i,ad} = \frac{y_A - y_O}{x_A - y_O} = \frac{30{,}88\ kN}{0{,}01} = 3088\ kN$$

$$k_{s,ad} = \frac{y_B - y_A}{x_B - y_A} = \frac{86{,}3\ kN - 30{,}88 kN}{1 - 0{,}01} = \frac{55{,}42\ kN}{0{,}99} = 55{,}98\ kN$$

As the constitutive law of the isolator has been plotted by normalizing the displacements, the stiffness must also be calculated scaled to the hypothetical design displacement for the isolators, assumed equal to 300 mm:

$$k_i = \frac{k_{i,ad}}{300\ mm} = \frac{3088\ kN}{300\ mm} = 10{,}293\ \frac{kN}{mm}$$

$$k_s = \frac{k_{s,ad}}{300\ mm} = \frac{55{,}98\ kN}{300\ mm} = 0{,}187\ \frac{kN}{mm}$$

It can be noticed that the sliding stiffness ks coincides with that initially assumed, that is:

$$k_{i,def} = \frac{\mu W}{D_y \cdot 300\ mm} = \frac{0{,}04 \cdot 777{,}8\ kN}{0{,}01 \cdot 300\ mm} = 10{,}37\ \frac{kN}{mm}$$

Where μ is the friction factor, D_y is conventionally assumed as 0.01 and W is the load applied on the isolator. It is observed that also in this case $k_{i,def}$, obtained by means of the theoretical definition , is approximated to k_i obtained from the actual constitutive law of the isolator. Finally, the effective stiffness related to the dimensionless displacement $K_{eff,ad}$ and to the design displacement K_{eff} are:

$$k_{eff,ad} = \frac{y_B - y_O}{x_B - y_O} = 86{,}3\ kN$$

$$k_{eff} = \frac{k_{eff,ad}}{300\ mm} = 0{,}288\ \frac{kN}{mm}$$

With reference to the definition of effective stiffness, it is:

$$k_{eff,def} = \frac{\mu W}{300\ mm} + W \cdot \frac{4 \cdot \pi^2}{g \cdot T^2} = \frac{777{,}8\ kN}{300\ mm} \cdot \left(0{,}04 + \frac{4 \cdot 3{,}14^2}{9810\ \frac{mm}{s^2} \cdot (4\ s)^2} \cdot 300\ mm \right)$$
$$= 0{,}299\ \frac{kN}{mm}$$

Also the effective stiffness obtained from the constitutive law reflects the one obtained with reference to the theoretical definition, unless of some negligible differences due to the approximation of the values assumed for the various parameters.

The numerical modelling is therefore correctly defined as the constitutive law in Figure 16 reflects the theoretical response of the isolators. To characterize an isolator, it is then necessary to identify optimal values for the friction factor and the horizontal stiffness.

As a starting hypothesis, it was assumed to have isolators of equal stiffness, assuming different values of the period of the isolation system and of the friction factor. The three most significant cases of this initial phase are reported in Table 3, in which the results in terms of displacement of the isolators have been obtained from the analyses carried out adopting the high seismic intensity accelerogram ED74.

Case	Modelling assumptions			Max displacements	
	Friction [%]	T_{is} [s]	k [kN/mm]	$\lvert s_{x,max} \rvert$ [cm]	$\lvert s_{y,max} \rvert$ [cm]
1	3	4	0,187	22,8	27,3
2	4	3	0,332	22	20,6
3	4	2,5	0,478	17,9	16,7

Table 3 First iterative phases

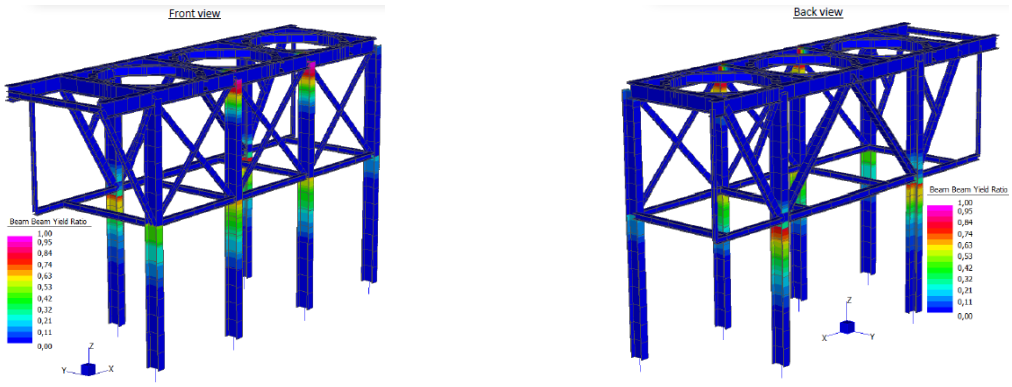
In general it can be observed that, by increasing the stiffness of the isolators and thus decreasing their period, the maximum displacements of the isolators in the two directions decrease.

One disadvantage when allowing high displacements in the devices is that this might easily result in increments of the displacements incompatible with the maximum allowable dis-

placements of the isolators. This is the most dangerous condition since exceeding the limit displacement might cause failure of the isolators and furthermore a sudden stop of the structure with high impact forces, a sort of hammering at the base of the structure.

On the other hand, limiting the displacements has the primary disadvantage that in this way smaller displacements are allowed. The dissipated seismic energy will also be lower and therefore the isolation system may not be sufficient to completely protect the structure. High stress concentrations might occur, although locally, which might lead to plasticization or extreme loading conditions in the connections.

Even considering an isolation system with period equal to 4 seconds, plasticisation of columns occurs in the first floor, as shown in Figure 17. For the cases 2 and 3, the stresses in the structure increase even more and not negligible plasticization occurs also in the top of the columns.



a. Case 1 – Side with X bracing

b. Case 1 – Side with chevron bracing

Figure 17 Inelastic behaviour observed with isolators placed at the column bases

This effect is due to additional torsional effects, caused by different displacement time histories experienced by the isolators, which cause rotations of the structure in the x - y plane (Figure 18).

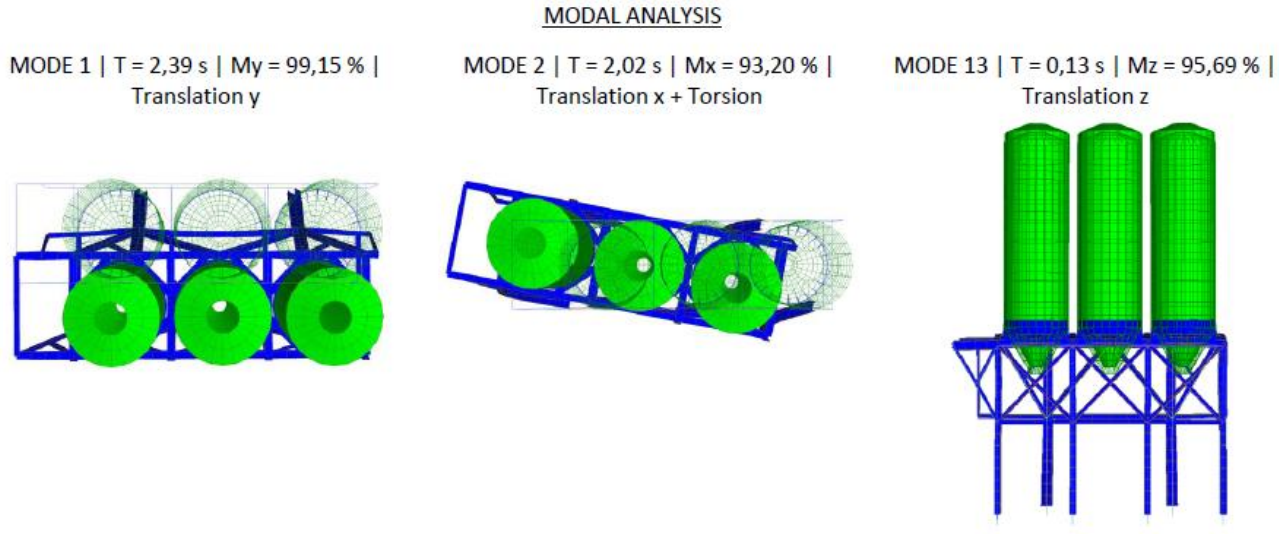


Figure 18 Torsional effects in the structure.

For example, in case 1 with isolators having a period of 4 seconds and a friction factor 3 %, it can be noticed that the isolator displacements in the x-direction (Figure 19) and in the y-direction (Figure 20) are not uniform, since the isolators are not connected with each other. Approximately after 12 seconds, the maximum difference between the displacement of the two isolators along x is approximately about 15 cm.

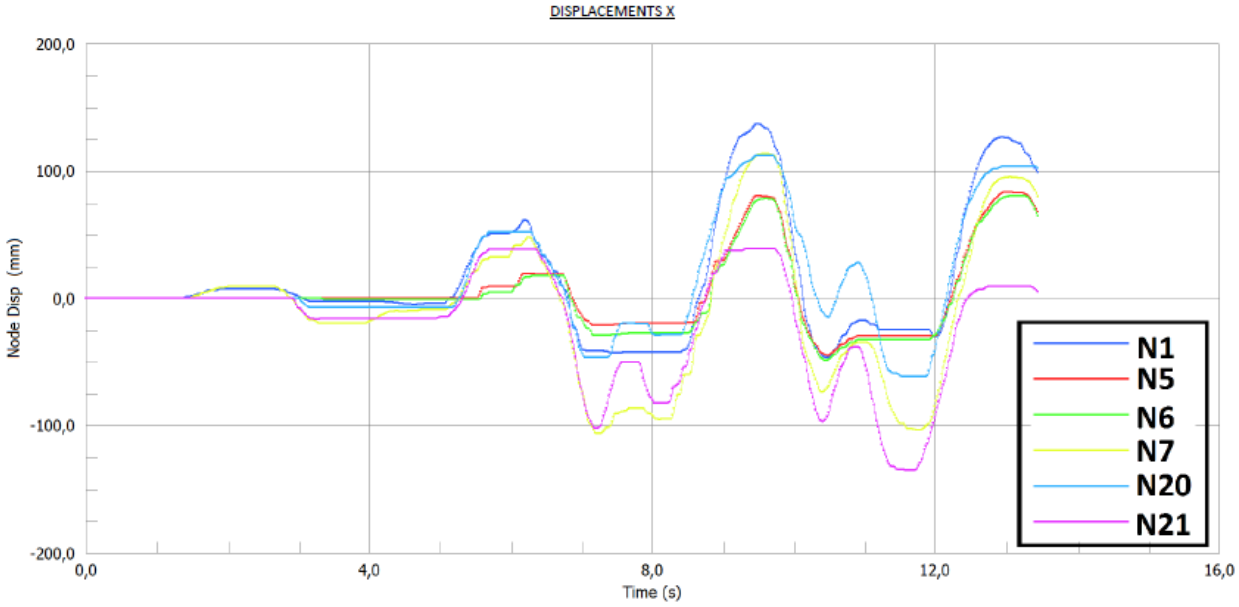

Figure 19 Isolator displacements along x-direction of the isolated structure for case 1

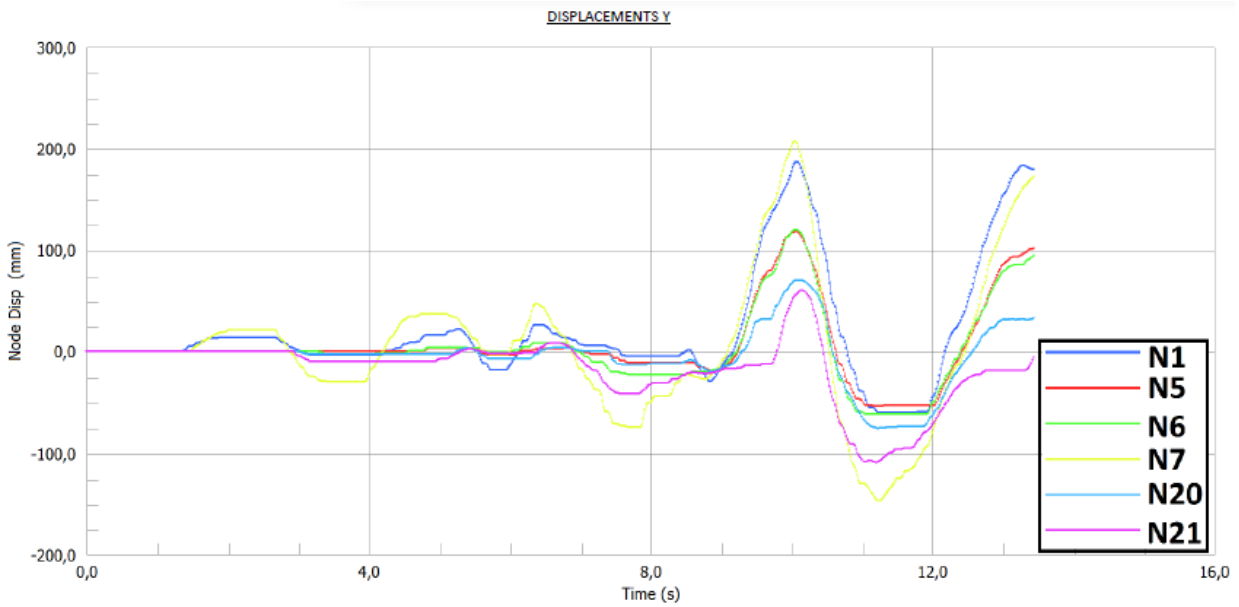

Figure 20 Isolator displacements along y-direction of the isolated structure for case 1

Such a solution is not optimal. To force the isolators to have the same displacement, and then get a translational motion in the x - y plane, different alternatives can be considered. Several solutions have been analysed to solve this asymmetry problem (Figure 21)

	CASE 2	CASE 4	CASE 5
Friction [mm]	4	4	2,5
Stiffness 1-7 [kN/mm]	0,478	0,115	0,0968
Stiffness 5-6 [kN/mm]	0,478	0,258	0,2219
Stiffness 20-21 [kN/mm]	0,478	0,352	0,3028
Isolator period [s]	2,5	/	/
Isolator equivalent radius [mm]	/	3100	3600

Figure 21 Different Retrofit strategies tried to solve asymmetry issue

After several iterations, the best solution has been obtained by using 6 seismic isolators connected by a rigid diaphragm made of as a horizontal steel frame with beams and horizontal bracing elements at ground level as shown in Figure 22. Solutions without a rigid diaphragm did not provide a feasible solution because of excessive global torsional behaviour.

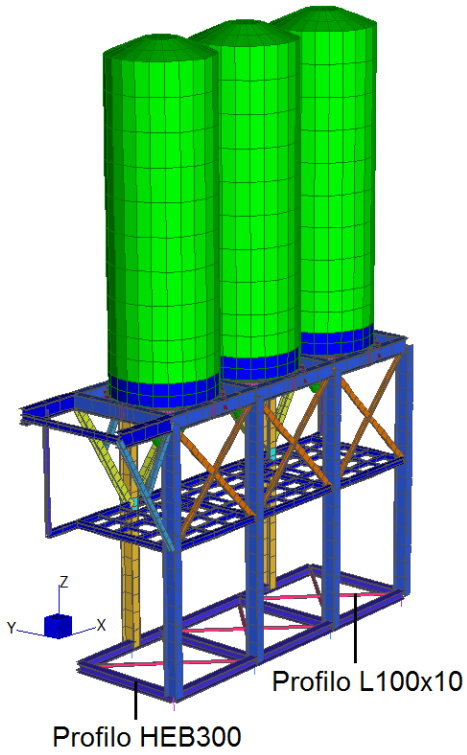

Figure 22 Retrofitted silo system

Horizontal stiffness and friction parameters have been iterated to find an optimal balance between best structural performance and acceptable maximum displacements. Inelastic deformations on the steel structure have been avoided (Figure 23).

Table 7 Max/Min displacements and base shear

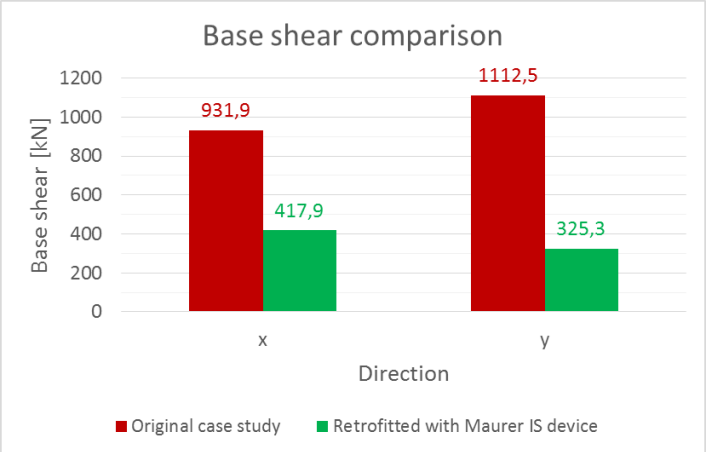

Figure 26 Max/Min base shear

Reductions in mean relative displacements of the two storeys are shown in Figure 27 for x and y directions.

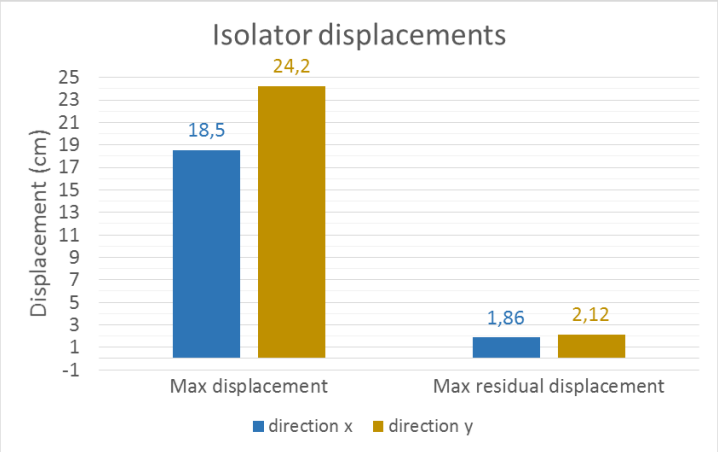

Figure 27 Reductions in mean relative displacements

Comparisons in terms of floor drifts are shown in Figure 28, Figure 29, and Table 8. The weak floor in the longitudinal direction of the structure is the first one, as the second floor is braced. The bracing was effective already in the case of a fixed base structure, wherein the average relative movement in the x direction of the second floor was equal to about 0.1%. In the isolated-base structure, the average relative movement of the second floor in the x direction is of 0.05% and is then maintained almost in the same order of magnitude as the previous case. In any case, the mean relative movement of the second plane in the direction x is negligible, and the reduction of 50% is relative and has just a minor impact on the structural response.

On the contrary, the first floor benefits from the isolation system. In particular in the x-direction (braced), in which the first floor is weak, the reduction is significant (approximately 64%) and the average relative displacement falls from a critical value equal to 3.49% in a fixed base structure to a value 1.24%.

In transverse y-direction (non-braced) a reduction of 35% for the first floor and 53% for the second floor can be observed. Also in this direction the structure takes advantage of the

isolation system, with limited mean relative displacements for both floors, unlike the fixed-base system in which values larger than 1.5% could be observed.

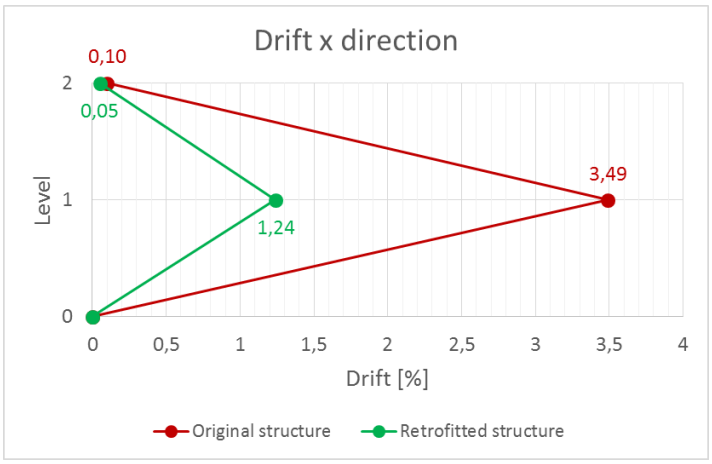

Figure 28 Drift comparison in x direction

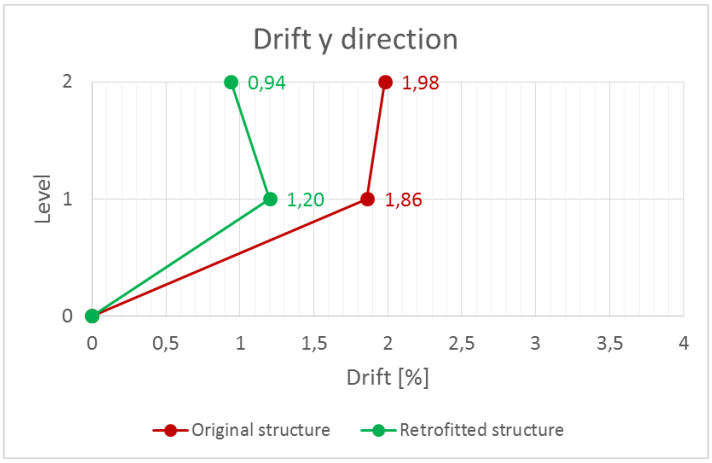

Figure 29 Drift comparison in y direction

Average interstorey drift				
Floor	Direction	Fixed-base structure	Isolated structure	Reduction
1	x	3,49 %	1,24 %	64 %
	y	1,86 %	1,20 %	35 %
2	x	0,10 %	0,05 %	50 %
	y	1,98 %	0,94 %	53 %

Table 8 Comparisons in terms of floor drifts

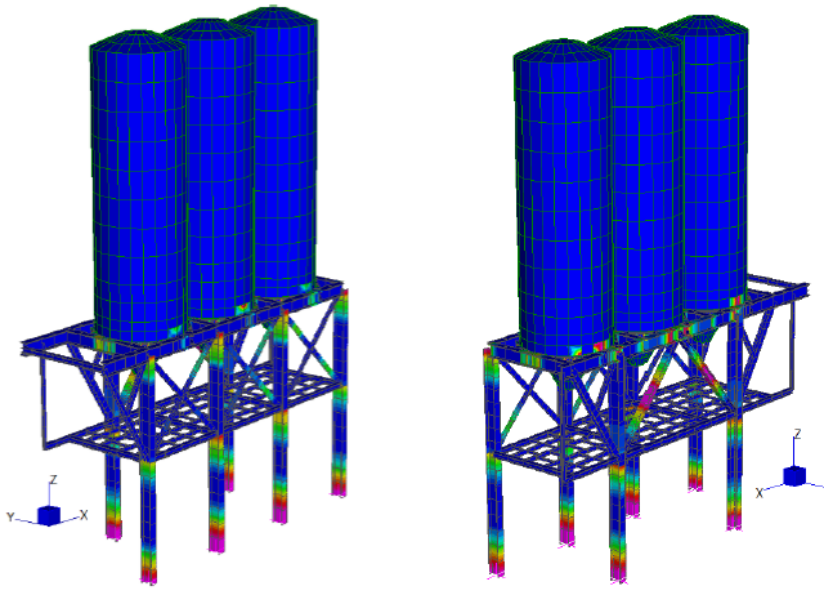

Figure 30 Yield index of the original structure

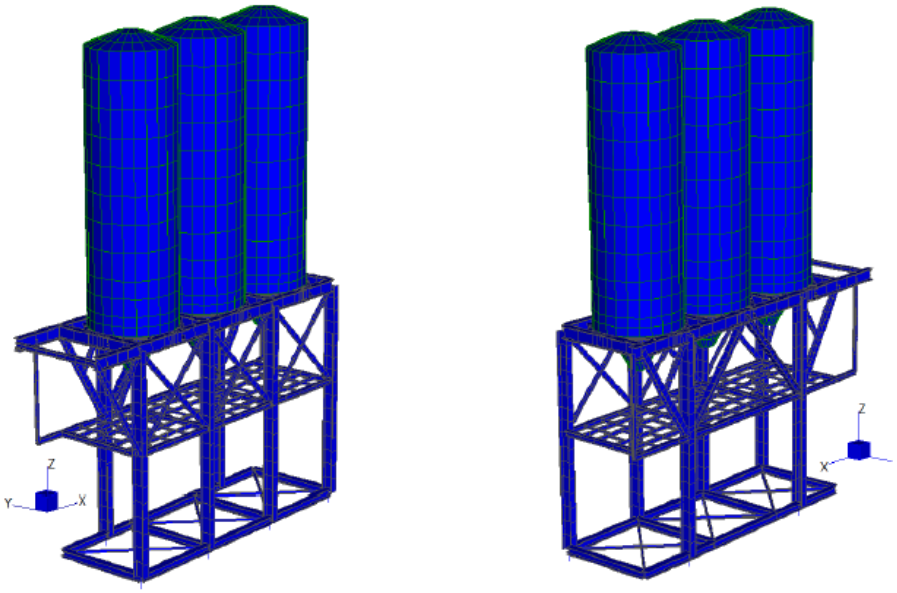

Figure 31 Yield index of the retrofitted structure

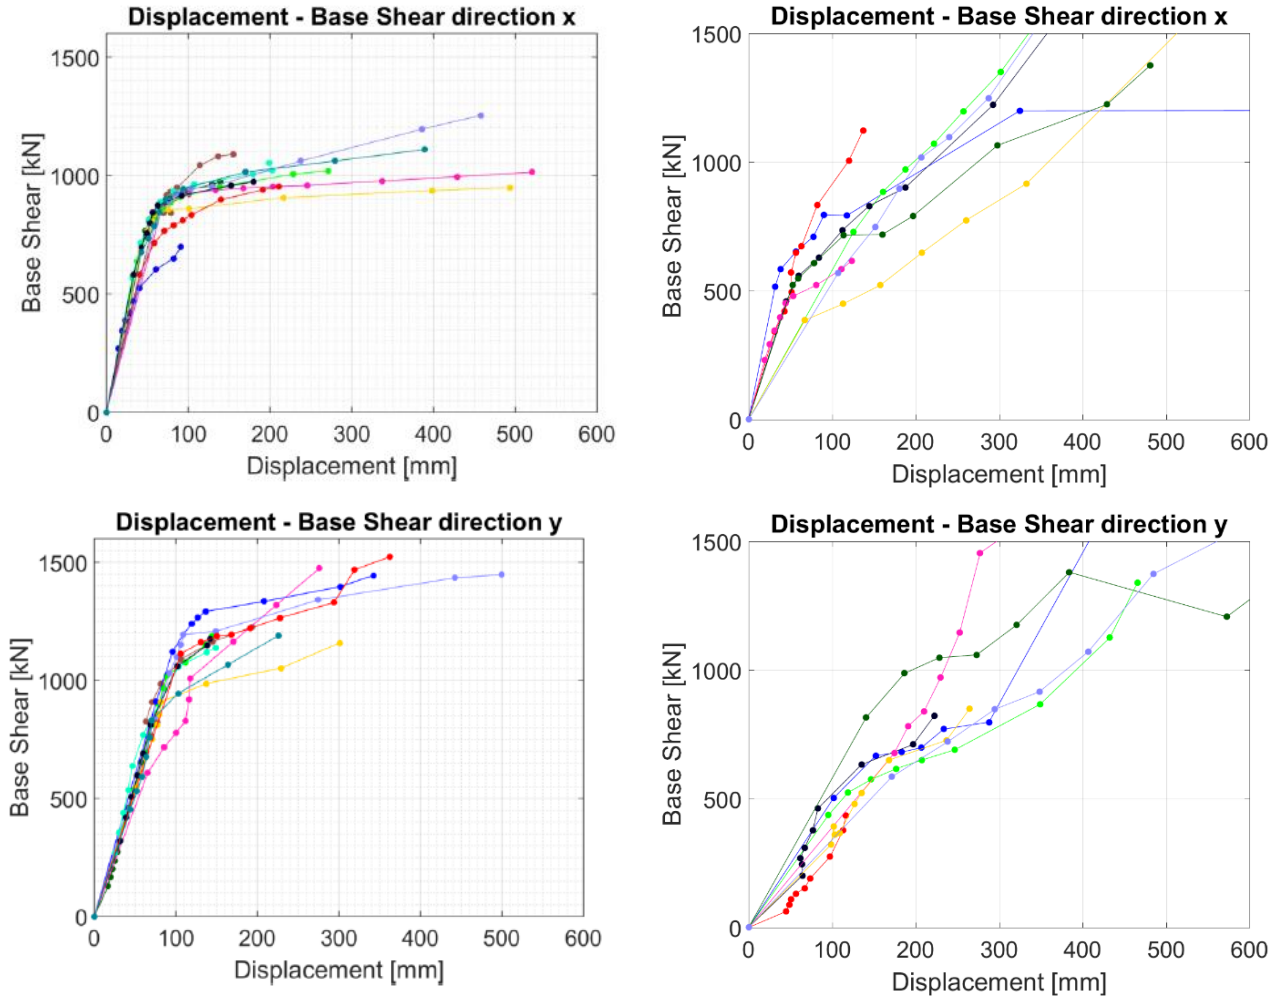
The yield index of the original and retrofitted structure can be compared from Figure 30 and Figure 31, with reference to the ED74 accelerogram. The retrofitted structure remains fully elastic.

5 IDA RESULTS IN HIGH SEISMICITY

Results of the IDA analysis based on high seismicity accelerograms are shown in terms of peak displacements and total base shear. For peak displacements, the control node is taken as the center of gravity of whole system. (x direction: longitudinal, y direction: transversal, z direction: vertical).

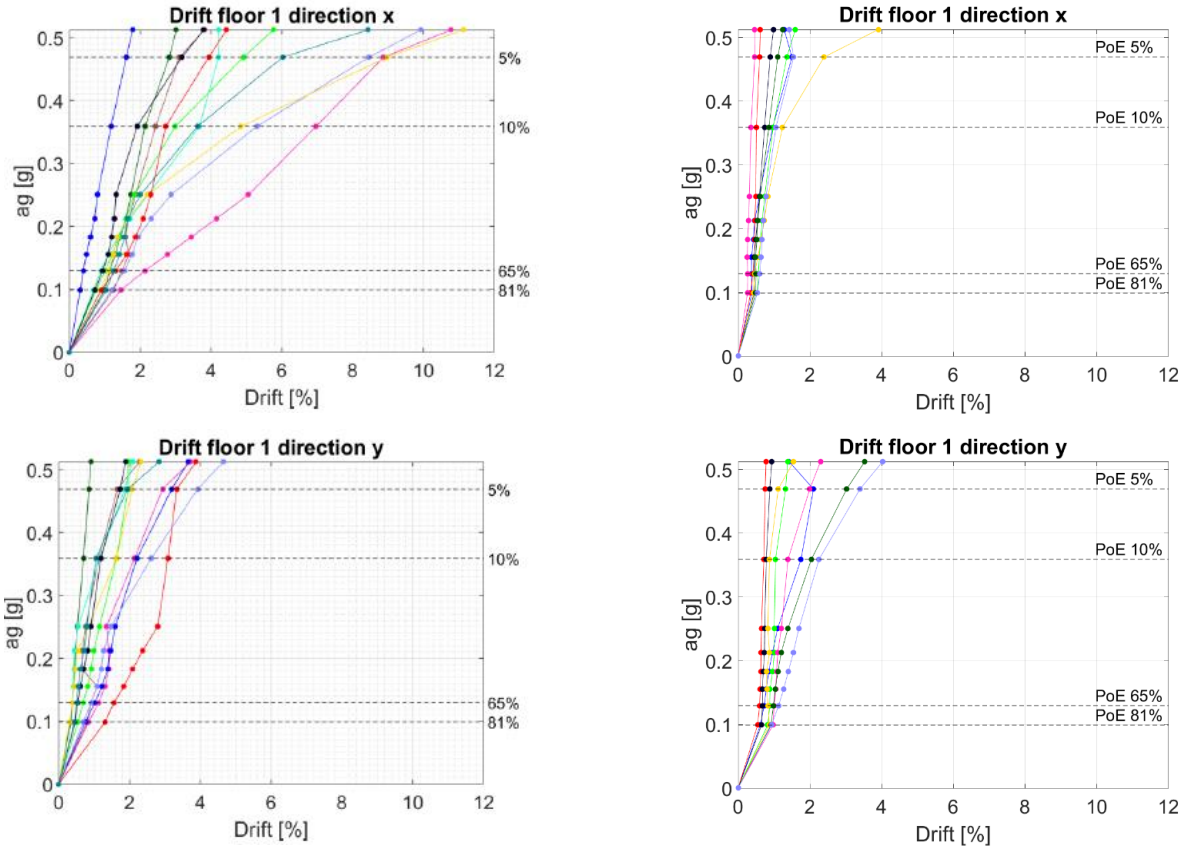
From Figure 32, it is seen that in general, retroffited structure responses in a linear manner to the increase in global base shear forces with increasing scale factors, while a global elasto-plastic behaviour is evident in case of the original structure.



a. Original Structure b. Retrofitted structure

Figure 32 IDA results in terms of global displacement vs base shear

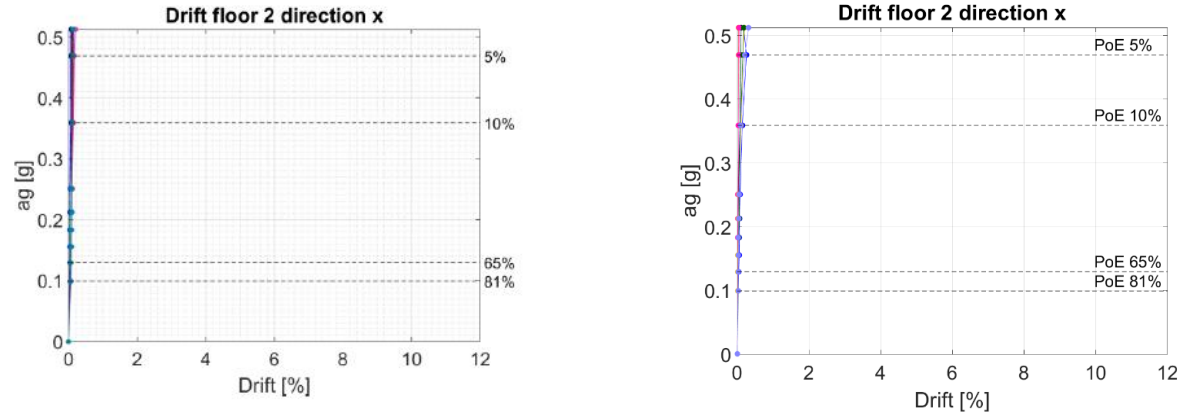
Figure 33 shows and Figure 34 show that drifts of both floors have been decreased significantly in case of retrofitted structure. Most importantly, the soft-storey behavior observed in the original structure has been eliminated thanks to the seismic retrofitting, as can be observed from the very low drift ratios of floor 1.

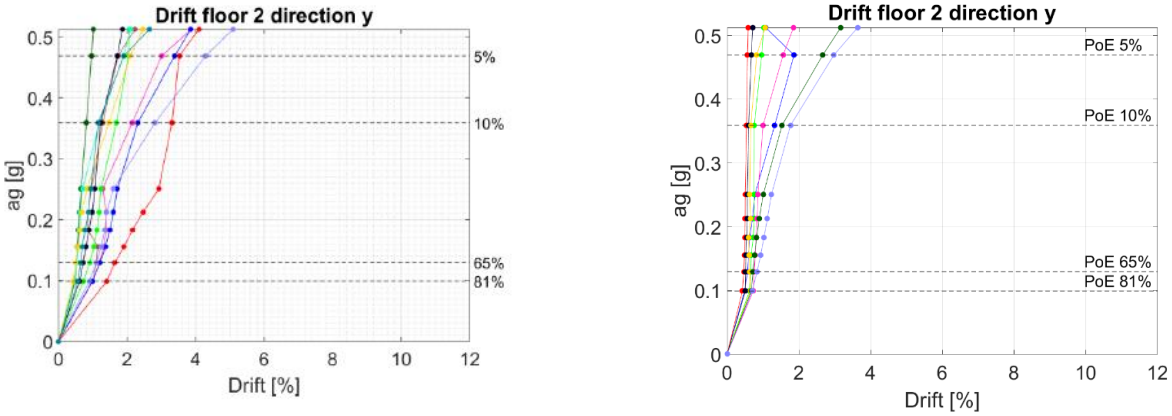


a. Original Structure

b. Retrofitted structure

Figure 33 IDA results in terms of drift 1st floor

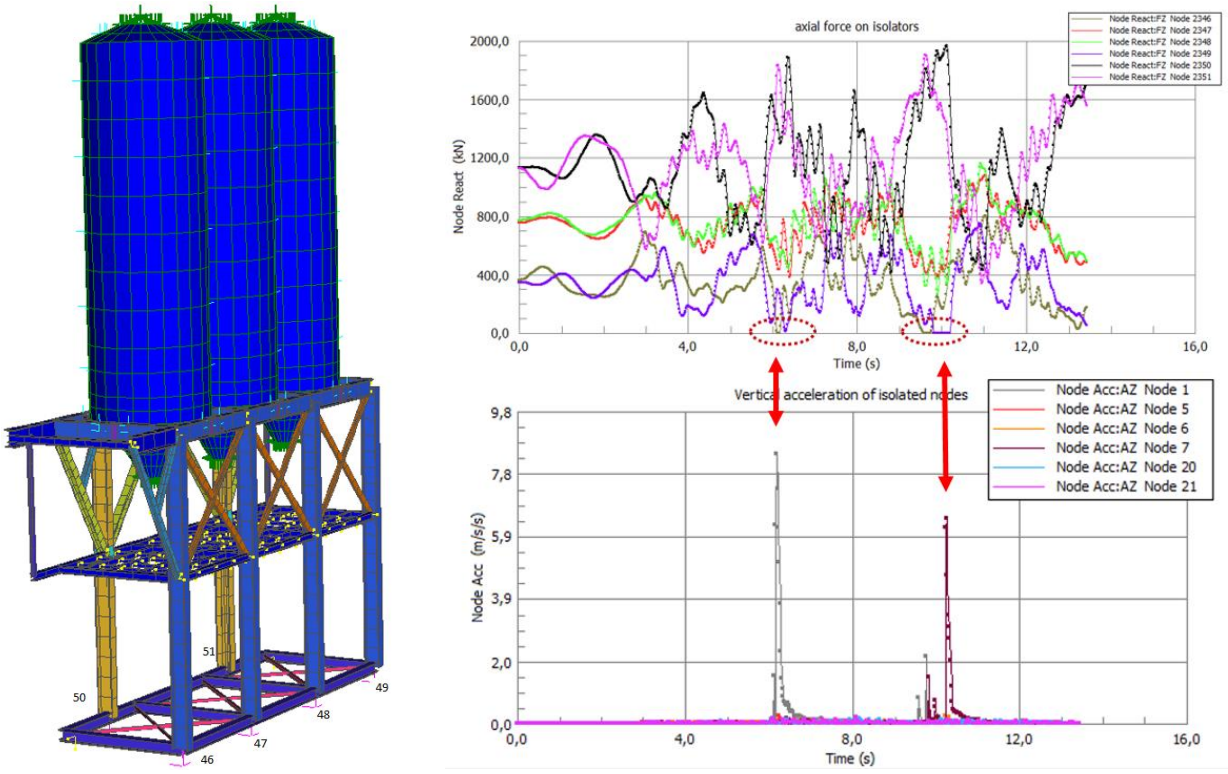




a. Original Structure b. Retrofitted structure

Figure 34 IDA results in terms of drift 2nd floor

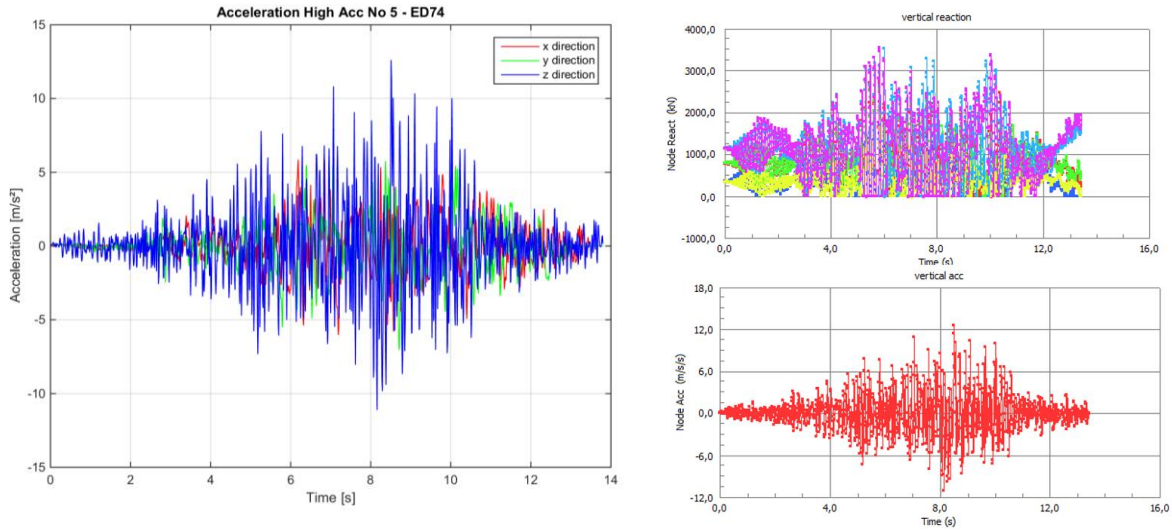
Although the global behavior of the structure is very satisfactory, in some cases, especially with high vertical earthquake component, uplift occurs (Figure 35). It could be avoided either with the introduction of proper ropes that prevent the uplifting of the isolation devices.



a. Retrofitted structure b. Uplift instants during ED74 time-history (without vertical accelerations)

Figure 35 Uplift problem

In the cases with high vertical acceleration content (Figure 36), uplift is inevitable with the seismic isolation solution.



a. Three components of the ED74 time-acceleration history

b. Uplift instants during ED74 time-history (with vertical accelerations)

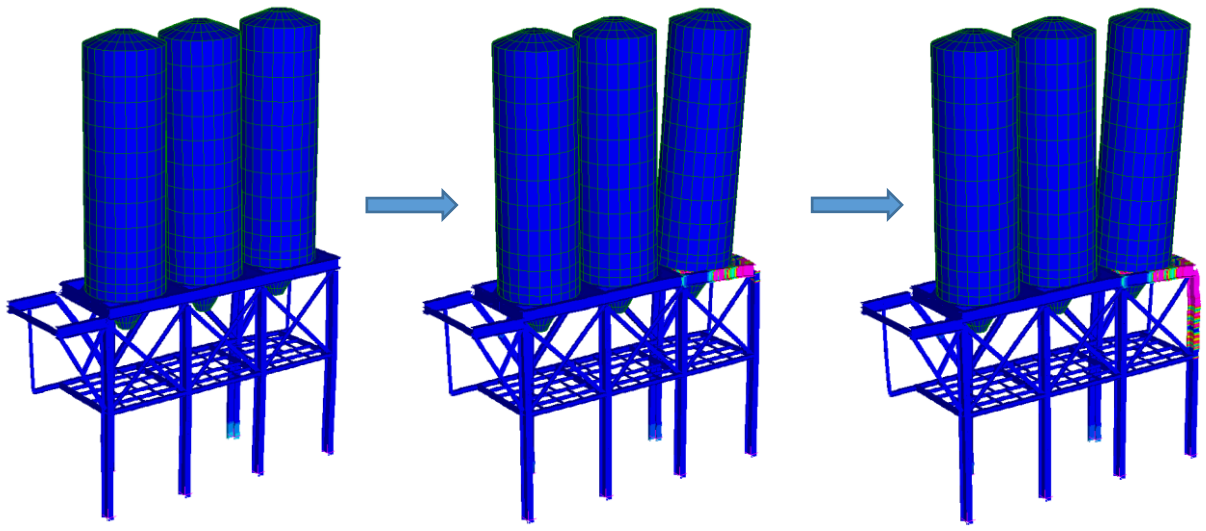
Figure 36 Uplift problem

To reduce the rocking effect and overturning moments which are the main causes of uplift, 2 other retrofitting strategies have been analysed:

i. Seismic isolators placed at the second floor level, under the silos

ii. Seismic isolators placed at the first floor level

The first approach resulted in global collapse of the system, causing high stresses in the beams which caused also a column loss and eventually the global collapse occurred (Figure 37). With the second approach, column bases suffer yielding due to second order effects caused by large displacements of isolated silos (Figure 38). Further analysis to investigate the performance of the structure with second retrofitting strategy is underway.



t= 6 sec t=8 sec (beam yielding starts) t=11 sec (column collapse)

Figure 37 Isolators placed at the second floor level, under the silos

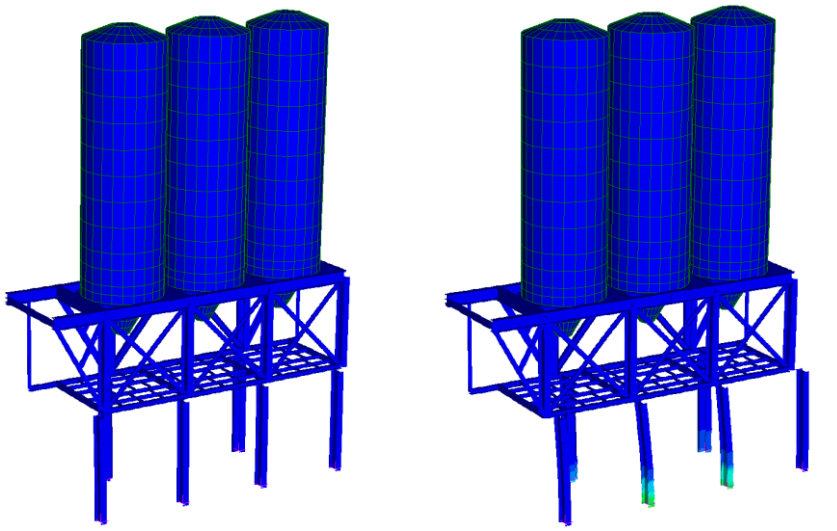


Figure 38 Isolators placed at the first floor level

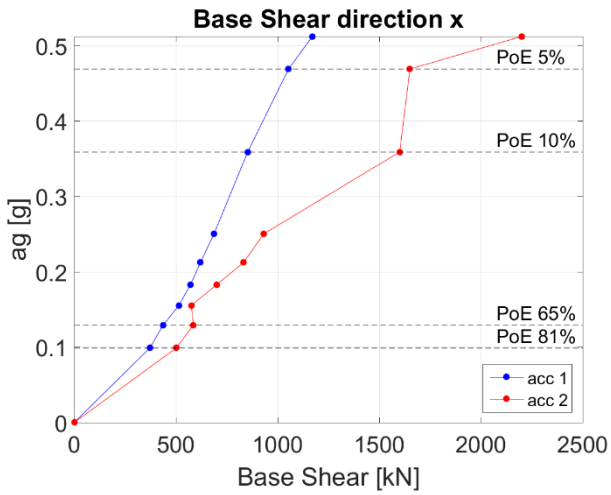
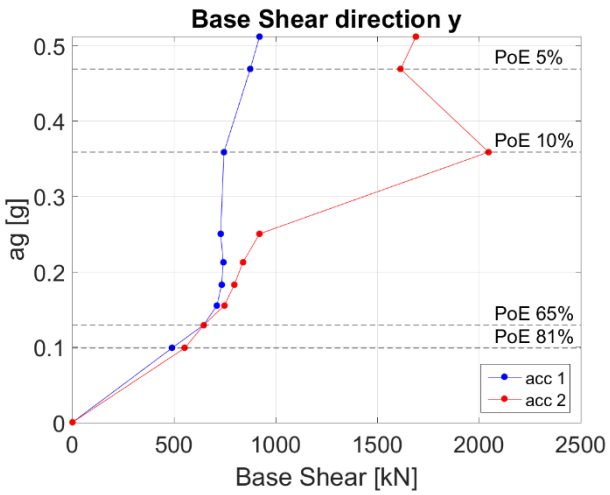
It has also been noted that, vertical component of the earthquakes impact significantly the global behavior of the retrofitted structure. This can be seen from Figure 39, Figure 40, and Figure 41 where the red colored curves represents the global behavior with vertical component of the ED74 earthquake. When they are compared with the blue curves representing the global behavior without considering the vertical acceleration component, it is seen that achievement of the full elastic behavior will not be possible. In these cases, retrofitted solution can be seen as an improvement rather than a total rehabilitation solution.





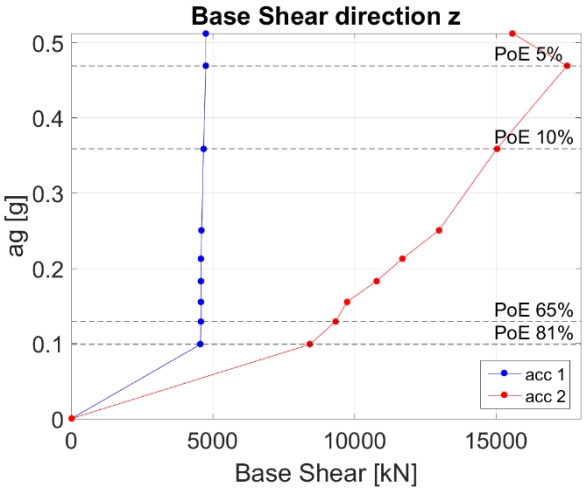


Figure 39 Impact of vertical component of ED74 earthquake in terms of base shear

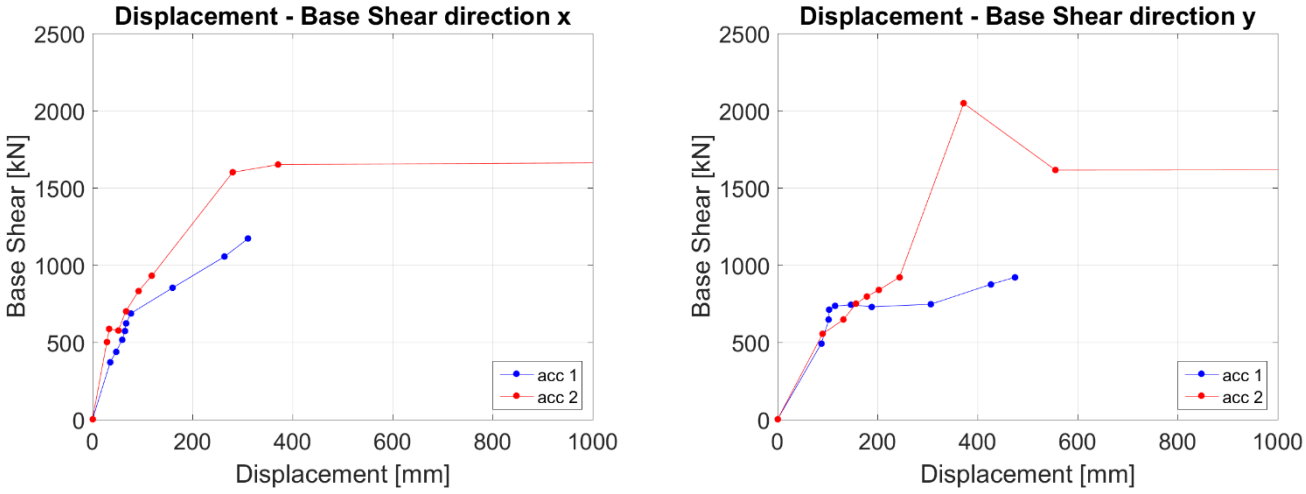

Figure 40 Impact of vertical component of ED74 earthquake in terms of displacement-base shear

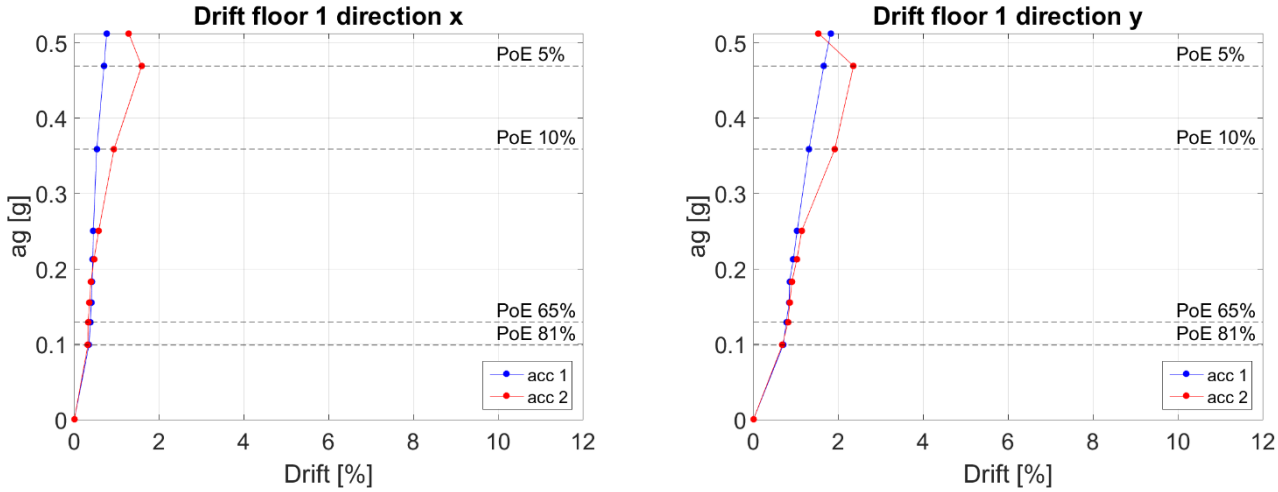

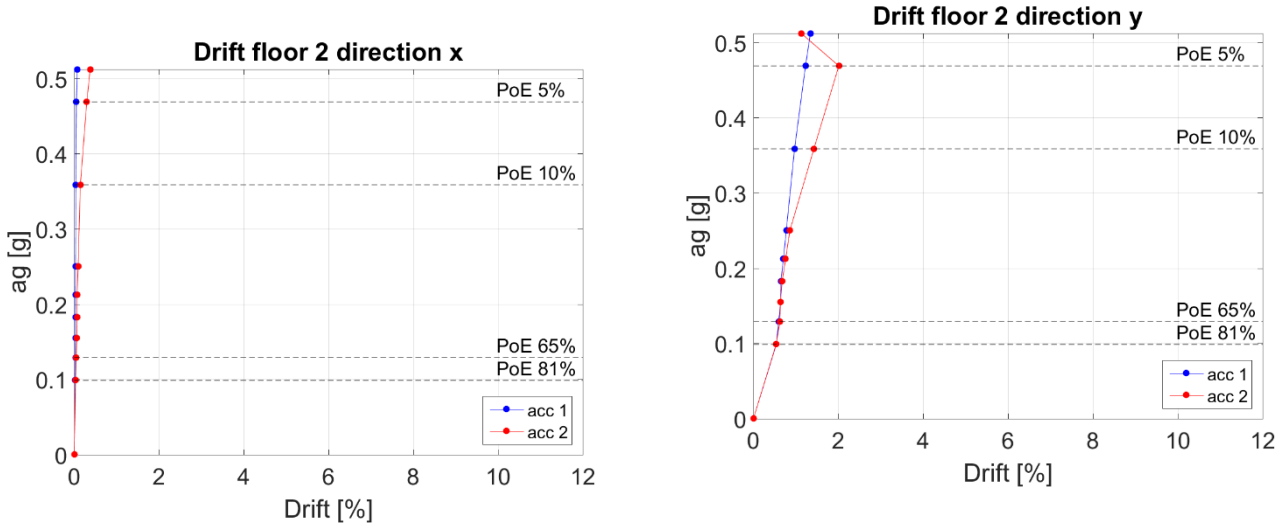

Figure 41 Impact of vertical component of ED74 earthquake in terms of floor drifts

6 CONCLUSIONS

The best seismic retrofit solution has been obtained by using 6 seismic isolators connected by a rigid diaphragm realized as a horizontal steel frame composed of beam and horizontal bracing elements at ground level. Global base shear values have been reduced significantly. Residual displacements of the retrofitted structure are very small, and much smaller than the residual displacements of the original structure. With the seismic retrofit, floor drifts are reduced, and the soft-storey behavior observed in the original structure has been eliminated. Vertical component of the earthquakes impact significantly the global behavior of the retrofitted structure. A fully elastic superstructure behaviour can be achieved only when the vertical component of earthquake is not significant. In summary, this retrofit solution improves significantly the seismic behaviour of the elevated silo system. In the final design of the isolators, uplift issue should be addressed.

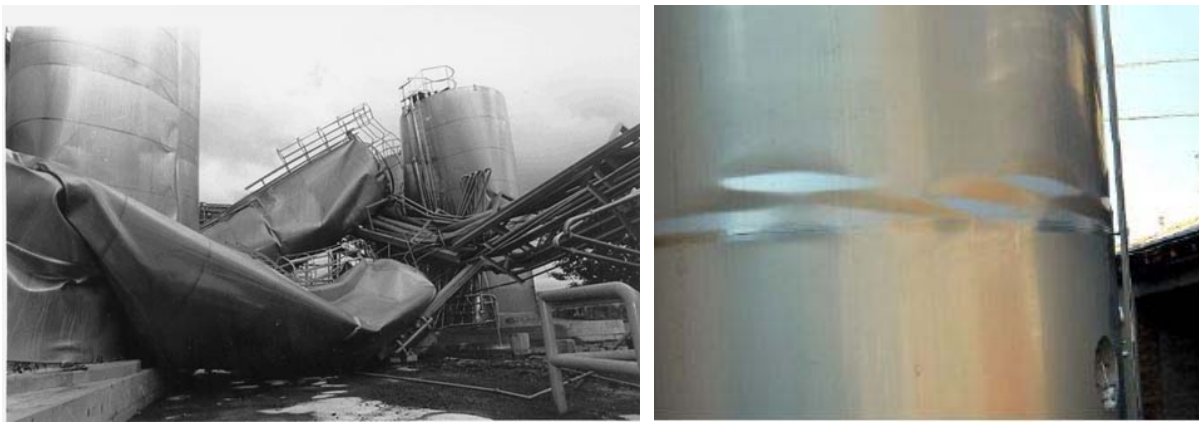
Abstract. *Recent earthquakes such as the one in Fukushima in Japan in 2011 highlighted the need of providing adequate protection to industrial installations. To answer this need, the ongoing RFCS research project PROINDUSTRY is addressing the question of the development of innovative seismic protection systems, both for the design of new industrial plants and for the retrofit of existing ones. This paper presents a specific aspect of the ongoing investigations within the referred project, namely a case study considering a Gas Tank. The protection systems under development contemplate both seismic isolation and energy dissipation techniques. For the presented case study, the base isolation system under development was finally chosen to improve the seismic performance of the Tank structure. In order to characterize the behavior of the Gas Tank structure, several numerical simulations were performed comprising modal analyses, push-over analyses and time-history nonlinear analyses. For the time-history nonlinear analysis ground motions were generated on the basis of available information on ground motion histories from national, European and Mediterranean Strong Motion Data-bases. Finally, the efficiency of the base isolation used in the Gas Tank structure is investigated by comparing the results of the time-history nonlinear analysis on the protected and the non-protected structure.*

1 INTRODUCTION

Recent earthquakes such as the one in Fukushima in Japan in 2011 highlighted the need of providing adequate protection to industrial installations storing a large amount of hazardous material. In the event of an earthquake, and following accidental scenario, the consequences may be severe for the neighborhood population, for the economy and for the environment [1]. In particular process plants, like process units, storage units and piping systems are characterized by high level of seismic risk [2]. The consequences of an earthquake may be the total collapse (Fig. 1-a) or a partial damage (Fig. 1-b) of the industrial unit. Consequently, providing adequate seismic protection to industrial installations is imperative to this construction sector.
In order to answer to this problematic, the on-going RFCS research project PROINDUSTRY [3] is addressing the question by developing innovative seismic protection systems, both for the design of new industrial plants and for the retrofit of existing ones. The seismic protection systems considered in the project programme are the Base Isolation (IS) and the Energy Dissipation (EDS) types. Emphasis is given to the self-centering capability of these systems, since it is an essential feature that allows the industrial facility not to discontinue its operations even after a strong earthquake and that makes eventual repair work easier. The work programme considers experimental tests on the developed devices, including application in substructures, and numerical modelling of real industrial structures used as study cases to investigate and calibrate the seismic protection systems developed. The cases studies of real industrial buildings consider process and storage units which the superstructure is made of steel [4].



a) Tank collapse (Edgecumbe Earthquake, New Zeeland) b) Local shell buckling (Emilia earthquake, Italy)

Figure 1: Earthquake impact on industrial units

This paper presents a specific aspect of the on-going investigations within the referred project, namely a case study considering a gas tank. For this structure, a base isolation system was chosen to improve its seismic performance. In order to characterize the behavior of the Gas Tank structure, several numerical simulations were performed comprising modal, push-over and time-history nonlinear analysis. For the latter, the Ground Motions generated within the project tasks have been used. The calibration of the foreseen base isolation system is under investigation and the preliminary results of the time-history nonlinear analysis on the protected structure are compared with the response of the non-protected structure.

2 SEISMIC PROTECTION OF INDUSTRIAL PLANTS

2.1 General

In the case of seismic event, the prevention of the collapse of buildings may rely in two strategies: i) capacity design; ii) seismic isolation and/or energy dissipation (seismic protection). The PROINDUSTRY research project is focus on the latter. Accordingly, base isolation systems and energy dissipation systems are under development for the retrofit intervention of existing industrial structures or the design of new ones. In the case study presented in this paper, the base isolation system has been selected to improve the seismic performance of the structure under analysis. Herein, only a brief description of the base isolation system is given. More detailed information on the base isolation and on the dissipation devices subject of the PROINDUSTRY investigations may be found in [4].
The aim of the base isolation system is to mitigate the impact of seismic action on the structure by decoupling the structure from the shaking ground. The principle of seismic base isolation is to increase the fundamental period of the structure and modify the mode shape leading to smaller rigid mass displacements, and consequently reduce the loads due to inertia effects. An isolator shall provide a combination of vertical-load carrying capability with one or more of the following functions: i) lateral flexibility; ii) energy dissipation; iii) re-centering capability. The base isolation system implemented in the numerical simulation is the Curved Surface Slider (CSS) which may present different versions: single CSS, double CSS and triple CSS. Within the project, an innovative version of this device is under development [4].

2.2 Base Isolation System: Curved Surface Slider

The simple version of the CSS was proposed in [5] and consisted in a single curved surface slider (Figure 2-a). In concept, the single surface slider is derived from the regular spherical bearing in which the flat surface accommodating the translation movements is substituted by a curved concave surface (Figure 2-b). The spherical sliding isolators are consisting of three main steel parts with inner sliding surfaces. The shape of the internal part is always spherical and allowing rotation and horizontal sliding displacements. The device transmits vertical loads, provides horizontal flexibility and dissipates energy simultaneously. The concave surface introduces the re-centering capability into the isolator: the slide moves up the concave surface (under the seismic excitation), increasing the potential energy, inducing in the bearing a restoring force, as the building should return to its stable equilibrium point. The theoretical behavior of the device is characterized by hysteretic bilinear relationship between horizontal force – horizontal displacement (Figure 3). From the single CSS, a double and triple CSS were developed (Figure 2-c). These modified versions of the single CSS improve its capacity to accommodate substantially larger displacements and allows the adaptation of device to the earthquake intensity.

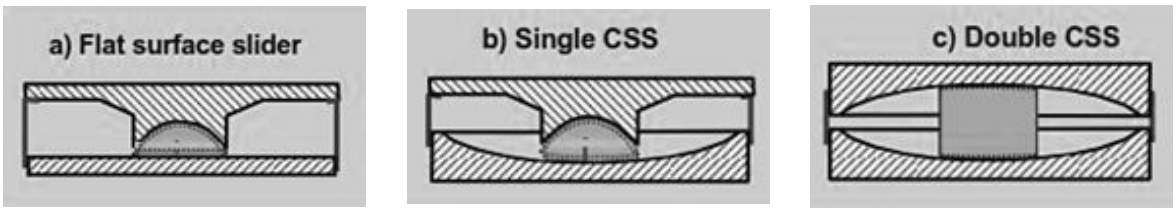


Figure 2: Flat and curved surface sliding isolators [4]

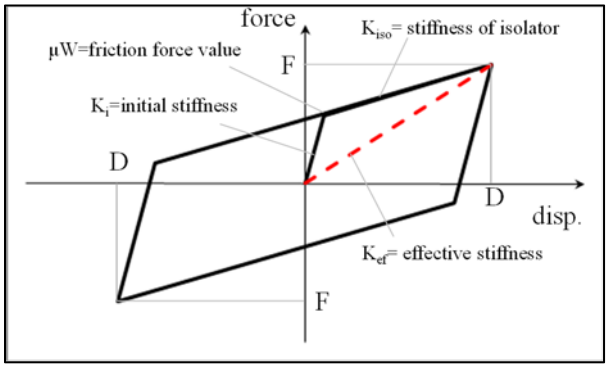

Figure 3: Hysteretic force – displacement relationship of the CSS [4]

3 CASE STUDY: GAS TANK

3.1 Geometric and mechanical properties

The present case study consists in a Gasometer which is used to store Gas AFO (Figure 4) and was constructed by Ilva s. p. a. in the early eighties. The gas tank is a steel cylinder where the walls are made with curved steel plates reinforced with circular steel rings (UNP 100) and with vertical steel columns (IPB 180). The roof is composed by a steel structure using a steel circular grid made of IPE, L and UNP steel profiles and steel plates. The tank works with a piston-fender system and a rubber sealing system which allows the variation of the sealed volume. In Table 1 the main geometric characteristics are summarized and in Table 2 are given the material properties of the main structural components. The self-weight of the different structural components is given in Table 3. Finally, the working pressure in this gas tank is 400mmH2O, and the volume between the roof and the sealed reservoir is full of air at atmospheric pressure. Detailed information on the tank properties is given in [4].

3.2 Finite element model

The finite element (FE) numerical model developed considered some simplifications, as only the main structural components of the tank were modeled. These parts are: i) wall shell; ii) columns; iii) wall stiffening rings; iv) roof shell; v) roof structure. In Figure 5 is illustrated the FE model developed. According to the parts modeled, the following types of finite elements were used:

- Wall shell and roof shell: the element used is the S4R. This is a 4-node doubly curved thin or thick shell, reduced integration hourglass control, finite membrane strains. Five integration points through thickness.
- Columns, stiffening rings and roof structure: the element used is B31. This is a 2-node linear beam in space.

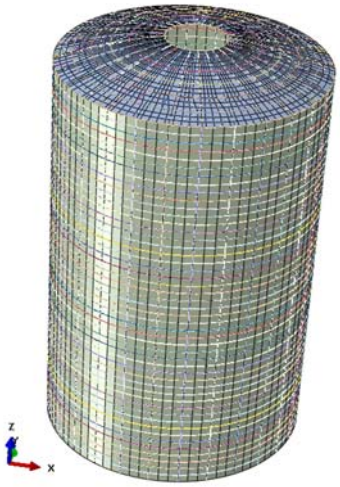

Figure 5: FE model developed

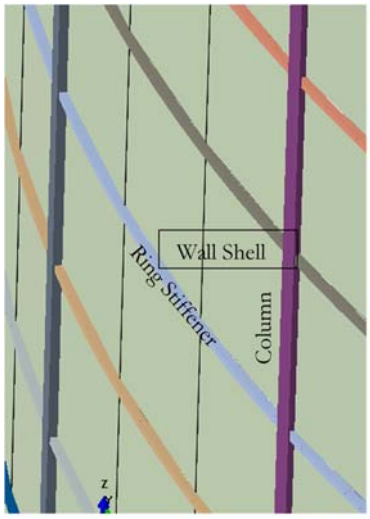
In order to consider the total mass of the tank, as the non-structural elements were neglected in the modelling, additional masses were introduced as non-structural masses. In Table 4 are described the additional masses considered. The total mass of the tank model, including structural and non-structural elements, is 1427ton. The connections between the different structural members have been considered continuous, even in the case of the wall shell-column. These two members are connected using rivets along the total height of the columns, as depicted in Figure 6. In what concerns to the supports, connection to the ground, the column base were modeled as pinned connections. For the material mechanical behavior, an elasto-plastic with hardening constitutive law was used. Finally, it should be noticed the following:

- In the non-linear analyses, both material and geometrical nonlinearities are considered.
- As the working pressure ($400mmH_2O \approx 0{,}039atm \approx 3{,}92kPa$) is relatively low; the mass of the gas was neglected.
- No geometrical imperfections and residual stresses were considered (analysis on perfect structure).

Table 4: List of non-structural masses considered in the FE model

Member	Additional Mass [ton]	Comments
Columns	0.25	Mass of the non-structural elements distributed along the total height of the columns.
	713.0	Piston mass applied at highest possible position. The mass is distributed amongst all columns and along ≈6m of the column length so that the resultant is at the highest working position.
Roof Structure	2.52	Additional mass due to non-structural elements and distributed along the total length of the roof structure members.

a) Connection detail



b) FE model detail

Figure 6: Connection between Column and Wall

3.3 FE model failure criteria

In order to identify a possible failure of the structure during the analysis, the failure criteria in Table 5 have been specified.

Table 5: List of failure criteria

Criterion	Description
1 – Limit of plastic strains	$\varepsilon_u = 0.2$
2 – Global or local instability	Global loss of stability of the structure or local instability of parts of the structure.
3 – Resistance of the column bases connection	Exceedance of the resistance of the column bases connection to uplift loads.

In order to avoid the complexities related to the modelling of the column bases connection, the third criterion is verified in the post-processing of the numerical results, comparing the uplift forces with the column base resistance. The resistance of the column bases was determined according to the design rules given in [6] and [7]. For the present case study, the resistance is 315kN.

In what concerns the wall shell of the gas tank, though at first one may regarded the tank structure as a shell structure reinforced by the columns (usually called stringers in shell structures), their resistance to buckling is barely inexistent. The resistance of the shell was estimated according to [8] and [9]. The tank structure stability is then guaranteed by a "classic" structure composed of columns and beams, being the main function of the wall and roof shells the resistance to the internal and external pressures, and consequently distribute these pressures to the main structural members. The second function of the wall shell is to contribute to the global lateral stiffness of the structure.

4 SEISMIC PERFOMANCE OF NON-ISOLATED STRUCTURE

4.1 General

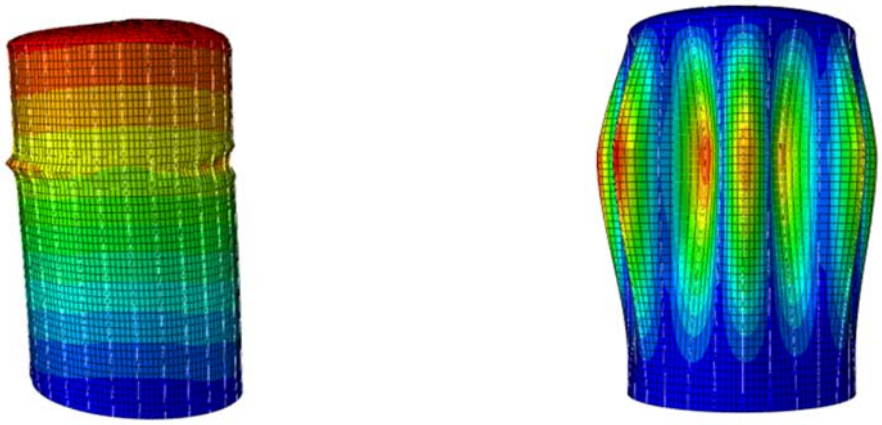
In a first stage, the performance of the original gas tank structure to seismic actions was evaluated. Several numerical simulations were conducted in order to characterize the structure response to dynamic actions, developing inertia forces on the structure, and to evaluate the seismic performance of the non-isolated structure. The performed simulations considered the following types:

- Modal Analysis
- Push-over Analysis
- Time-History Nonlinear Analysis → Incremental Dynamic Analysis

For the Time-History Nonlinear Analysis, and Incremental Dynamic Analysis, and within the scope of the PROINDUSTRY project [4], two sets of 11 Ground Motions (GM) have been generated on the basis of available information on ground motion histories from national, European and Mediterranean Strong Motion Data-bases. One set is representative of areas with low-medium seismicity and another set is representative of areas with high seismicity. ground motions were

4.2 Modal analysis

In order to obtain the natural vibration modes, a modal analysis was executed. The procedure used consists in the Lanczos method. The range of frequencies in the calculation was limited to 20Hz. Within the range of frequencies between 0Hz and 20Hz, only two global modes were observed and these correspond to the same mode though, for each orthogonal direction. Many local modes (percentage of mass participation is almost zero) were obtained. The first natural frequency is 2,64Hz with a total mass participation of 88,65% in the main direction and nearly 0% in the other orthogonal direction. Figure 7-a) presents the shape of the 1st natural frequency. The local deformation at approximately 2/3 of the height is due to the consideration of the piston mass at this position (highest position possible). Figure 7-b) presents the first mode obtained in the calculations which represents a local mode.



a) 1st global mode b) 1st local mode

Figure 7: Natural vibration modes of the gas tank structure

4.3 Push-over analysis

The push-over analysis consisted in applying a horizontal force at the center of mass of the tank. Given the magnitude of the piston mass, the position considered was the highest working height of the piston, approximately 2/3 of the gas tank height (see Figure 8). The load was applied directly to the columns, as these members are the vertical support of the piston. The load was distributed within a length which approximates the length of the piston structure inside the tank. The load was increased until one of the following failure criteria was achieved: i) plastic limit strain attained; ii) local or global instability detected by the numerical calculation. In this analysis the column bases connections resistance was disregarded.

In Figure 9 is presented the force-displacement curve obtained from the push-over analysis. The force corresponds to the base shear and the displacement is the displacement measure at the top of the gas tank structure (at the top of the columns). The maximum load is identified by a peak in the force-displacement curve. A sudden loss of resistance after this peak load is observed which is due to loss of stability of the gas tank structure. Then, there is an increase of resistance after equilibrium is recovered. The ultimate strain is attained in the tank structure members later for a significant lateral displacement.

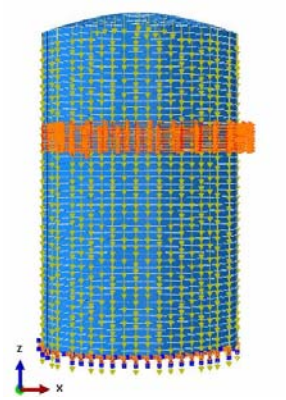


Figure 8: Location of the loading in the push-over analysis

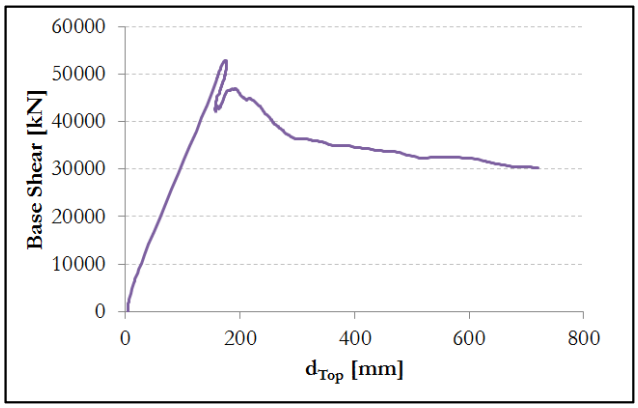

Figure 9: Force-displacement curve obtained from the push-over analysis

4.4 Incremental dynamic analysis

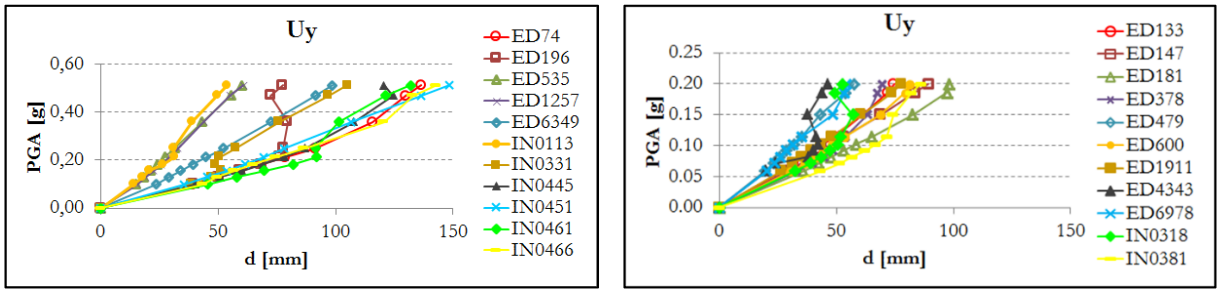
The nonlinear time-history analysis, basis of the incremental dynamic analysis (IDA), were performed using the general nonlinear dynamic analysis available using implicit time integration to calculate the transient dynamic or quasi-static response of a system.
The procedure used consisted in imposing base acceleration at the support nodes of the gas tanks structures. The base acceleration applied represent the ground motions generated within the project and referred above. These ground-motions are characterized by a time-history acceleration for each orthogonal direction (X, Y and Z). In the performed calculations, the ground motions (base accelerations) for each orthogonal direction were applied simultaneously. Two sets of ground motions were considered; one representative of low-medium seismicity areas, and one representative of high seismicity areas. In Table 6 are listed the spectral accelerations and the corresponding scale factors considered in IDA analyses.

Table 6: List of spectral accelerations used in the IDA

Low Seismicity Areas				High Seismicity Areas			
Pvr	Tr	ag	S. F.	Pvr	Tr	ag	S. F.
%	Yrs	g	\	%	Yrs	g	\
4	2475	0.199	2.78	4	2475	0.512	1.43
5	1950	0.1854	2.592	5	1950	0.4687	1.307
10	949	0.1501	2.098	10	949	0.3586	1.000
22	402	0.1140	1.593	22	402	0.2502	0.698
30	280	0.1016	1.420	30	280	0.2122	0.592
39	202	0.0916	1.280	39	202	0.1829	0.510
50	144	0.0812	1.135	50	144	0.1552	0.433
63	101	0.0715	1.0	63	101	0.1292	0.360

In all executed calculations, the time-history was completed. Consequently, the two first failure criteria specified in Table 5 were not violated. In order to evaluate the global deformation of the structure, the relative displacement of the roof was computed. In Figure 10 are presented the results for both sets of GMs, High and Low-Medium seismicity areas, and for one of the orthogonal directions in the ground plane. The values represent the maximum values obtained

through the time-history simulation. For almost all cases the structure is on the linear range. Local yielding is observed however; this is not reflected on the global response. The maximum value is 150mm. Taken into account the height of the gas tank and that in the vicinity, at least 2m separate this gas tank from other structure, the values is barely insignificant.



a) High seismicity areas b) Low seismicity areas

Figure 10: Gas tank roof relative displacements result of IDA calculations on non-isolated structure

In Figure 11 is plotted the parameter which expresses the plastic strains, the equivalent plastic strain (PEEQ). These plastic deformations are located in the members, mainly in columns and ring stiffeners, in the region of the piston mass and consequently, the region were the inertia forces are greater. In Figure 11 only the maximum values are shown, for each time-history simulation of the IDA analysis. Since for Low-Medium Seismicity GMs these are barely inexistent, only the values for the High Seismicity GMs are presented. In the chart is included the limit strain considered in the numerical models (0.2). It can be observed that not only this limit was not exceeded, but the maximum equivalent plastic strain is approximately half of this limit. Up to a scale factor of 1.0, an almost linear relation between the peak ground acceleration characterizing the GMs and this parameter is obtained. For higher scale factors, for some cases this linearity is lost. This may be due to the damping effects when the plasticity becomes higher. However, in general this is not significantly reflected in the global response, as discussed above.

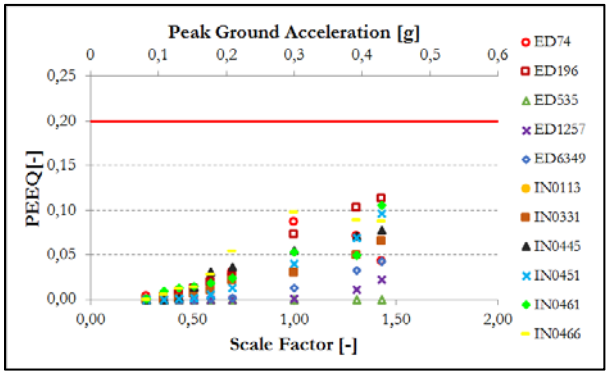


Figure 11: Maximum PEEQ result of IDA calculations on non-isolated structure (only High Seismicity areas GMs)

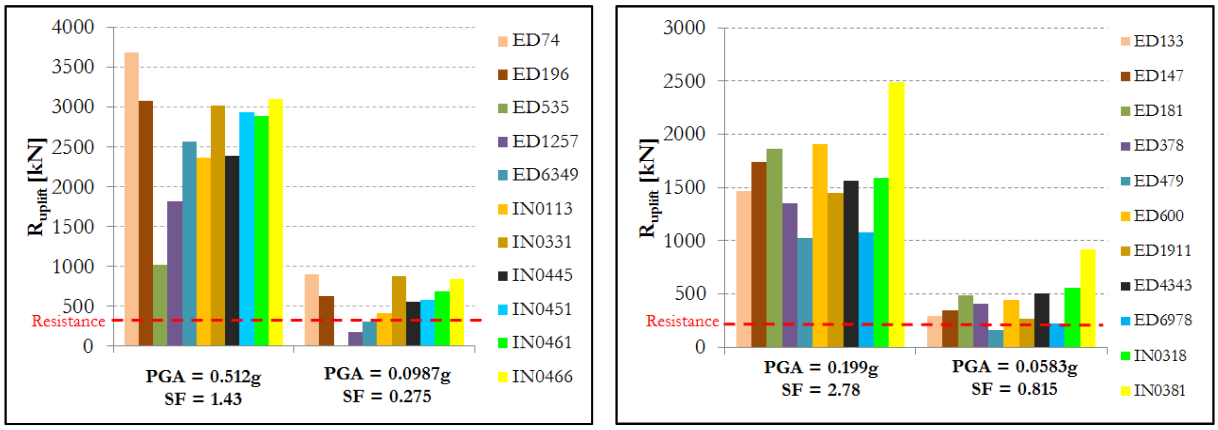
In order to verify the third failure criterion, the uplift forces on the column bases and the respective resistance were compared in Figure 12. These forces are due to the tank overturning and the vertical component of the seismic action. It can be seen that this is clearly a critical point of the structure. Only for few cases, amongst all GMs representing both seismicity's areas, and for the lowest scale factors, this resistance was not exceeded. In the case of the High Seismicity areas, the maximum values are considerably high, approximately 10 times greater, and

almost impossible to overcome with improvement of the connection and therefore, seismic protection is required.



a) High seismicity areas b) Low seismicity areas

Figure 12: Column bases uplift forces results of IDA calculations on the non-isolated structure

5 EFFICIENCY OF THE SEISMIC PROTECTION SYSTEM: BASE ISOLATION SYSTEM

5.1 Model of the base isolation system

For the base isolation system of the gas tank structure 28 units (isolators), one under each column, are foreseen. Note, that this should be placed in the same vertical position of the columns, not directly under the columns, but between a "Support" slab and the foundation (isolation interface), as illustrated in Figure 13. The incorporation of the isolators on the FE model consisted in a system that combines a spring element and an elastio-plastic element (or friction element) working in parallel. The spring element has a pure elastic linear behavior which represents the isolator stiffness to slip (dynamic friction). The friction element, incorporates the friction force (static friction) developed between the slider and the concave surfaces. The friction force is proportional to the superstructure mass (M). It is usually assumed that the behavior of this element is rigid until the static friction is exceeded. Then, free deformation of this element is considered.

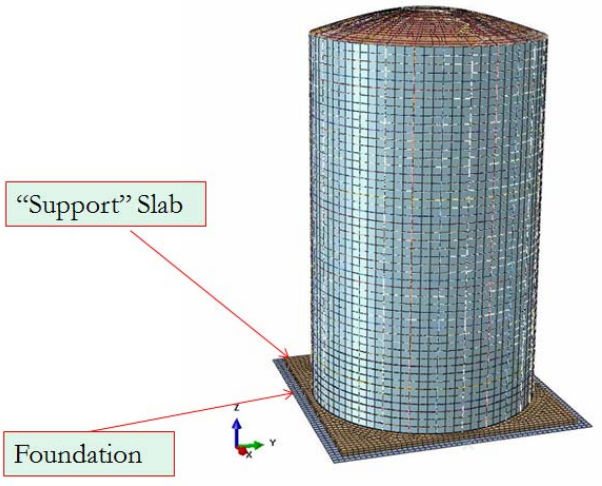


Figure 13: FE model of the base isolated gas tank structure

To model the behavior of the isolation system, the following parameters are determined:

- The total weight (W) and mass (M) of the superstructure and of the "Support" slab above the isolation system.
- The friction coefficient (μ) between the slider and the concave surfaces.
- The fundamental period of the device. This values are usually between 3,5s and 4s (T).
- The stiffness of the Isolator which may be approximated by the following equation:

$$k_{isol} = M\frac{4\pi^2}{T^2} \quad (1)$$

In Table 7 are presented the values of the parameters described above and assumed in the present case study. In Figure 14 is illustrated the force-displacement response of the isolation system.

Table 7: Properties of the base isolation system of gas tank structure

M [ton]	W [kN]	μ [-]	T [s]	$K_{iso,system}$ [kN/m]
1581.1	15495.3	0.3	3.5	5095.6

The determination of the properties of each isolator unit is obtained through "decomposition" of the equivalent isolation system properties described above. Remember, that in this case 28 individual isolators are considered. Given the symmetry of the structure, these 28 isolators have equal properties. Thus, the equivalent isolation system reproduces the behavior of 28 parallel isolators and accordingly the properties of each isolator unit are obtained: the elastic spring stiffness and friction element maximum force are divided by 28. In Figure 15, the properties of these two elements representing an isolator unit are shown.

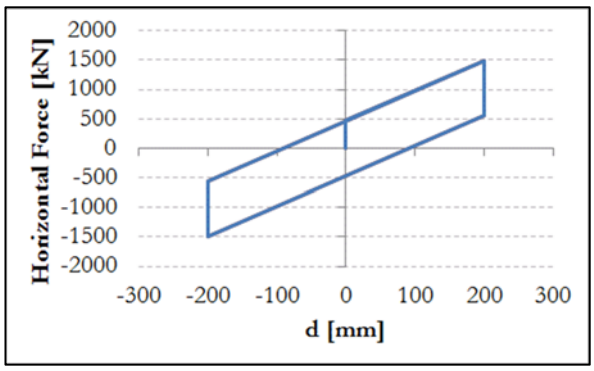

Figure 14: Force-displacement behavior of the base isolation system

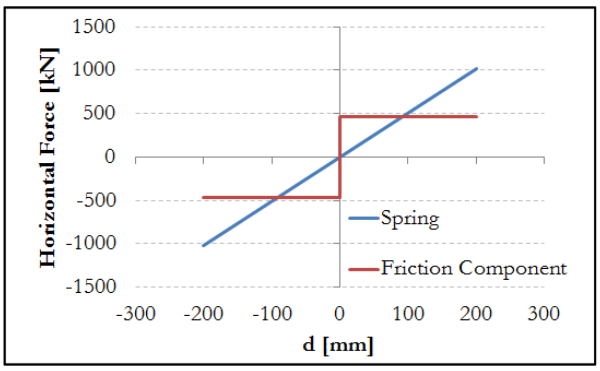

Figure 15: Behavior of the spring and friction element representing an isolator

5.2 Impact on the structure response

The purpose of the base isolation system is to reduce the horizontal (soil plane) base displacement of the superstructure. This is achieved through the seismic energy dissipated by the isolation system. At this stage, the isolators properties are in a process of calibration and therefore, only the time-history nonlinear analysis using the GMs, representing the high seismicity areas, were used. Furthermore, the simulations only considered the scale factor equal 1. In Figure 16 is shown the time-history tank roof relative displacement for one of the orthogonal direction on

the base (ground) plane for GM ED74. The chart includes the results for both cases, non-isolated and isolated structure. The impact of the base isolation system is evident. The tank roof relative displacement on the isolated structure is 26% of the value obtained in the non-isolated structure. In Figure 17 are presented the maximum tank roof relative displacement, for one of the orthogonal directions (ground plane) achieved during the time-history nonlinear simulation. The chart includes all GMs representative of the high seismicity areas. The reduction on the gas tank roof relative displacement is a constant for all GMs. The results of the different GMs show that the most demanding GM for the non-isolated structure do not correspond to those for the isolated structure. This is expected as the isolated structure has a different response due to the modification on the fundamental period, which corresponds to that of the isolation system.

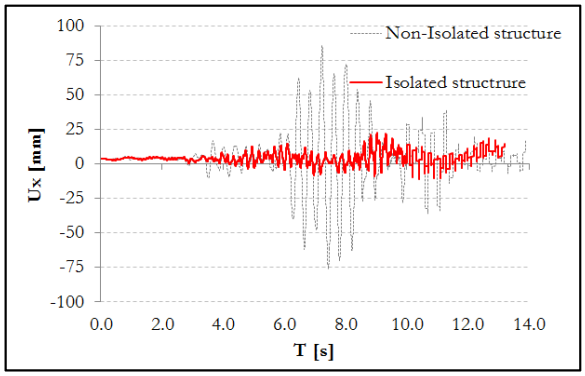

Figure 16: Time-history gas tank roof relative displacements comparing non-isolated and isolated structure

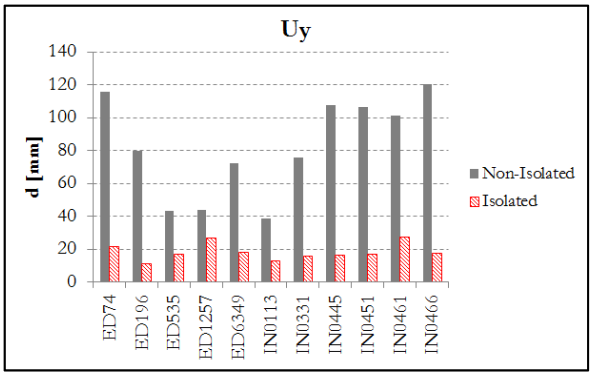

Figure 17: Maximum gas tank roof relative displacements comparing non-isolated and isolated structure (all GMs)

In Figure 18 are presented the results of the uplift forces on the columns. Remember that, according to the simulations on the non-isolated structure, column bases resistance to uplift forces are the critical parts of the present structure. A comparison with the results of the simulations on the non-isolated structure and the theoretical resistance of the column bases to uplift forces is included. Again, it is evident the impact of the base isolation system. It possible to see that for the isolated structure only GM ED74 exceeds the theoretical resistance of the column bases. In the case of the non-isolated structure, all GMs exceeded this value. Though, in the case of the GM ED74 the uplift forces, on the isolated structure, are greater than the column base resistance, the values are now closer (of the same order). Thus, an improvement of the column base may solve the problem. The values on the non-isolated structure were impossible to bear with reasonable modifications. As explained above, the uplift forces arise from two sources: the vertical component of the seismic action and the structure overturning due the inertia forces. The base isolation system is capable of mitigate the impact of the latter, but not of the first. In Figure 19 this is demonstrated. In one simulation, the vertical component of the seismic action was considered, and in the other neglected. The simulations were performed on the isolated structure. One can observe that when the vertical component of the seismic action is removed, the uplift loads are barely inexistent. It also clear that the base isolation system manages to eliminate almost 2000kN of uplift load showing clearly its efficiency. On the other hand, it must be noted that the vertical component of the seismic action is real and cannot be neglected. Therefore, together with the base isolation system, an auxiliary system has to be considered to transfer these forces.

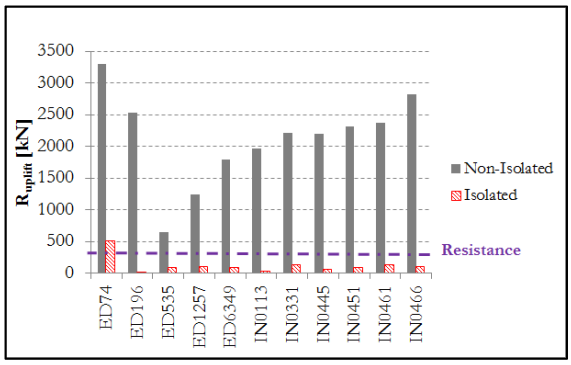

Figure 18: Maximum uplift loads on column bases (all GMs) and theoretical resistance

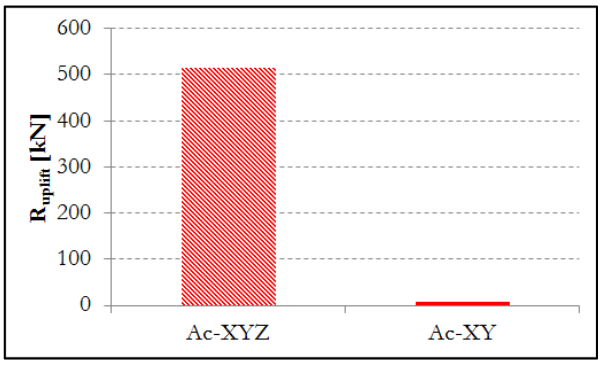

Figure 19: Effect of the vertical component of the seismic action (GM ED74)

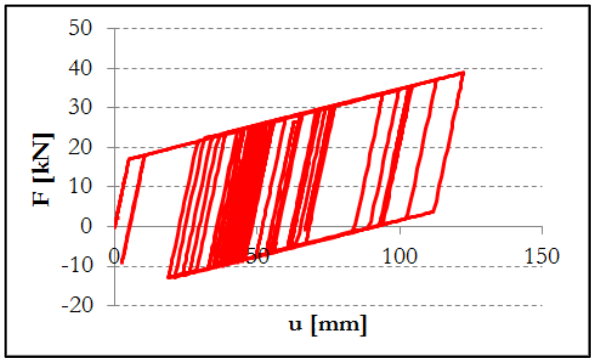
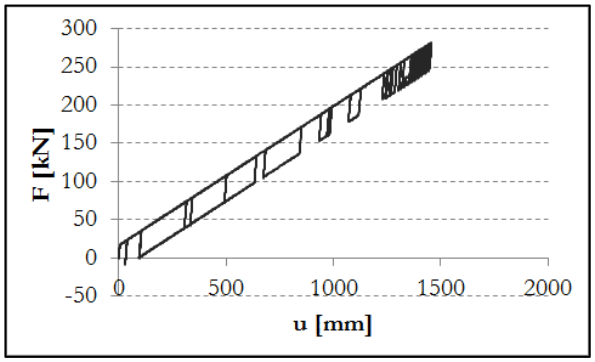
5.3 Performance of the base isolation system

In order to evaluate the isolators performance demands, the results of the numerical simulations, on the elements of reproducing the devices behavior, are herein discussed. In Figure 20 are shown the force-deformation curves obtained for two GMs. Remember that the deformation represents the distance between the superstructure base and the foundation. This has to be accomplished through movement of the slider on bottom and upper sliding surfaces. The force represents the inertia forces developed in the superstructure which have to be transferred to the supports through the isolators. The two GMs shown represent the extreme cases: the one with smaller deformations and the one with higher deformations. The values measured are considerably different. In the case of GM ED196 the maximum deformation is approximately 125mm, while in the case of ED1257, the maximum is of approximately 1500mm. If in the first, the value is perfectly within the deformation capacity of the isolator, the second overcomes this limit excessively. The reason for such differences is on the fundamental period of the base isolation system and on the period at which the ground displacement spectrum attains its maximum. As it can be seen in Figure 21, the latter occurs at approximately 3,5s which corresponds to the fundamental period of the isolators. Thus, a calibration of the isolator properties is required in order to have an isolator that can also perform in the case of seismic actions as GM ED1257. This issue is under investigation at the current stage.



a) ED196



b) ED1257

Figure 20: Force-deformation curve on isolators

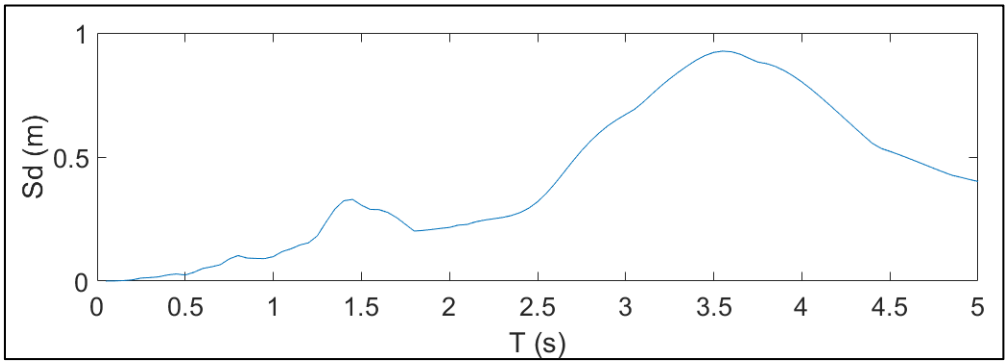


Figure 21: Ground displacement spectrum for GM ED1257 in the X direction (in soil plane)

Figure 20 shows that several cycles are accomplished. A quantification of the number was performed and is shown in Figure 22. The chart presents the number of cycles for different ranges of cycles amplitude. Intervals of 50mm of amplitude were defined. In the chart are included all GMs representative of the high seismicity areas. The following observations highlight from these results: i) the majority of the cycles have a small amplitude; ii) only for few GMs high amplitude of cycles occur; iii) the maximum amplitude of the cycles is smaller than the maximum displacement shown in Figure 20-b) for GM ED1257. The latter shows that cycles may occur with minimum deformations of the isolators greater than zero (considerably in some cases). In Figure 23 are quantified the total number of cycles the isolators undergo, independently of the cycles amplitude. The maximum number is 35 and this occurs for the GM ED1257. The minimum is 7 for ED6349.

6 CONCLUSIONS

This paper presented the work in progress within the RFCS research project PROINDUSTRY dedicated to the seismic protection of industrial plants. In particular, a case study of a gas tank was discussed. The behavior of the tank structure was characterized based on several numerical simulations considering: modal, push-over and time-history nonlinear analysis (in an incremental dynamic analysis procedure). From the latter, the column bases resistance to uplift loads have been identified has the critical part of the structure. Subsequently, the investigation considered the implementation a base isolation system to provide seismic protection to the structure. The base isolation system considered is the double curved surface slider (CSS). From the numerical simulations, on the isolated structure, has been observed that the seismic impact on the structure is mitigated using this device. However, for some ground motions, the deformation

required on the isolation system, to dissipate the seismic energy, is excessive. This happens because, for some ground motions, the fundamental period of the seismic device is very close to the peak ground response spectrum. Consequently, a calibration of the base isolation system is under investigation.

ACKNOWLEDGEMENTS

The research leading to these results has received funding from the European Union's Research Fund for Coal and Steel (RFCS) research programme under grant agreement n° [RFSR-CT-2013-00019].

Keywords: Nonlinear Response History Analysis (NL RHA), Performance Based Earthquake Engineering (PBEE), Incremental Dynamic Analysis (IDA), Ground Motions (GM), Uniform Hazard Spectrum (UHS), Conditional Mean Spectrum (CMS).

Abstract.*Within the PROINDUSTRY project a Performance-based analysis framework is defined for seismic assessment of industrial structures, based on Nonlinear Response History Analysis (NL RHA) using in particular the Incremental Dynamic Analysis (IDA) method. This paper describes the choice of the PBEE and IDA analysis methods starting from an overview of state-of-the-art methods. The choice is analyzed in relation to: analysis goals for the selected case studies (design-based vs. risk-based), availability of databases/tools for hazard analysis and GMs selection, accuracy of criteria to scale and match GMs to a target spectrum (UHS, CMS, etc.) and treatment of record components. Three possible approaches of GMs selection are described and analyzed: (1) UHS-coherent Unscaled (Design), (2) UHS-coherent GMs scaled to Sa(T1) (Risk/Loss), (3) CMS-coherent GMs scaled to Sa(T1), (Risk/Loss). Within the scopes of PROINDUSTRY, the approach (1) is proposed, as a trade-off between simplicity of conventional PBEE design methods and probabilistic robustness for a heterogeneous portfolio of structures/facilities.*

1 INTRODUCTION

Recent seismic events in Europe have pointed out the importance of assessing, managing and mitigating the seismic risk of industrial plants [1], [2]. The"Seismic PROtection of INDUSTRial plants by enhanced steel based sYstems" (PROINDUSTRY) project aims at developing enhanced seismic protection systems for process plants, process units, storage units, pipeline and pipe systems, through innovative antiseismic techniques: seismic isolation and energy dissipation systems (such as the one described in [3]). The project includesthe definition of a framework for seismic assessment of industrial structures, based on Nonlinear Response History Analysis (NL RHA) using in particular the Incremental Dynamic Analysis (IDA) method. The framework shall be defined to allow not only the assessment of the current case studies seismic vulnerability, but also the comparison between the seismic behavior before and after the application of the anti-seismic systems.

Seismic design provisions for industrial plant structures can be found under the ASCE/SEI 7-10 provisions [1], particularly for the structure types of 'non-buildings similar to buildings', and 'non buildings not-similar to buildings'. Design codes classify structures types and behavior based on q, R factors for use in force-based linear analysis and design. Correspondence between US codes and Eurocode 8 [5] and capacity design rules are described in [6] and [7]. A comprehensive review of NL RHA code procedures for different types of structures is carried out in the NIST GCR 11-917-15 document 'Selecting and Scaling Earthquake Ground Motions for Performing Response-History Analyses', [8]. In general, the different seismic design codes prescribe a reference spectrum and indicate the number of Ground Motions (GMs) needed to perform NL RHA. The general requirement is to use 7 different GMs and process results in terms of best estimates, or use 3 different GMs and the max response values.

A review of current Performance-Based Earthquake Engineering (PBEE) code provisions for NL RHA in terms of their evolution and underlying vision is useful to analyze what is the most appropriate context, what are the objectives of the prescriptions, and what should be the expectations of a chosen protocol of analysis. Two main types of PBEE design and assessment are identified and discussed: (A) 1st Generation PBEE approach, described in the most commonly used codes of practice; and (B) a Next generation PBEE approach, with new performance metrics and a broader vision in terms of risk analysis.

1.1 First Generaton PBEE (Design-based)

1st Generation reference codes/guidelines for design/assessment prescribe force-based linear methods of analysis/design classifying structures based on type (new/existing buildings, bridges, seismically isolated structures, nuclear plants, liquefied natural gas tanks), and define structural performance matching limit states (identification of component damage level) with a probability of exceedance of the seismic intensity (FEMA356/ASCE41). These codes prescribe also methods of NL analysis, both static and dynamic, and rules for RHA and GM selection. The objective of these code provisions is the performance assessment at the component level, checking/comparing member demand with capacity. Assessment/design of industrial structures and their retrofit using innovative devices are covered by the following documents:

- **Eurocodes**:
  - UNI EN 1998-1 (New Buildings)
  - UNI EN 1998-3 (Assessment and retrofit of buildings)
  - UNI EN 1998-4 (Silos, tanks and pipelines)
  - UNI EN 1998-6 (Towers, piles and chimneys)

- **US codes and guidelines**:
  - New buildings, ASCE/SEI 7-05 (2005), ASCE/SEI 7-10 (2010)
  - Existing buildings, ASCE/SEI 41-06 (2007)
  - Isolated and conventional bridges (AASHTO, 2010 a, b)
  - Nuclearfacilities, ASCE/SEI 43-05, (2005)
  - Liquefied natural gas facilities (FERC, 2007)
  - Dams, FEMA 65, (2005)
  - Civil works, EC1110-2-600 (U.S. Army Corps of Engineers, 2009)
  - Department of Defense facilities, UFC 3-310-04, (Dept. of Def., 2004, 2007, and 2010)
  - Storage tanks, API Standard 650 (2007), API Standard 620 (2009)

Whether used with linear force-based analyses or nonlinear procedures, design methods of the first generation contain a number of limitations regarding in particular:

- *Discrete limit states*: the definition of performance, with respect tosingle components or to the structure as a whole, related to the achievement of a certain limit state is still coarse and often involves questionable margins of conservatism.
- *Accuracy and reliability of procedures.*
- *Performance measures:* Engineering parameters used for definition of performances, such as drift, accelerations, stresses, strains etc., are not understood by entrepreneurs, investors, lenders, and decision makers.
- *Deterministic approach:* the assessment of performance is purely deterministic, only the intensity of the seismic action is modeled in a probabilistic way.

Figure 1. PROINDUSTRY project: someof the industrial case study structures.

1.2 Next-Generation PBEE (Risk/loss-based)

To address these limitations the Pacific Earthquake Engineering Research center developed a Performance Based Earthquake Engineering methodology (PEER PBEE, [12]) and tested it on a number of benchmark structures. For building structures these efforts culminated in the release of the FEMA P-58guidelines, which is a fully probabilistic new paradigm for risk/loss based PBEE [13], [14], and of its companion tool for damage-based accumulation of monetary performance/loss at the global level (PACT tool, [15]). Uncertainties are explicitly considered in terms of: human losses (loss of lives, injuries, etc.), direct economic losses (cost of repairs, replacements, etc.), and indirect economic losses (downtimes, Unsafe placarding, etc.).

The methodology incorporates the components of the PEER PBEE approach, namely the Probabilistic Seismic Hazard Analysis (PSHA), the Structural Analysis, the Damage and Loss analyses. The seismic hazard is defined in terms of Uniform Hazard Spectrum (UHS), or alternatively in terms of Conditional Mean Spectrum (CMS) [16] and Conditional Spectrum (CS) [17]. Three main types of assessment are considered: a) Intensity-based, b) Scenario-based and c) Risk/Time-based. At the core of the methodology is the structural analysis module, based on NL RHA with sets of natural GMs.

Analysis of these documents is important to define a protocol for PROINDUSTRY, giving due consideration to the fact that the FEMA P-58 methodology is developed specifically for building structures, and there is no codified reference document on application of complete PBEE risk/loss framework for industrial structures in general. It is also very important to remark that a comprehensive risk-based approach is beyond the scopes of PROINDUSTRY, which foresees a 1st-gen design/assessment approach. Therefore an appropriate, sufficient, and closer reference document for the analysis approach to develop in WP2 is the NIST GCR 11-917-15. This document is intended for practicing engineers and structural analysts, and contains recommendations on NL RHA analysis protocols and ground motions selection/scaling/matching to target spectra.

An important aspect to consider is that the analysis protocol should be aimed at comparing the structural performance and behavior before and after retrofit with innovative protective devices. Since isolation and energy dissipation devices change drastically the structural system and properties, and in particular the parameter $S_a(T_1)$, and modify the system response as a whole as well as the nonlinear interaction with the superstructure [18], it is desirable that the analysis method and the inherent scaling criterion of the input GMs is as much as possible independent on the properties of the structure.

The FEMA P-58 and NIST guidelines would be easy to follow selecting GMs from the PEER NGA database [19], and scaling to the UHS or CMS provided by USGS, using the extensive database and interactive online tools. However this approach may not be consistent with this EU project. On the other hand some difficulties may arise using the currently available interactive tools (INGV-ESSE project, [20], [21], [22], [23], [24], [25]) or those under development [26] from the Italian/EU databases and PSHA. Some limitations may persist if the CMS is used as target spectrum, and if the GMs are to be scaled to this CMS, particularly due to the inherent type of the local seismicity, both related to the intensity and to the causative sources, [16].

2 OVERVIEW OF NL RHA AND IDA

A key component of modern codes for PBEE design and assessment is the simulation of the structural behavior through realistic nonlinear models, and appropriate analysis protocols. For few cases of very simple and regular structures (1st mode dominated response) the analysis protocol can be of the static type (NL Pushover). In all other cases a dynamic type (NL RHA) is needed to simulate the realistic response due to multi-mode contributions, velocity-dependent effects, randomness of the input, etc.Although many traditional performance-based codes and guidelines describe methods for performing RHA, it must be noted that most of these documents contain rules that were developed in the 80s and were intended for performing analyses of structures with nonlinearseismic isolation and energy dissipation devices [8], with less evidence from application to structures with NL behavior due to plastic hinging, buckling, or structural damage in general.

A crucial point for the selection of the method for NL RHA analysis is to identify the project's goals in terms of analysis, and the key Engineering Demand Parameters (EDP) representative of the structural response/behavior.

This choice is reflected in the two types of approaches that can be found in traditional and more recent PBEE codes/guidelines:

- DESIGN approach: the analysis goal is to compute mean values of response (few GMs are needed, codes prescribe 7 or 3 GMs).
- FRAGILITY/RISK approach: the analysis goal is to compute mean and distribution of response and evaluate collapse probabilities. (Many more GMs are needed, normally 30+, or 11 if conditioning to an IM, less if particular spectra are used).

The Incremental Dynamic Analyses (IDA is a parametric extension of the NL RHA used to estimate performance under seismic loads subjecting a structural model to one (or more) GM records [27]. It consists in a sequence of Monte Carlo analyses, and performs an intensity sweep for each GM by scaling the records to an increasing reference IM until collapse occurs.

IDA has been proposed as 1) a dynamic protocol capable of describing the structural behavior over a number of intensity/response levels and ranges, (to capture the changing in the dynamic structural behavior increasing the seismic intensity, conceptually similar to static pushover), and 2) a probabilistic analysis protocol that incorporates the randomness inherent to the detail of the GM input record, and the randomness in the seismic hazard intensity, through scaling/conditioning the GMs to an appropriate Intensity Measures (IM). Usual choices for IM have been the PGA and the spectral acceleration at the fundamental period $S_a(T_1)$.

IDA can be used for different types of assessment, depending on what kind of information is sought, whether the interest is on structural performance and component checks, or on fragility and decision-oriented information. It may be useful to note that in some cases, the inherent computational burden of performing a large number of Monte Carlo simulation runs, which can be typical of IDA, can be overcome by running parallel parametric probabilistic simulations of a same FEM model, [28]. This approach is feasible with FEM software with capabilities to run relatively simple models on parallel supercomputers [29].

2.1 GMs SELECTION

The first step to perform NL RHA or IDA is the selection of appropriate sets of GMs. The NIST guidelines [8] present a comprehensive overview of codes provisions for NL RHA and provide guidance on methods for selection/modification of input GMs.

2.2 ASCE/SEI 7-05

Rules for selecting and scaling GMs provided by ASCE/SEI 7-05(§16.1.3) [1] can be summarized as follows:

- A GM shall consist of a horizontal acceleration history, selected from an actual recorded event having magnitudes, fault distance, and source mechanisms that are consistent with those that control the maximum considered earthquake.
- The GMs shall be scaled such that the average value of the 5 percent damped response spectra for the suite of motions is not less than the design response spectrum for the site for periods ranging from 0.2T to 1.5T where T is the fundamental period of the structure in the fundamental mode for the direction of response being analyzed
- For 3D analysis GMs shall consist of pairs of appropriate horizontal ground motions components.

- For each pair of horizontal GM components, a square root of the sum of the squares (SRSS) spectrum shall be constructed by taking the SRSS of the 5% damped response spectra for the scaled components (where an identical scale factor is applied to both components of a pair). Each pair of motions shall bescaled such that for a period between 0.2T and 1.5T, the average of the SRSSspectra from all horizontal component pairs does not fall below 1.3 times thecorresponding ordinate of the design response spectrum by more than 10 percent.
- If 3sets (or more) of GMs are selected, the component checking must be done with the maximum values that come from the analysis.
- If 7 sets (or more) of GMs are selected, the component checking must be done using the average values that come from the analysis.

It must be noted that the SRSS method for spectrum matching has no solid technical basis, and the use of Geomean Spectrum is suggested by NIST for spectrum matching [8]. These guidelines point out clearly that the use of a certain number of sets of GMs (in this case 3 or seven are suggested) has no sound technical basis too. As mentioned above, these rules were developed mostly in the 80s in the context of NL RHA of structures with nonlinear base isolation and energy dissipation devices. The correct number of GMs needed depends on many factors such as the goodness of fit of the scaled motion to the target spectral shape, the expecteddispersion in the response, the required degree of confidence, and the required level of accuracy. Some formulations are available which permit to estimate the correct number of GMs needed independentonthe spectral shape [30]. In general more than seven GMs are needed to obtain a reliable and accurate evaluation of the mean response and, as a consequence many tens of GMs are needed to obtain correct evaluations of the dispersions.

2.3 ASCE/SEI 7-10

Rules defined in ASCE/SEI 7-10 [31] are similar to those defined in ASCE/SEI 7-05, the main difference being that the design spectrum definition is done using the maximum rotated component spectrum instead of the geomean spectrum, and so the SRSS method for spectrum matching of 3D components should be preferred to have more reliable results.

2.4 FERC 2007

The US Federal Energy Regulatory Commission drafted the Seismic Design Guidelines andData Submittal Requirements for LNG Facilities (FERC, [32]), whichidentify the performance criteria to be met for this type of structures and refer to ASCE/SEI 7-05 for the procedures for GMs selection.

2.5 Eurocode8 (buildings)

UNI EN 1998-1defines the methods for representing the seismic action through GMs in §3.2.3.1 and prescribes that:

- Recorded GMs may be used, provided that thesamples used are adequately qualified with regard to the seismogenic features of thesources and to the soil conditions appropriate to the site, and their values are scaled tothe value of a_g*S for the zone under consideration.
- A minimum of 3 GMs should be used.
- The mean of the zero period spectral response acceleration values (calculated from singleGMs) should not be smaller than the value of a_g*S for the site inquestion.
- In the range of periods between $0,2T_1$ and $2T_1$, where T_1 is the fundamental period of

the structure in the direction where the GM will be applied; no value of themean 5% damping elastic spectrum, calculated from all time histories, should be lessthan 90% of the corresponding value of the 5% damping elastic response spectrum.

In §4.3.3.4.3 EC8 defines the required number of GMs:

- If the response is obtained from at least 7 nonlinear time-history analyses with GMs in accordance with 3.2.3.1, the average of the response quantities fromall of these analyses should be used as the design value of the action effect E_d in therelevant verifications of 4.4.2.2. Otherwise, the most unfavorable value of the responsequantity among the analyses should be used as E_d.

2.6 Eurocode8 part 4 (silos, tanks, pipelines)

For the definition of the seismic action UNI EN 1998-4 refers to UNI EN 1998-1.

2.7 Eurocode8 part 6 (towers, pile, chimneys)

For the definition of the seismic action the UNI EN 1998-6 in §3.4 refers to UNI EN 1998-1 in general and allow the use of rotational components of ground motion. These provisions also suggest paying specific attention to the long period components of the time-histories which affect in a critical way the response of this type of structures.

2.8 FEMA P-58 (Next generation PBEE methodology. Buildings)

As noted above the prescriptions of FEMA P-58 could apply to industrial structures in those particular cases where the structural type is similar to buildings. The same hazard and analysis modules would apply in this case, however the exposure and loss modules would have to be made consistent to the particular case studies. We already discussed how exposure and risk/loss are beyond the scopes of PROINDUSTRY. As far as the NL RHA and IDA analysis module is concerned, the FEMA P-58 guidelines are in agreement with the NIST 2011 guidelines.

FEMA P-58 dedicates the entire third chapter to the definition of the seismic hazard, and to themethodsfor selection and scaling of GMs, with the following recommendations:

- Three different kind of spectrum are defined: UHS (Uniform Hazard spectrum), CMS (Conditional Mean Spectrum), and CS (Conditional Spectrum).
- Regardless of the type of selected spectrum, the selected ground motions must match (without specific limitation), on average, the selected spectrum over the period range T_{min} to T_{max}, where $T_{max}$is taken as twice the period of the fundamental translational mode (the larger of T_x, T_y if a 3D analysis is performed) and T_{min} is taken as 0.2 times the fundamental period (the smaller of T_x, T_y if a 3D analysis is performed).
- Selected records should have faulting mechanisms, earthquake magnitudes, site-to source distances, and local geology that are similar to those thatdominate the seismic hazard at the particular intensity level.
- At least 7 pairs of GMs should be used, but when fit with spectral shape is poor eleven or more pairs of motions are needed to correctly capture the median response.

3 POSSIBLE APPROACHES

Inthe scientific literature and in building codes it is difficult to identify a general ruleNL RHA and IDA method, and the protocols are strictly dependent upon what is the goal of the analysis, in terms of what is the type of assessment sought, and in terms ofwhat are the critical mechanisms and the relevant Engineering Demand Parameters (EDPs) and response indicators (drift-governed structural damage, force-controlled mechanisms, floor acceleration-

governed component vibrations, anticipated relevance of higher modes, etc.), and what is the level of confidence requested.

Based on the building codes and guidelinesalready described, three different approaches for selecting and scaling GMs are analyzed. For each approach advantages and disadvantage are discussed, with respect tothe specific goals and challenges of the PROINDUSTRY project, and of the specific case-study structures.

In general, the possible methods comprise the following steps:

1) Definition of facilities and locations;
2) Identification of the analysis needs;
3) Identification of the Ground Motions Intensity Measure (PGA or IM=$S_a(T^*)$, etc.) for a specific Hazard Level (HL);
4) Development of the Probabilistic Seismic Hazard Analysis (PSHA) in terms of IM, (Attention to how the local PSHA is derived, one horizontal component, maximum, or geomean, etc.);
5) Definition of the Target Spectrum (UHS, CMS, or CS);
6) *Selecting horizontal GMs for coherence/scaling to the target spectrum*;

The three approaches suggested herein differ in how point 6) is developed, based on which of different kinds of target spectra and on the use of scaled vs. unscaled GMs.

The criteria to perform the spectrum matching are similar in most guidelines/codes, and require that the average spectrum of the set does not differ from the reference spectrum with a tolerance of +30% / -10%. The period range where it is necessary to ensure this tolerance is between $0.2T^*$(to account for higher modes) and $2T^*$(to consider inelastic response with relative loss in stiffness and shift of period, as per UNI EN 1998-1). If the structurehas identifiablemodes associated with translational response along two orthogonal axes, X and Y, the corresponding fundamental translational periods associated witheach axis are denoted with T^*_X andT^*_Y, respectively. The reference period T^* to use for spectrum matching/anchoring can be the mean of the two periods T^*_X andT^*_Y. For the particular case of this project, and due to the difficulty of defining a reference period, it would be desirable to enlarge the period range used for coherence as much as possible.

Table 1. NL RHA and IDA GM selection/scaling approaches as per ASCE-7, NIST 2011, FEMA P-58.

APPROACH	Reference Spectrum	Scaling	Goal(s)	Coherence	GMs
1. UHS, Unscaled	Uniform Hazard Spectrum (UHS) Design Spectrum (DS)	Unscaled	Median	Y	**7+**
			Median and STD	Y	30+
2. UHS, Scaled	Uniform Hazard Spectrum (UHS) Design Spectrum (DS)	Scaled to IM=$S_a(T^*)$	Median and STD	Y	7+
				N	11+
3. CMS, Scaled	Conditional Mean Spectrum (CMS)	Scaled to IM=$S_a(T^*)$	Median	Y	7+
			Confidence on median	Y	<11

With reference to spectral matching and scaling, specific attention deserves the choice of the directional GM components. A common method suggested by several guidelines (FEMA P-58) performs the spectrum matching or in general the coherence assessment based on the geomean of the X and Y components. Other reference codes, in particular building codes provisions, may consider the two components separately, their maximum or a different combination, such as the SRSS. The consistency of the methods is strictly related to the hazard definition, whether the reference spectra and the underlying PSHA are derived based on the geomean, or on a single GM component. The consistency should be checked on a case-by-case basis, particularly for those case study structures where the directional effect can be significant due to different behavior in two orthogonal directions.The three candidate approaches for the WP2 of the PROINDUSTRY project are summarized in Table 1, in terms of number of GMs needed, of scaling/unscaling criterion, of spectral coherence, and goal in statistic confidence.

3.1 APPROACH 1 (UHS-coherent Unscaled GMs, Design).

IDA with unscaled GMs, consistent with a design spectrum (UHS), referred to PGA of HL.

The first approach is a 'design' approach, in line with 1st generation PBEE codes/guidelines. It is based on unscaled recorded GMs coherent with the UHS or with the Design Spectrum. In this method the PGA is used as reference IM, therefore the definition of the input is independent on the structure.

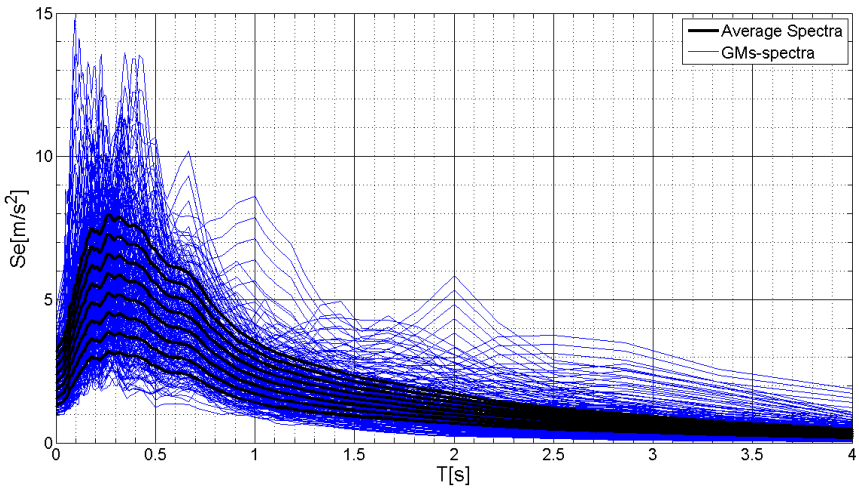

Figure 2.Example of relatively unscaledGMs sets, uniformintensity-scalingto different HLs based on PGA.

Unscaled natural GMs will have a fairly uniform dispersion of spectral ordinates over the range of periods of interest. This type of input is not specific to a particular structure or behavior and is intended to give the same importance to first mode, higher modes, and period-elongated/damaged fundamental modes. This will be reflected in the estimates of the different response parameters (drifts, accelerations, etc.). As a consequence of this dispersion, a greater number of GMs will be required to capture the median response and dispersion, normally 7+ GMs to capture the median, and 30+ GMs to capture a distribution. Given the design/check-oriented objectives of PROINDUSTRY, the suggested number of GMs is 11.

3.2 APPROACH 2 (UHS-coherent GMs scaled to $S_a(T_1)$).

IDA with scaled GMs conditioning/anchoring to Sa(T_1) of HL on the UHS.

This approach uses as reference IM the spectral acceleration at a defined conditioning period IM=$S_a(T^*)$. Usually, for structures that are 1st mode dominated $S_a(T_1)$ is a good predictor of the response, and is well correlated with nonlinear response at increasing intensity levels. However, in general T^* could differ from the 1st mode period and should be selected on a case-by-case basis as the period whose spectral ordinate more influences the EDP that governs the seismic behavior and the design/assessment process.

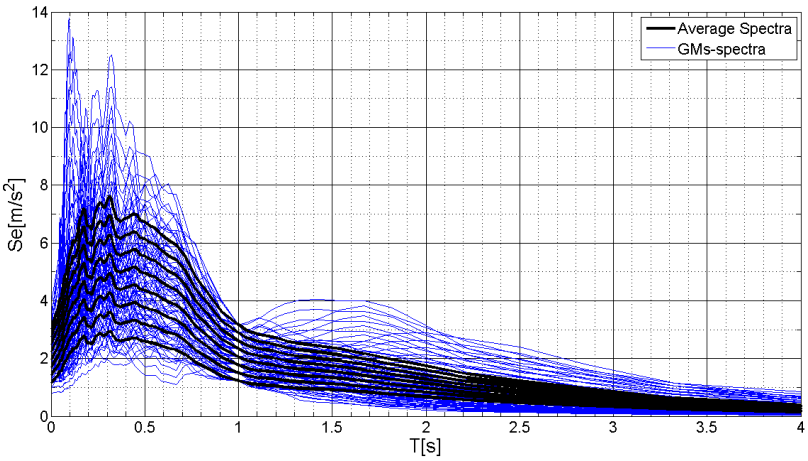

Figure 3. Example of GMs sets with different intensity, scaled to $S_a(T^*)$ values.

Scaling/anchoring the GMs to a given IM allows obtaining sets with less variability around the selected spectral ordinate, resulting in a reduced number of GMs needed to capture the distribution of the response. On the other hand, scaling to a specific IM can result in overly inflated ordinates and increased dispersion at other frequencies (Figure 3). For this reason this method could introduce inconsistencies if the analyzed structures and the selected response parameters are not well correlated to $S_a(T^*)$, since this IM can be not sufficient nor efficient [34] for many structures. For the PROINDUSTRY case studies, and in particular for those sensitive to acceleration spectra [35], [36], this method could result in too conservative and not realistic IDA estimates of forces as well as of displacements/damage.

3.3 APPROACH 3 (CMS-coherent GMs scaled to Sa(T1)).

IDA with scaled GMs conditioning/anchoring to $S_a(T_1)$ of HL on the CMS.

Recent studies proposed the so-called Conditional Mean Spectrum (CMS), [16], to overcome the limitationsof UHS.In a single event it is very unlikely that the spectral ordinates of the UHS are observed at all periods, especially for rare events and so coherence of GMs with UHS is not realistic. The CMS refers to a scenario event for a given HL and conditioning period T^* based on disaggregation data (M, R); the spectral ordinate at this period is maximized (through the parameter ε) and should reach the value given by the UHS for the HL selected. The spectral ordinates at other periods are then related to the $S_a(T^*)$ through conditional probability and correlation factors, and their values are less than those of the UHS. In this way it is possible to reduce the seismic demand for periods away from the conditioning period (reduc-

ing overestimates of high-mode response for example) while retaining consistency with the seismic hazard derivation in terms of a primary IM at a given HL.

The CMS provides the expected (mean) response spectrum, conditioned on occurrence of a target spectral acceleration value at the period of interest. This is a better tool for GMs selection because it is very unlikelyfor a single event to containall the spectral ordinates with the same probability of exceedance. It is more realistic to correlate the different spectral ordinates through conditional probability. The limitations of this method are similar to those of for the approach n.2, and are due to the definition of a specific spectral ordinate for scaling. In addition, computing the CMS could be difficult due to limited disaggregation data for Europe [37], and due to the multi-modal hazard scenarios in most cases, [16], particularly for the sites where the case-study facilities are located.

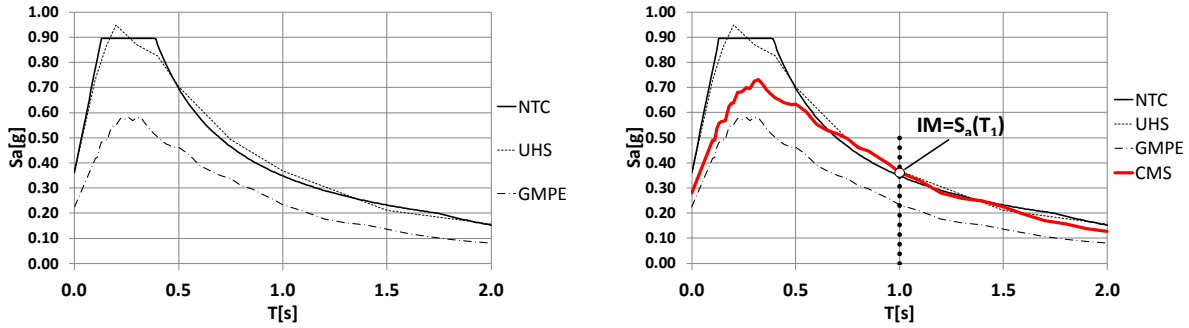

Figure 4.Reggio Calabria site, (a) determination of the median Spectrumusing M, R values, (b)determination of the CMS.

4 CONCLUSIONS AND RECOMMENDATIONS

The three methods illustrated herein can produce different results. It is therefore necessary to identify a reference method that would lead to consistent results for the different project case studies. It is also desirable to compare analysis results among partners working on different case studies. As requested by the project, in order to achieve the worst damage scenarios with a robust and reliable procedure, the first method suggested should be preferred.

The approach n.1 is based on unscaled GMs and is consistent with 1st gen. PBEE design/assessment. This would decouple the definition of the action from the evaluation of the response, and render the seismic input not strictly structure-specific. A major drawback of using unscaled GMs is that a higher number of records need to be used.The project focus is on the assessment of the structural behavior [38] and on proposing retrofit solutions [39], and the interest is on capturing the mean response. To achieve this goal at least 7 GMs are needed but, considered the high variation of the selected GMs (Approach n.1) a higher number of GMs is to be preferred, at least 11 GMs. The results will be processed in terms of best estimates and where necessary also in terms of distribution. This would allow, in a subsequent phase, to compare results and performance assessment based on 2nd gen. risk-based PBEE approaches, by introducing scaling criteria to key IMs, and perform more accurate probabilistic analyses, as well as loss-based comparisons of retrofit solutions [40], [41], 0.

Keywords: Industrial Plants, Performance based assessment, Incremental Dynamic Analyses, Retrofit, Friction Isolators.

Abstract. Recent seismic events pointed out the high vulnerability of existing industrial facilities, stressing on safety and high losses inherent to interruption of economic activities and release of environmentally hazardous materials. These structures often have irregular geometry and structural configuration, are subject to aging and corrosion, and are designed without specific performance-based or seismic design criteria. Due to these inherent complexities, retrofit using friction isolators can be a viable and practical solution for performance improvements. This work presents a case study of irregular industrial storage plant structure consisting of a group of six elevated silos resting on a steel frame on one side and connected to a vaulted RC structure on the other. A computational model is built incorporating nonlinearities from the components (braces, beams, columns, etc.) and from the mitigation devices. Retrofit using friction isolators is analyzed and evaluated through linear and nonlinear dynamic analyses under a set of natural ground motions. Results show the effectiveness of the mitigation strategy in terms of performance improvement.

1 INTRODUCTION

Recent seismic events (Bam 2003, Chile 2010, Fukushima 2011, Emilia 2012, etc.) [1–4] pointed out the high vulnerability of industrial plants both in life threatening, economical losses and environmental contamination terms. Damages were observed both in structural and non-structural components such as mechanical equipment, piping systems and storage racks. The consequences of such damages ranged from the complete collapse of the structure to interruption of the activities, including the triggering of fires and the release of hazardous content.
Within the framework of the Seismic PROtection of INDUSTRial plants by enhanced steel based sYstems (PROINDUSTRY) project, a group of case studies has been selected. Each case study is representative of a particular category of structures, depending on the geometry, the activity of the plant and the type of material processed. This paper presents a retrofit solution of a storage structure consisting of a group of elevated silos containing sodium percarbonate.
The main cause of damage observed on elevated steel silos during earthquakes lies in the failure of the support structure, which generally results in the collapse of the structure [6]. The shell structure of the silo can be considered safe since the acceleration needed to cause buckling phenomena of the wall is generally several times higher than the one causing damage to the substructure or the anchorage [6– 8].
The retrofit solution proposed for the structure object of this study focuses on the reduction of the action transmitted to the substructure.

2 CASE STUDY STRUCTURE

The case study industrial structure consists of a group of six elevated silos supported by a steel structure and connected on one side to a concrete vaulted industrial building. The silos, located approximately 7m above ground, have a cylindrical shape with a diameter of 3.1m, a height of 6.77m and a wall thickness of 5mm. The content is sodium percarbonate, a typical product used in the cleaning industry, characterized by a weight per unit volume of 1200kg/m^3. A single silo can contain up to 16.3m^3 of material. The silos rest on a steel structure composed of a deck and two slender columns. The two columns are HEA360 profiles with an S235 steel grade. The deck is composed a series of main beams realized through HSU profiles, several secondary beams (IPE profiles) with the function of transferring the weight of the silos to the main beams and two horizontal bracing systems, located at the top and at the bottom of the HSU profiles, mainly composed of L or double L profiles. The connection to the RC structure is made via two spherical hinges. The concrete structure is composed of four hollow pillars with a dimension of 1400x900mm and a central hole of 800x300mm and a 30mm thick vault anchored to the pillars at a height of 6m and with a maximum rise of 2.5m.

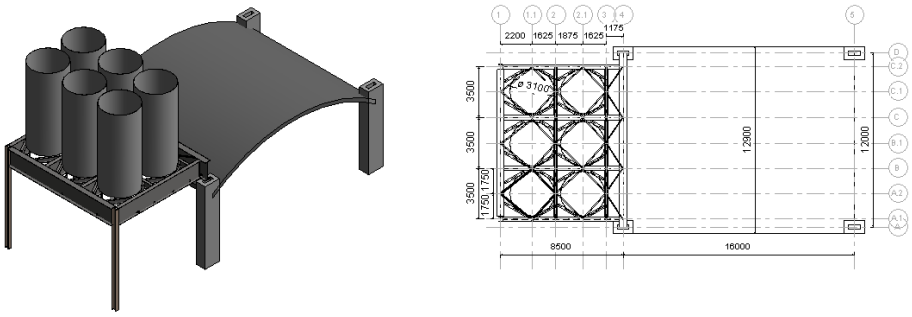

Figure 1: Case study silos structure 3D and plan view.

The actual performance was established through an assessment study of the structure. A preliminary analysis on the components has shown how a traditional or simplified model may lead

to large errors. In particular the attention was focused on the main beams, the silos and the RC vault. On the first two components the comparison has been carried out between a frame and a shell model. The last one was investigated in terms of actions transmitted to the steel structure and of stiffness. Comparisons are reported in Figure 2. The numerical model was built using SAP2000. The main beams have been modeled through linear elastic shell elements with connection only on the web. The secondary beams have been modeled as frame elements with fiber plastic hinges while the braces have been modeled using multi-linear plastic links incorporating a phenomenological model for their buckling hysteresis cycle. The steel columns are modeled with frame elements and fiber plastic hinges. The concrete structure is linear elastic; the pillars are modeled with frame elements while the vault is made with shell elements. The foundations blocks are modeled with rigid shell elements to simulate the soil-structure interaction with linear springs. The silos are modelled through elastic shell elements with distributed mass so to correctly account for their deformability.

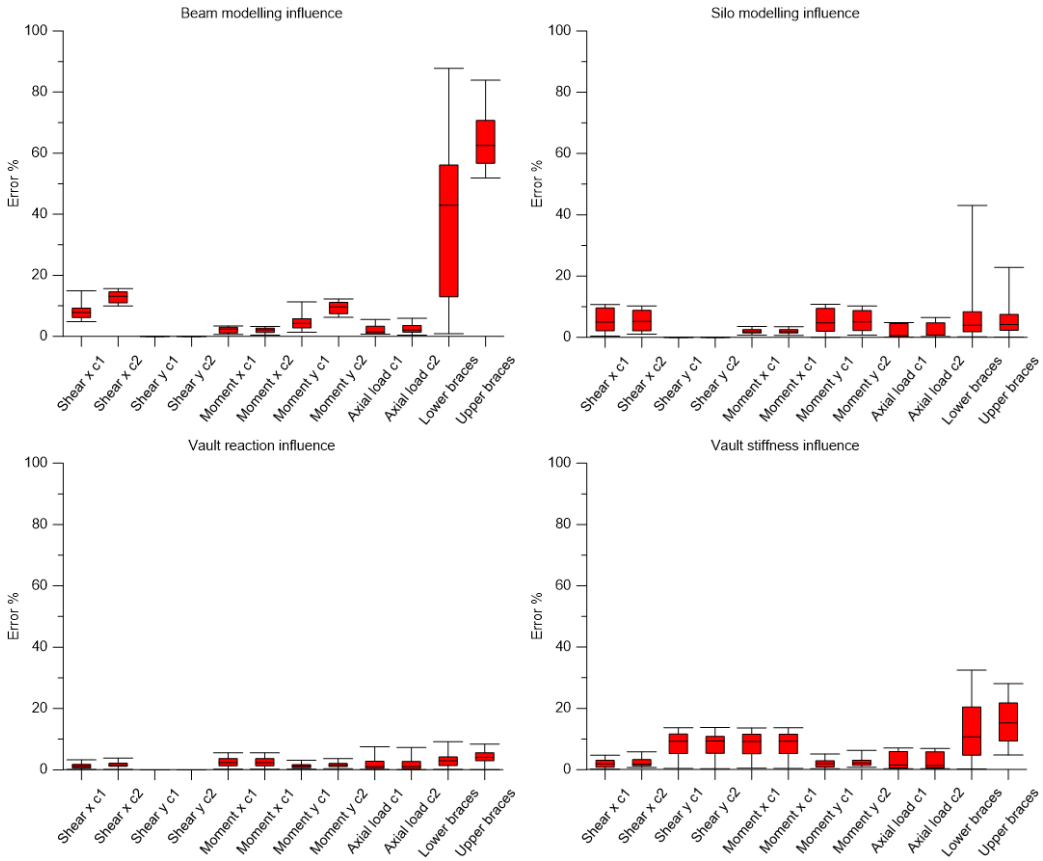

Figure 2: Influence of the different models in the numerical response of the structure.

Static and dynamic analyses, which considered the variability of the action through through a suite of earthquake records [9], were used to establish the main damage causes, which were due to a fragile failure of the steel columns, caused by buckling effects, resulting in a complete collapse of the system. The silos remained fully elastic, consistent with observation found in the literature [6–8]. The braces suffered extensive yielding without however triggering any brittle behavior. The consequences of the damage were mainly economic (collapse of part of the plant, interruption of activities, loss of content) and environmental (dispersion of polluting material). As a reference performance objective for the retrofit solution, prescription of the Eurocodes were adopted [10]. It is worth noting that different performances were evaluated using

nonlinear static and response spectrum dynamic analyses, as it is reported in Figure 3. Although the pushover curve shows a qualitative representation of the behavior under horizontal forces, it fails to correctly estimate the actual performance of the structure since it does not take into account the vertical component. Vertical actions in combination with relative high displacements due to a torsional behavior, produce a collapse mechanism governed by buckling in the column, which can correctly be detected only using nonlinear dynamic analysis.

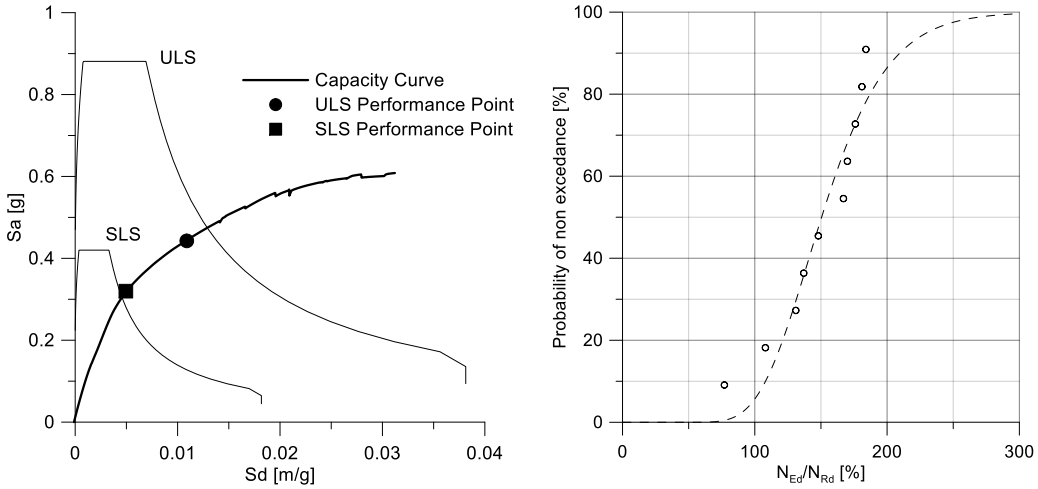

Figure 3: Structure assessment using nonlinear static analysis (left) and response spectrum dynamic analysis (right).

3 NONLINEAR ANALYSES AND RETROFIT

The retrofit solution chosen consists of isolation of the main mass (i.e. the silos) of the system. Curved surface sliders have been introduced between the vertical elements (pillars and columns) and the deck, thus limiting the horizontal action transmitted to the substructure and decoupling the behavior of the system. The steel columns have been connected to the pillars introducing three beams positioned below the isolation plane. The substructure in this configuration was, however, too flexible, thus reducing the effectiveness of the isolation solution (Figure 4). A vertical bracing has been introduced between the two steel columns in order to stiffen the substructure, which has been considered to remain elastic and thus has been modeled with linear elastic truss elements. The friction devices have been modeled with nonlinear link elements with parameters reported in Table 1.

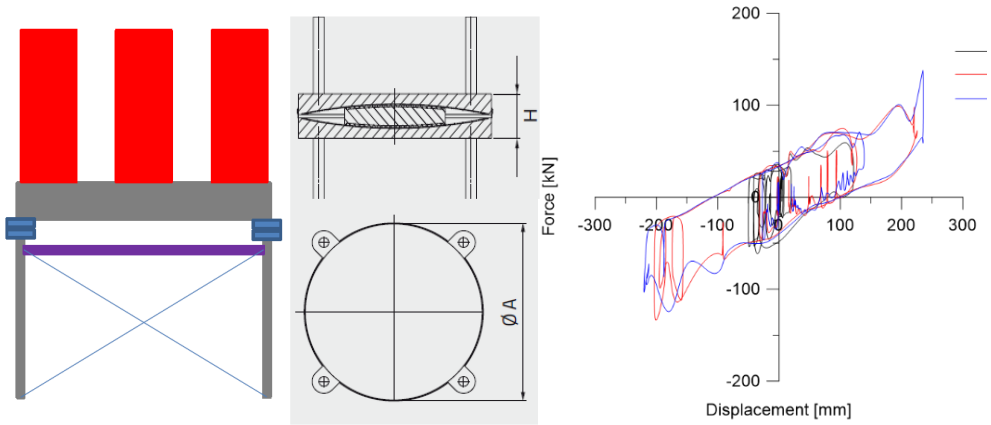

Figure 4: Retrofit scheme: Isolation and bracing of the substructure.

R	3000mm
d_{max}	350mm
N_{Ed}	1000kN
A	580mm
H	135mm

Table 1: Friction Isolator Device parameters.

The seismic action has been modeled with a set of unscaled Ground Motions (Figure 5) [9] and various scale factors calculated dividing the probabilistic hazard curve in regular steps. The hazard curve has been calculated from the hazard definition of the Italian Code NTC08 [11-12]. The resulting limit states however were different from Eurocodes prescriptions, for this reason other two scale factors were introduced: 0.86, corresponding to an Ultimate Limit State with an importance factor of 1.2, and 0.41, corresponding to a Serviceability Limit State with an importance factor of 1.2 (Figure 5) [10].

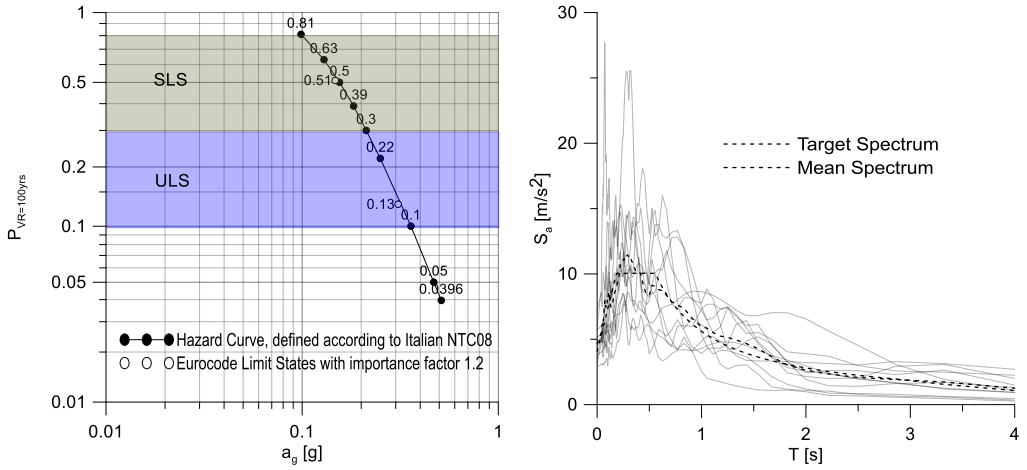

Figure 5: Action definition. Left: Probabilistic Hazard Curve. Right: Ground Motions spectra matching to the target spectrum.

The linear analyses were done using the response spectra of the set of selected ground motions. CQC was used as modal combination and CQC3 as directional combination.
Since the only source of nonlinearities, in the retrofitted structure, were the links used to model the isolation devices it has been possible to perform Fast Nonlinear which were more computationally efficient than Direct Integration method (D.I.) both in terms of time and accuracy of results, due to the issue of damping leakage [13]. Results of the modal analysis show how the introduction of the isolation devices just below the deck is effective in decoupling the structure response. Figure 6 clearly shows the differences in the modal response of the structure before and after the retrofit intervention and how the retrofit solution strongly reduces the torsional behavior of the structure. The increment in period can be found in Table 2

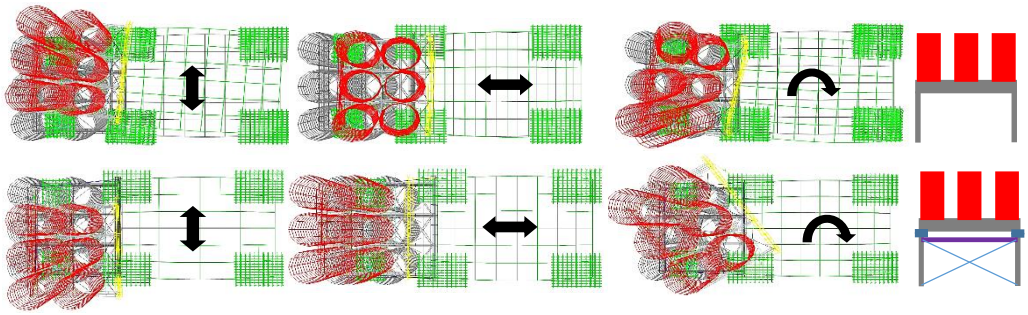

Figure 6: Comparison of the behavior of the structure at ULS.

Existing		Isolated	
Period [s]	Mass	Period [s]	Mass
0.87	74%	3.02	60%
0.65	81%	3.07	60%
0.37	35%	1.61	12%

Table 2: Modal Periods and Masses.

Results of the non-linear dynamic analyses presented in Figure 7 show the improvement of the structural behavior after the introduction of the isolation devices. In particular in the pre-retrofit situation, the structure exhibited a critical behavior, due to the collapse of the columns for buckling phenomena, triggering a complete collapse of the structure. The introduction of the isolation devices proves to be an effective strategy since, due to the reduction of the displacement of the substructure, the vulnerability of the steel columns is greatly reduced, both in terms of critical load and moment at the base, especially in the y direction.

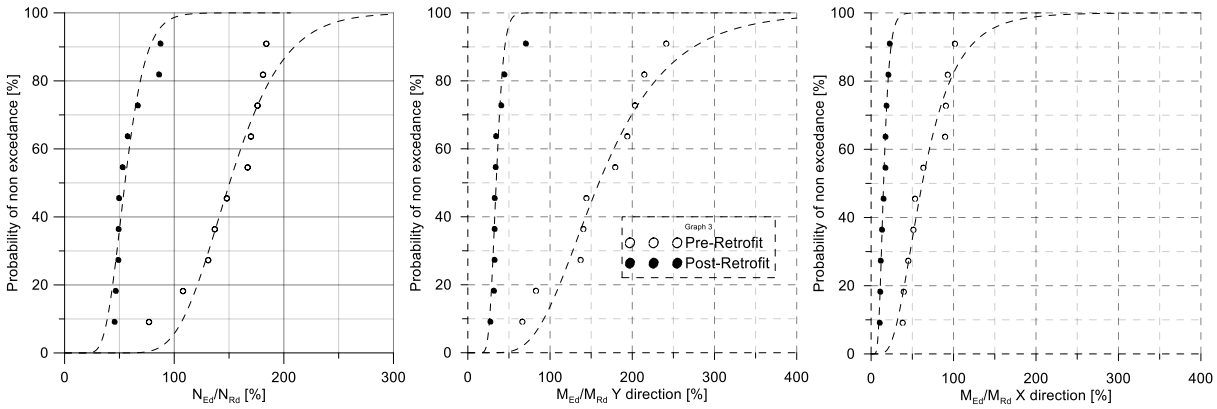

Figure 7: Comparison of the behavior of the structure at ULS.

4 CONCLUSIONS

Performance based assessment of an existing steel silo structure was carried out through linear, nonlinear static and incremental dynamic analyses, both in the existing and retrofit solution using sliding devices. Results have shown that:

- The complex geometry of most industrial structures needs a thorough study of the single components. Using traditional models may lead to important errors in describing correctly the behavior of the system;
- Static nonlinear analyses neglect the effect of the vertical component and may thus lead to inaccurate results;

- The use of isolation devices regularizes the structure behavior, eliminating the torsional effects;
- The use of Direct Integration nonlinear dynamic analyses on very deformable or isolated structures, due to damping leakage phenomena, can cause a strong reduction of the displacement, thus providing nonrealistic results as compared to Fast Nonlinear Analyses;
- Placing the isolation plane just below the stock units, and thus just below the main mass, can significantly increase the performance of the sub structure, both in terms of reduction of the horizontal component and in the protection against buckling phenomena induced by the vertical component;
- The strong reduction of the stiffness of the superstructure enables the designer to have a wider range of choices in terms of stiffening the substructure, being thus able to find an optimum solution, which can take into consideration the processing activities.

Keywords: Seismic Risk Mitigation; Existing RC buildings; Fragility Curves; Structural Performance; Damage Levels.

Abstract. *In recent years, many studies were been carried out in order to understanding and later mitigate the seismic risk. Several important projects have been funded, different methodologies have been developed; in particular, for emergencies management several application have been carried out with good results. On the contrary, mitigation and prevention of seismic risk could be more efficient by setting a careful assessment, maintenance and retrofitting of the built. In this sense, it to be noted that the seismic capacities of existing RC buildings have shown a key role in recent seismic events (e.g. Southern Italy 1980, Turkey 1999, L'Aquila 2009, Lorca, 2011, Emilia plan 2012). In particular, old RC buildings have often shown a poor and brittle behavior. Moreover, the low seismic performances of these buildings are the main reason of significant earthquake losses (in terms of economic, social and political activities) that can been considered generally as a direct consequence of physical damages on the buildings. About these important topics, it is the opinion of the authors, that quantitative models of fragility, referring to the most common types of buildings, have a key role in the evaluation process of risk and should been continuously improved. Therefore, in the seismic risk studies, a fundamental step is the development and use of fragility curves representative of the behavior of existing RC buildings. A significant number of proposals are currently available in the scientific literature. In this study, a critical review of existing different procedures for RC with Moment Resisting Frames (MRF) has carried out in order to highlight advantages and weakness of each proposal. A great variability in terms of geometrical, mechanical and structural characterization, structural modeling, method of analysis, scale of damage, parameters of seismic intensity and statistical procedure has been highlighted, and finally an optimal procedure of fragility analysis has been outlined.*

1 INTRODUCTION

Recent European earthquakes have shown that the economic loss and urban resilience are closely related to the seismic performance of existing buildings, designed without seismic criteria or with old codes, that showed an unsatisfactory behavior [1]. For this reason, in order to mitigate the seismic risk and increase resilience in urban areas, reduction strategies risk should be developed.

In seismic risk mitigation polices, with regard to the most common types of existing buildings the quantitative fragility models have a key role. Exist different approaches for the construction of fragility models: analytical approaches, empirical approaches, approaches based on expert opinion and hybrid method. In this paper, only analytical methods have been considered; they are based on damage distributions simulated from the numerical analyses. Due to the importance of the topic, a significant number of studies were developed and published in the last years. In first part of the paper, a short critical review of different methods and procedures has been performed. In this way, the difference due to choices about analysis method, idealization, seismic hazard, and the damage model, have been highlighted. In particular, following a careful literature review, six studies have been selected, with the same analysis object and purpose. In fact, the selected seismic risk studies , have investigated the existing Reinforced Concrete (RC) with Moment Resisting Frame (MRF). These typologies represent the highest percentage of building stock in several European areas with high seismicity, and they have similar properties.

For each study the main advantages and weakness have been pointed out. Then, the paper focuses on the importance of an adequate damage model; damage model should be able to take in to account the different damage state, as structural and non structural damage. The main topics of different damage models considered have been highlighted.

2 CRITICAL REVIEW OF METHODS

A wide literature review have been carried and six studies have been selected; they are focused on the construction of fragility curves and resulting FCs have been defined for similar structural typologies of existing Reinforced Concrete with Moment Resisting Frame structures (RC-MRF).

The selected studies are following listed and in the following they will be called with relative acronym: Masi et Vona 2012 [2] (MV12), Vona 2014 [3] (V14), Kyriakides et al. 2015 [4] (K15), Polese et al. 2008 [5] (P08), Erberik 2008 [6] (E08) and Silva et al. 2014 [7] (S14). In this studies, different methodologies have been defined in order to obtain fragility curves. In table 1 are reported the main characteristics of each study.

Several main steps can be identified in all studies:

- Selection of the structural types most vulnerable and widespread in region under examination;
- Geometrical, structural and mechanical characterization of selected structural class;
- Generation of adequate sample of structural models able to represent the real geometrical, structural and mechanical variability;
- Selection of ground motion;
- Structural modeling and evaluation of the seismic response;
- Definition of damage model;
- Construction of fragility curves.

In each step, a probabilistic approach should be used, because a high degree of uncertainty involved each of them. The structural models for numerical simulation should be able to rep-

resent the real probabilistic variability (for example material and geometric-structural, properties of structural, ect).

In several cases, it is excessive consider probabilistic some topics, especially when their variation is negligible, and not affect substantially the structural behavior. Farther, a probabilistic approach requires an accurate and extensive investigation in order to obtain reliable probability distributions. Actually, the highest computational power and the available numerical method allow a significant diffusion of the probabilistic approaches.

	Framework	V14	K15	P08	E08	S14

Table 1: Main characteristics of frameworks selected.

In any cases, the trivial uses of probabilistic approaches carry out to unnecessary or incorrect choice about structural models or unrepresentative characteristics (for example, for beam length and column depth). Therefore, several simplified approaches (for example MV12/V14/E08) that consider any probabilistic variables as deterministic are more reliable. In other words, RC-MRF structural models are able to reproduce the behavior of real buildings also choices several deterministic values. For example, in MV12, V14 and E08, the role of infill masonry walls have been considered; they have been investigated with deterministic approach.

Generally, reliable FCs should be defined on the based of more accurate NonLinear Dynamic Analyses result (as in MV12, V14, K15, S14). On the contrary, FCs based on NonLinear Static Analyses (P08/S14) could be less able to simulate the real behavior of buildings. In E08, FCs have been defined on NLDAs; nevertheless the global response of buildings have been investigated using SDOF equivalent analytical models that have been characterized from structural non linear static analysis.

The seismic input plays a key role in FS definition. In order to obtained a realistic evaluation of structural performance, the accelerograms recorded during real earthquakes should be considered further less appropriate synthetic events. In V14, S14, E08 natural accelerograms extracted from different data-base have been used; in K15, time-history have been derived from response spectrum; finally, in P08, EC8 [10] spectrum has been used.

Equally relevant, the seismic intensity should be able to represent the damage potential of ground motion. Integral seismic parameters, such as Arias Intensity I_A and Housner Intensity I_H seem more effective with regard to peak or spectral parameters [11].

2.1 Characterization of Damage Models

In FCs definition, the Damage Model plays a key role. Damage Model should be defined from limit states that define the thresholds between different damage conditions. The limit states should be able to take into account the structural e nonstructural damage and their evaluation. Further, for each limit state should be associate an analytical characterization using a Damage Measure.

The main distinction in terms of Damage Measure (DM) is local or global DM. The first is structural response parameters due to single structural members; the second is referred to whole structure. The choice of local or global DM is strongly linked with modeling and analysis methods choices. For example, if the equivalent SDOF are considered, the limit states cannot be defined in a detailed way (e.g. based on member behavior, local strains or hinge mechanisms, ecc). In these cases, the global DM will be defined in terms of simplified global parameters. In addition, for each limit state a qualitative description of non-structural e structural damage should be considered (for example, using a typical damage scale as EMS98 [8] or specific defined scale). In the tables 2-3-4, the damage models used in the investigated studies are reported.

Damage model (V14)			**Damage model (MV12)**
EMS98	**Damage Level**	**Limit condition**	**Limit condition**
0	SD=None; NSD=None	IDR ≤ 0,05%	IDR≤ 0,1%
1	SD=None; NSD=Weak	$R_y \leq 1$ and 0,05%<IDR≤0,1%	0,1% < IDR≤ 0,25%
2	SD=Low; NSD=Moderate	$0<R_p \leq 0,25$ or IDR>0,1% and $R_y \leq 1$	0,25% < IDR ≤ 0,5%
3	SD=Medium; NSD=Significant	$0,25< R_p \leq 0,75$	0,5% < IDR≤1%
4(5)	Near Collapse/Collapse	$0,75 < R_p \leq 1$	IDR>1%
SD=Structural Damage; NSD=NoStructural Damage $R_y=\phi/\phi_y$; $R_y=\phi-\phi_y/\phi_u-\phi_y$			

Table 2: Damage Model in V14 and MV12.

Near Collapse	$\theta_{column} = \theta_u$ and $V=V_R$
Building Collapse	all columns of floor reach L.S.3 or IDR=4%

Table 4: Damage Model in K15.

Generally, the interstorey drift is considered as Damage Measure. The interstorey drift is a good damage index for RC-MRC structures but reliable specific values should be defined. In this way, some results could be used: real test building during several earthquakes; laboratory experimental dynamic and pseudo-dynamic tests on models in scale or in full-scale; virtual experimental tests using numerical simulation.

Experimental calibration and validation of interstory drift limit is an hard work [9]. Generally, specific values should be defined in each studies and projects. In S14 and E08 each limit state has been defined through specific interstorey drift value; these values are corresponding to limit state in terms of base shear and roof displacement.

In order to verify the representativeness of these condition, these values have been compared with the interstory drift as defined in V14. The interstory drift limit values for each classes in according to E08 and S14 are reported in Table 5 and Table 6.

DM S14	IDR%(BF 2storey Pre71)	IDR%(IF 2storey Pre71)	IDR%(PF 2storey Pre71)
LS1	0,48	0,07	0,32
LS2	0,80	0,33	0,71
	IDR%(BF 4storey Pre71)	IDR%(IF 4storey Pre71)	IDR%(PF 4storey Pre71)

Damage Control LS	0,75	0,50	0,60
Prevention Collapse LS	0,94	0,67	0,77
	IDR% (BF 8storey Pre71)	IDR% (IF 8storey Pre71)	IDR% (PF 8storey Pre71)
Serviceability LS	0,53	0,15	0,22
Damage Control LS	1,19	0,70	0,66
Prevention Collapse LS	1,57	0,93	0,91

Table 6: Inter-story drift values for Limit States of DM E08

On the basis of the values reported in Table 5 and 6, it must highlighted that LS and LS2 is generally equal, except for structures high-rise types buildings. Generally, the limit LS3 is not able to represent the limit between extensive damage and structural collapse. The values reported in Table 5-6 have been compared with interstory drift (IDR) values defined from V14. In this work, the comparison between frameworks reported described in table 1 has been carried out in a graphic way (figures 1 - 6) for 2 storey Bare Frame Pre71 type buildings.

As main results, the global limit condition used by S14 and E08 are not consistent with local condition of V14; in particular, it to be highlighted that the base shear not are able to take into account the ductile capacity of the structures.

However, the Damage Model in E08 is able to bring into account the deformation capacity of structure; a better correspondence with the local limit condition (V14) is realizable considering the ultimate deformation, not the 75%.

The quantitative characterization of limit states must take into account of real capacities of structural class. In addition, if the definition of a single interstory drift value for each limit

states, of a certain sub-class, is reductive because an extreme variability was been found, and the probabilistic approach is more complex, an alternative is the approach used in V14.

In fact in V14 the Damage Model has been characterized for each limit states; on the basis on the NLDAs results, an accurate assessment of repair cost is possible.

3 CONSIDERATION AND IMPROVEMENT ABOUT THE GENERATION A FRAGILITY MODEL

The accuracy of the FCs and consequent seismic risk studies (economic loss, cost-effectiveness of repairing damage and seismic retrofit) are mainly linked to structural modeling and analysis, structural performance and Damage Model. Therefore, a different efforts are need to define these topics.

The critical review of different procedures, models, choices in the construction process for fragility curves definition is carried out. A great variability in terms of geometrical, mechanical and structural characterization, structural modeling, method of analysis, scale of damage, parameters of seismic intensity and statistical procedure has been highlighted, and finally an optimal procedure of fragility analysis has been outlined.

An optimal procedure of FCs construction must be based on numerical simulations performed through NLDAs; the seismic action must been modeled by natural accelerograms. The Damage Model must been defined considering a representative limit states; they should be able to describe the different damage conditions. At each limit state must been associated a clear description of structural and nonstructural damage.

Keywords: Dynamic identification, ambient vibration test, modal analysis.

Abstract. *The conservation of structures mainly relies on our ability to monitor their aging and to promptly detect relevant damage. Dynamic characterization is considered a powerful technique for testing the conservation status of buildings as their natural frequencies, damping and modal shapes are directly related to their stiffness and structural integrity. In this work a dynamic monitoring based on ambient vibrations measurements has been performed on a case-study, i.e. a RC 4-storey Hospital building. An identification procedure based on the Enhanced Frequency Domain Decomposition has been performed to evaluate the modal parameters of the building. The dynamic information provided by the experimental analysis have been compared to the one found by performing the analytical modal analysis. To this purpose a structural model has been built, by representing all the major geometrical and mechanical properties of the building, through the Seismostruct software. The comparison has pointed out the role of the non-structural component and of the interaction between the monitored structure and the adjacent buildings on the dynamic response of the case-study.*

…

1 INTRODUCTION

The seismic assessment of existing buildings can be performed by different alternative procedures. In all cases the dynamic properties of the building, i.e. the vibrational periods, the amount of damping and the waves propagation within the building, play a crucial role in the evaluation of its seismic response. In these years, the improvement of data acquisition and processing capabilities, has increased the diffusion of experimental campaign based on the dynamic monitoring of the buildings [1, 2].

Dynamic characterization is considered a powerful technique for testing the conservation status of structures as their natural frequency, damping ratio and modal shapes are directly related to their stiffness and integrity [3]. The dynamic monitoring of a sample building requires a wave propagation motion, and, consequently, an accelerations source. The acceleration sources consist in forced vibrations, weak earthquakes and ambient vibrations. The ambient vibrations have been extensively used in these last years [4, 5, 6, 7], since they are always available without requiring any specific effort. They are characterized by low intensities, and therefore the dynamic response of the monitored building can be investigated in the elastic range only. Furthermore, for RC buildings, such response can be even more rigid than the theoretical elastic one, since the cracking limit is hardly achieved [8].

In this work the dynamic monitoring based on ambient vibrations has been applied to an Hospital building located in Sansepolcro (Italy), with a medium seismic hazard (PGA equal to 0.227g for the Severe Damage, *SD*, limit state), i.e. the highest seismicity in Tuscany [9]. The building has been built before the current seismic legislation, so requiring a special attention in terms of seismic reliability, and it has been object of careful investigations. The building, 4 storey height, has rectangular shape and a framed RC structure. Two stations at each level, one at the foundation, and further three ones at the top of the three adjacent buildings have been adopted in the analysis, for a global number of 9 stations. The location of the stations at each storey has been carefully evaluated, in order collect meaningful data, and to check the possible interaction between the examined structure and the next ones. The recording phase had a duration of about 20 hours; the long time recording interval has allowed to check the stability of the vibrations and to get robust average values of the frequency response. An automatic identification procedure via Enhanced Frequency Domain Decomposition (EFDD) [10, 11, 12] has been used to evaluate the modal parameters and to remove any user interaction.

The dynamic information provided by the experimental monitoring analysis have been compared to the one found by performing an analytical analysis. To this purpose a structural model has been built, by representing all the major geometrical and mechanical properties of the building, by using the Seismostruct [13] software. A modal analysis has been performed, and the elastic vibrational periods, together with the corresponding modal shapes, have been found.

The comparison between experimental and analytical data have evidenced some differences between the two analyses. The first one is about the stiffness found for the building: the experimental campaign provides a n higher estimation of the building stiffness, since it is based on a completely elastic response, due to the low intensity of the adopted acceleration source, and to the contribution of some non-structural components, like partitions, and architectural finishing, not included in the analytical model. The second difference is about some of the modal shapes, which are conditioned by the buildings adjacent to the checked one, which are not included in the analytical model.

2 THE CASE STUDY

The Hospital complex, shown in Fig. 1, is made by 18 independent buildings, differing for age, material and number of storeys. The buildings shown in Fig. 1 have been classified during the assessment analysis made in the jointed agreement between the University of Florence and the Regional Government [14]. The examined building, named 07 in Fig. 1b, adjoins three other ones, along three of its sides, as can be seen even by views shown in Fig. 2. It has a rectangular plan, of sides of 30.15 m and 18.90 m respectively. The RC structure is made by 10 transversal frames along the E-W direction, and by three RC frames along the N-S direction. Figs 3 and 4 show, respectively, the standard plan and two 3D views and cross sections of the building.

Figure 1: Hospital complex of Sansepolcro a) Air view b) General plan

Figure 2: The examined building.

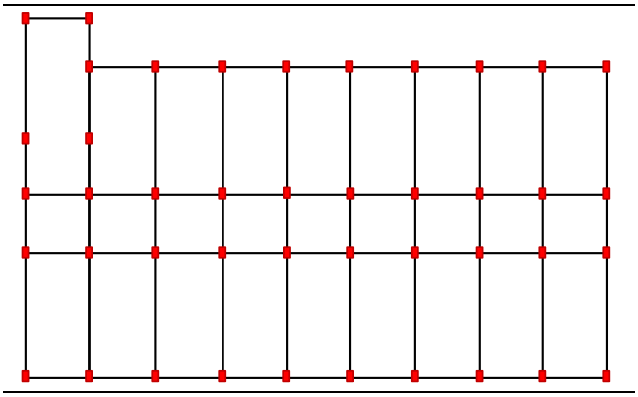

Figure 3: Plan of the building

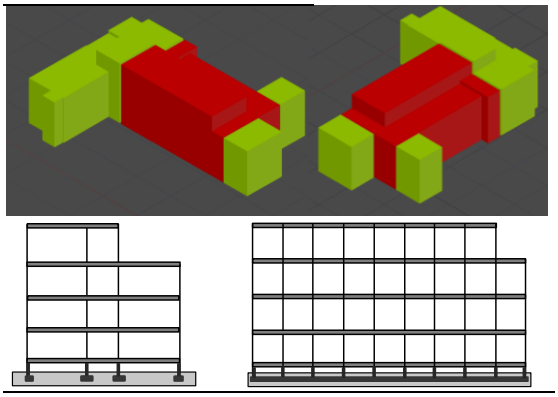

Figure 4: 3D views and sections of the building

The columns have different sections at each storey, ranging between 30x50 cm at the first level, and 30x35 cm at the top one. The transversal beams (EW direction), which sustain the floors, have a section of 30x60 cm, with the exception of some beams on the external wall, which have a special S shape to sustain the infill panels. The longitudinal beams (NS direction) have a lower depth at the first level, whilst they have the same dimensions of the transversal ones (30x60cm) at the upper storeys. The ceiling is made of two different floors, next each other, while the flat roofs includes 1m long cantilever along the entire perimeter. More details about the building can be found in [14].

3 THE DYNAMIC MONITORING

Ambient vibration measurements were performed for 20 hours from 23 to 24 April 2015 with 9 seismic stations (Fig. 5). Each seismic station was equipped with 3-component seismometers; more precisely, six stations were made by Lennartz 3D/5s (sensitivity 400 V/m/s and flat transfer function up to 5 s); one station by Guralp CMG-6T seismometer (sensitivity 2400 V/m/s and flat transfer function up to 10 s), one station by Guralp CMG-40T seismometer (sensitivity 800 V/m/s and flat transfer function up to 30 s) and one station by Trilium Compact 120s model (sensitivity 750 V/m/s and flat transfer function up to 120 s). All the seismometers were digitized by with a 24 bit Guralp CMG24 Digitizer at 100 Hz, and the time synchronization between stations was achieved using GPS.

The F01 station, located on the foundations of the building, has been used as reference station, while two stations were installed at each floor in the opposite corner (Fig. 5).

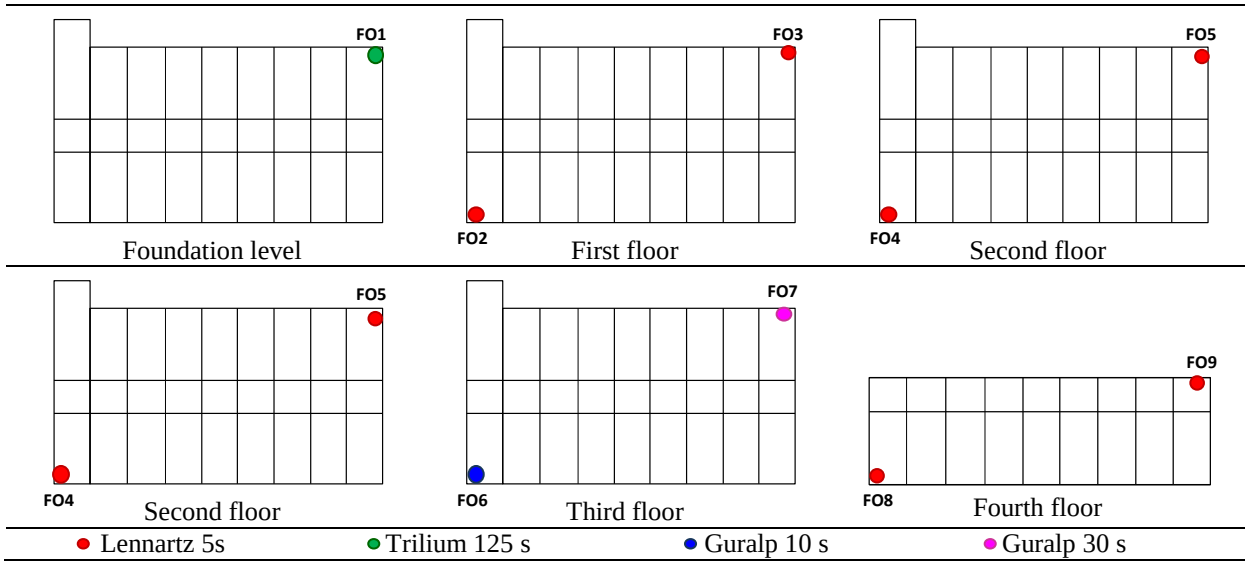

Figure 5: Position of the nine stations used to measure the effects of the ambient motion.

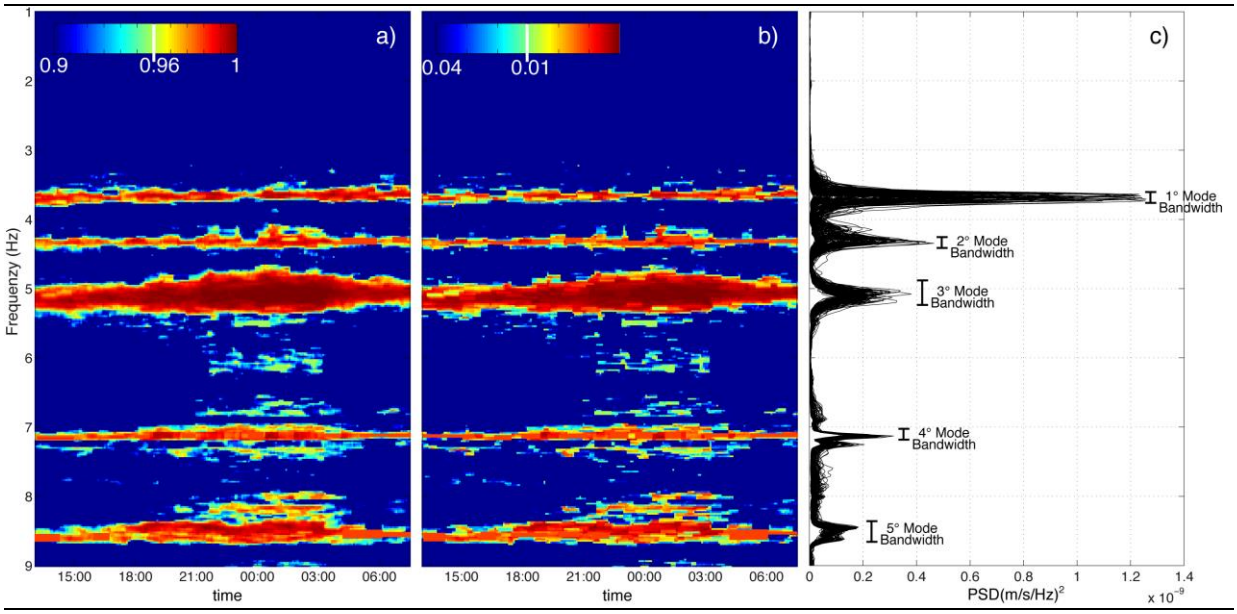
In order to apply the operational modal analysis, the 20 hours long record has been divided into times windows of 300 s and the data have been first deconvolved for the instrument response function and then filtered to frequencies above 0.1 Hz. The time window of 300 s is long enough with respect to the Brincker criterion [10], which requires time series ~1000 times longer than the fundamental oscillation period (~0.3 s in our case). An automatic identification procedure via Enhanced Frequency Domain Decomposition (EFDD) [15] has been used to calculate the modal parameters (frequency, damping and modal shape).

The EFDD is a frequency domain technique for operational modal analysis of structures, whose theoretical background is described in numerous papers [15, 16, 17]. The EFDD is an

extension of the Basic Frequency Domain technique (BFD), often called Peak-picking method, which is based on the Singular Value Decomposition (SVD) of the Power Spectral Density (PSD) matrix $G_{yy}(\omega)$, where ω_i are the single angular frequency. The modal shapes are automatically found within the modal domain (or modal bandwidth) using the modal coherence [14, 16, 12]. The latter is evaluated between each frequency line of two first singular vectors calculated for two consecutive records 300 s length.

The modal coherence is equal to 1 for stationary signals and allows to define the modal domain due to the structural modes. A *mean* value over 0.96 (Fig. 6a) and a *standard deviation* below 0.01 (Fig. 6b), calculated for a set of 10 consecutive modal coherences, are used to reduce the noise and to identify the modal domain. This procedure is repeated for the entire record every 300 s. Within each modal bandwidth, the maximum amplitude of the first singular value indicates the modal frequency. For such frequency peak, the corresponding first singular vector provides the modal shape every 300 s long data set. The application of the EFDD method has allowed to automatically identify the first five bandwidth modes of the checked building (Fig. 6c).



a) *mean* of modal coherence evaluated during the observation time on 10 consecutive records, the white line on the color bar indicates the threshold (>0.96) used for the identification of the mode bandwidth;
b) *standard deviation* of the modal coherence evaluated on 10 consecutive records, the white line on the color bar indicates the threshold (<0.01) used for identification of the mode bandwidth;
c) 240 first singular values calculated for all the observation time (20 hours).

Figure 6: Modal coherence found by the analysis.

An example of the five modal shapes calculated following the EFDD procedure during 300 s time window relative to the 15:00 to 15:05 interval is illustrated in Fig 7, which shows the first five modal shapes found from the analysis. As can be seen by the plots, the first mode is translational and occurs along the X direction (Fig. 7a), with a frequency of 3.71 Hz (T_1 = 0,27 s) and a damping ratio of 1.3 %, whereas the second mode shape is still translational, but along the Y direction (Fig. 7b) with a frequency of 4.32 Hz (T_2 = 0,23 s) and damping ration of 1.4 %. The third mode has a torsional modal shape with a frequency of 5.08 Hz (T_3 = 0,20 s) and damping ratio of 1.61%, while the fourth and fifth modes have a frequency of 7.12 Hz (T_4 = 0,14 s) and 8.54 Hz (T_4 = 0,12 s) and a damping ratios of 0.5% and 0.7% respectively.

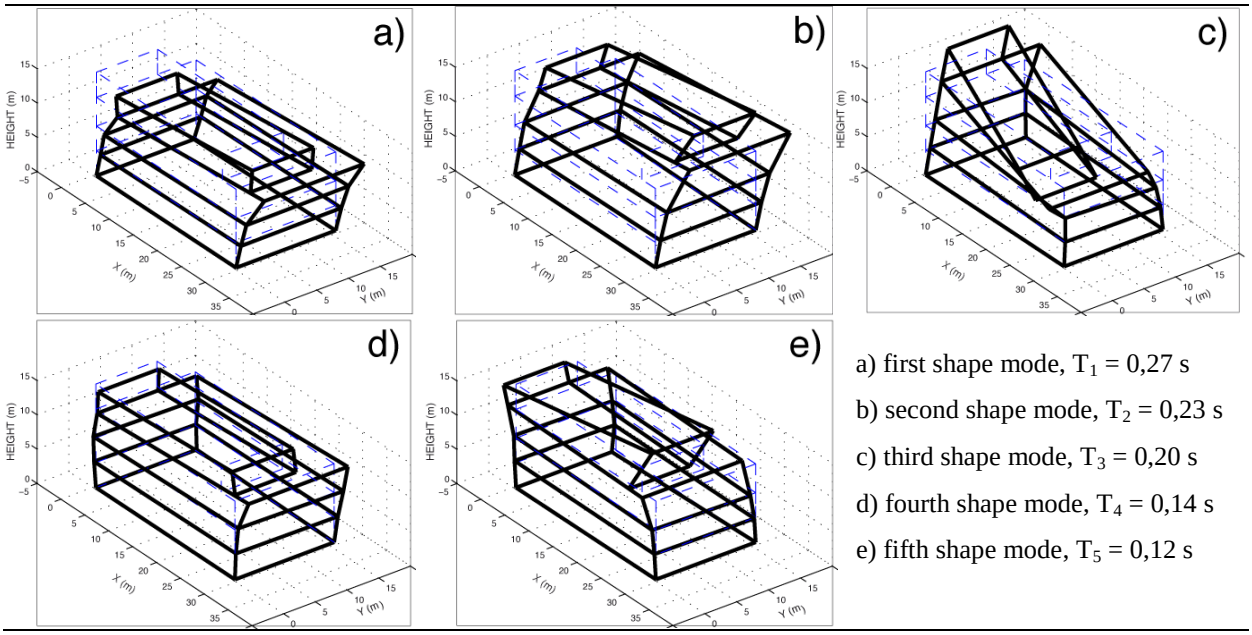


Figure 7: Tri-dimensional representation of the first five modes.

4 THE MODAL ANALYSIS

An analytical model has been made through the computer code Seismostruct [13] to achieve an analytical representation of the seismic response of the building. A detailed representation of the building geometry has been achieved, by tracing the original architectural and structural drawings. The mechanical properties of the materials have been carefully checked during the knowledge process, but in the current analysis only the concrete Young modulus is adopted, which is assumed to be equal to 27000 MPa.

A fiber model has been adopted to describe the cross sections; the Mander *et al*. model [18] has been assumed for the core concrete, a three-linear model has been assumed for the unconfined concrete, and a bilinear model has been assumed for the reinforcement steel. Contribution of floor slabs has been considered by introducing a rigid diaphragm. The model only represents the structural system of the building, neglecting the non-structural components, like the internal partitions and the architectural accessories. In the same way, in this first approach to the numerical representation of the seismic response of the building, the possible interaction with the adjacent buildings has been neglected. Fig. 8 shows two views of the model adopted in the analysis.

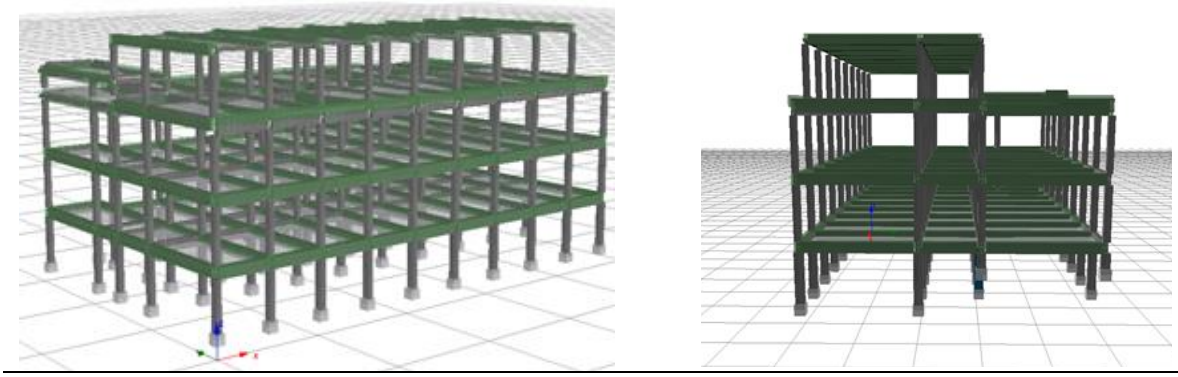

Figure 8. Views of the structural model.

The modal analysis has been performed by assuming an elastic behavior of the structure. Tab. 1 shows the main information (period and percentage of the total mass activate by each motion) of the first modal shapes, while Fig. 9 shows the corresponding modal shapes.

Table 1. Modal shapes found by the numerical analysis

Mode	Period (sec)	% of participation mass		
		Ux	Uy	Rz
1	0.462	80.23%	0.16%	2.30%
2	0.377	0.33%	78.14%	2.90%
3	0.333	1.94%	1.91%	73.07%
4	0.179	5.81%	0.00%	0.26%

5 COMPARISON BETWEEN EXPERIMENTAL AND ANALYTICAL DYNAMICAL RESPONSE

Before proceeding to the comparison between the numerical results and those provided by the experimental campaign, some observations should be made. The dynamic response of buildings related to ambient vibrations is largely affected by all the non-structural components that, at the increasing of the dynamic intensity, lose their entirety, and, consequently, their influence on the building response. The checked building is separated by the adjacent ones through seismic joints: at the occurring of an earthquake, therefore, it should experience an independent dynamic response, resulting not affected by their behavior. Under ambient vibration, instead, the seismic joints have not lost their entirety, and therefore the dynamic response of the case- study found through the experimental test is affected by the dynamic properties of the next buildings. Moreover, the internal partition and the perimeter infill walls are known to largely affect the initial stiffness of the building, before they become ineffective due to the amount of the experienced stress.

The analytical model used in this work is very simple: it only considers the structural elements of the building and the mass distribution, and therefore it can be assumed to be a first attempt to represent the dynamic response of the case-study. The effects of the adjacent buildings is not taken into account, and the non-structural components have been neglected. Therefore, a more deformable system should be foreseen, and only the first shapes can be expected to be comparable, since the torsional behavior of the building is certainly affected by the contribution of the neglected aspects. In the following, therefore, only the first two modes, which represent the translational response of the building along the two main directions, have been discussed.

As regards the elastic periods of the first two modes, it should be noted that the numerical model provides values about 40% larger than the ones obtained by the experimental campaign. The amount of this increase is compatible to more general studies [19] referred to the contribution of the non-structural components on the dynamic response of RC structures.

Fig. 10 shows the comparison of the modal shape found for the first (translational) two modes through the two approaches. The shapes have been normalized to the maximum response along the main direction.

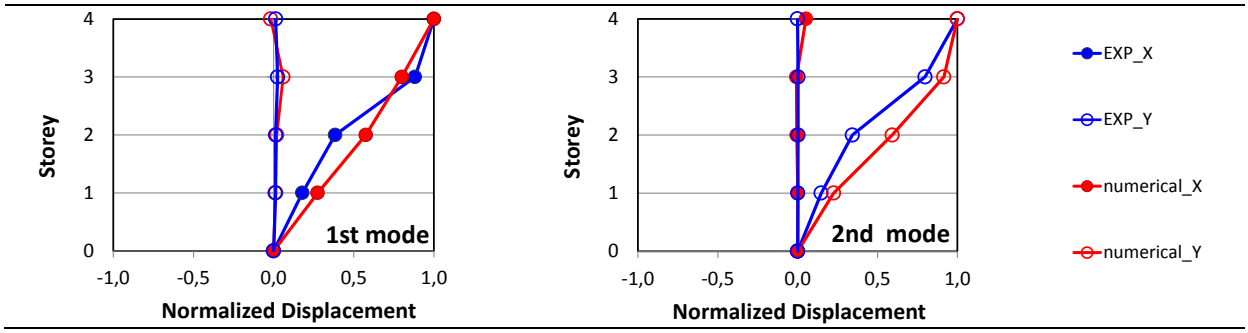

Figure 10: comparison between the first two modes of the dynamic response of the case-study.

6 CONCLUSIONS

In this work a dynamic monitoring based on ambient vibrations has been applied to an Hospital building located in Sansepolcro (Italy). Nine seismic stations, consisting in 3-component seismometers, have been placed in the building, checking every floor, included the foundation level. The recording phase had a duration of about 20 hours, and an automatic identification procedure via Enhanced Frequency Domain Decomposition (EFDD) has been performed on the obtained data to evaluate the modal parameters, i.e. frequency, damping and corresponding modal shape.

The dynamic response found through the experimental campaign has been numerically simulated by representing the building by means of a simplified model. The model represents a first attempt to describe the dynamic response of the building, since it does not take into account the non-structural components, or the possible interaction between the building itself and the adjacent structures. It has been prepared through the platform Seismostruct, and takes into account the effective geometry of the building, and its main dynamical properties, like the mass and the stiffness distribution.

The fundamental periods provided by the numerical model for the building are about 40% larger than the ones provided by the experimental campaign, whilst the two first (translational) modal shapes are very similar with each other. A more detailed model of the building should be made in order to check the effects related to the experimental campaign, like the continuity between the case-study and the adjacent buildings and the effects of the non-structural components.

Abstract. *This work deals with the evaluation of the seismic vulnerability of urban areas. The city of Florence has been selected to be the case-study of the analysis. The work is organized in two main parts. The first one consists of the representation of the area hazard. Starting from the PGA of the area, a map of the amplification factors and of the fundamental frequencies has been made, by performing an extensive experimental campaign. The second step is focused on the buildings properties, and on the increase in the seismic hazard – and the consequent vulnerability – due to the possible occurrence of resonance. A large data-bank of the buildings has been collected, and they have been classified after their structural material (masonry versus reinforced concrete) and height. As a result of the collected information, a map of the fundamental period of vibration of the buildings has been obtained, by adopting the expressions provided by the current International Codes. The comparison between the period of each building and the one of its foundation soil has provided the resonance index (RI), which can be considered as an hazard parameter related to each building.*

1 INTRODUCTION

The evaluation of the safety of urban areas is one of the most important challenges that the Community is facing in these decades. The increase of the scientific and technical knowledges, together with the outstanding development of the capacity to collect and to manage databases, let the territory protection more affordable than it never was in the past. Many different retrofitting techniques [1, 2, 3] have been developed, suitable to be applied to all types of existing buildings. Nevertheless, the achievement of a satisfactory safety level of the building population is totally impossible, at the current time. If the inadequacy of the economical sources is certainly the first reason of this impossibility, also the lack of an intervention plan plays an important role. In many Italian towns, in fact, the buildings population is made mostly by ancient or, anyway, pre-normative structures. If the historical buildings, made in the past centuries, have been made without any anti-seismic criteria, even the pre-normative ones present, in many cases, an unsatisfactory safety level. The Italian country, indeed, experienced an economic boom in the 1960s, which was characterized by a great expansion, and by the construction of many buildings. Many of them have been made with poor materials [4], which did not comply with the technical requirements of the time. As a consequence of these observations, the Italian towns are, in most cases, vulnerable, i.e. they have an unsatisfactory seismic capacity. In the last decades, many procedures have been developed to check the seismic vulnerability of urban areas [5, 6, 7, 8, 9], which can be divided into three main groups: the empiric, the analytical and the hybrid methods. The vulnerability analyses are focused on the reliability of the buildings with regard to the seismic actions expectable for the area.

The current work deals with the urban vulnerability of the city of Florence, (Italy), which is an example of complexity, both for the outstanding architectural heritage and the for multi-level dimensions. The work develops a previous research [10], aimed at evaluating the urban vulnerability of Florence through an empirical approach based on a simplified vulnerability index. The analysis was based on the database available at the time, consisting in the information collected by GIS, which was very basic, providing only the total height and the age of the building population.

This work is focused on the seismic hazard of the buildings located in the area of Florence. The maximum seismic acceleration expected for each point of the urban area has been defined by assuming a PGA equal to 0.13g over the entire urban area, according to the Code [11] classification, and determining the amplification factor map, which is a function of the specific geological features of each micro-zone of the area.

A further development has been achieved, by determining the maximum acceleration which each building of the Florence area can experience as an effect of the relationship between its own dynamical properties and the ones of the foundation soil. To obtain this information, the maps of the fundamental period both of the soil and of the buildings would be needed. The map of the fundamental period of the soil has been found after an extensive experimental campaign made on the Florence area. The map of the fundamental periods of the buildings, in turn, has been found by applying a simplified approach to the buildings population. To this purpose, further information has been achieved on the buildings population, like their structural system and material. As a consequence of the more detailed classification, a reliable evaluation of the main frequencies of the building population has been made. The comparison between the maps of the fundamental periods of the area and of the buildings pointed out the probability of the buildings to experience resonance phenomena during seismic events. A “resonance index” (*RI*) has been defined to measure the sensitiveness of the buildings to this phenomenon, and a *RI* map of the area has been consequently drawn.

2 THE CASE-STUDY: FLORENCE

Florence is a city of about 353,000 inhabitants, with a larger number of people (supposed to almost achieve 700,000 units), living in the whole urban area. This work is focused on the vulnerability of the buildings population of the urban area of Florence, made by about 55,000 units. The area has been historically subjected to earthquakes, with local magnitude ML until 5, and maximum intensity equal to VIII MCS (Mercalli-Cancani Sieberg scale).

Despite the high density of population and the not negligible seismicity, the buildings of the area do not present any anti-seismic criteria, since most of them are ancient or – anyway – built before the seismic regulations have been introduced.

In this study each building is ranked by the Florence municipality database through few main parameters, i.e. the total height and the range of the construction year. This research does not include the area of the historical center (UNESCO protected area), since it is object of another survey. The current investigation, therefore, has been applied over about 40,000 buildings. The town lies in a valley (about 50 m a.s.l.) crossed by Arno river and surrounded by hills. Many investigations [12, 13] have been made on the soil of the Florence area, providing a detailed knowledge of the lithostratigraphic subsurface, of the lithoid substrate profile and of the geotechnical properties of its soils. In these years all the available drilling data have been collected and implemented into a GIS. Each data has been expressed in terms of unconformable boundary stratigraphic units [14] and unified soil classification system (USCS), and then transcribed into a geodatabase (UBSU).

The Florence basin had been developing since late pliocene thanks to the role played by the Fiesole faults on its NE border; these faults have no any sign of tectonic activity in the last 200ky. This geological evolution led to the filling of the basin by plio-pleistocene palustrine and alluvial deposits, followed by two sedimentary cycles related to the paleo-Arno river and the holocene geomorphic evolution, respectively (Fig. 1).

3 HAZARD MAPS OF THE SOIL

The seismic hazard of the area of Florence has been checked by performing an extensive experimental investigation [12], consisting in a 1,850 drillings, whose location has been shown in Figure 2, enhanced by 32 downhole proofs. For each test the maximum peak of the transfer function has been found, which has been combined with information provided by the downhole proofs about the stratigraphy of the area. A seismic-stratigraphic analysis has been performed, which provided the transfer function of the area. By integrating the transfer function found over a range of periods between 0,1s and 0,5s (the range of major interest as re-

gards the buildings interaction), the amplification factor of each test has been found. Figure 2 shows the map of the amplification factor obtained after the experimental investigation [12]. In the map the values below the unity have not be evidenced, while the red area represents the points with the highest amplification.

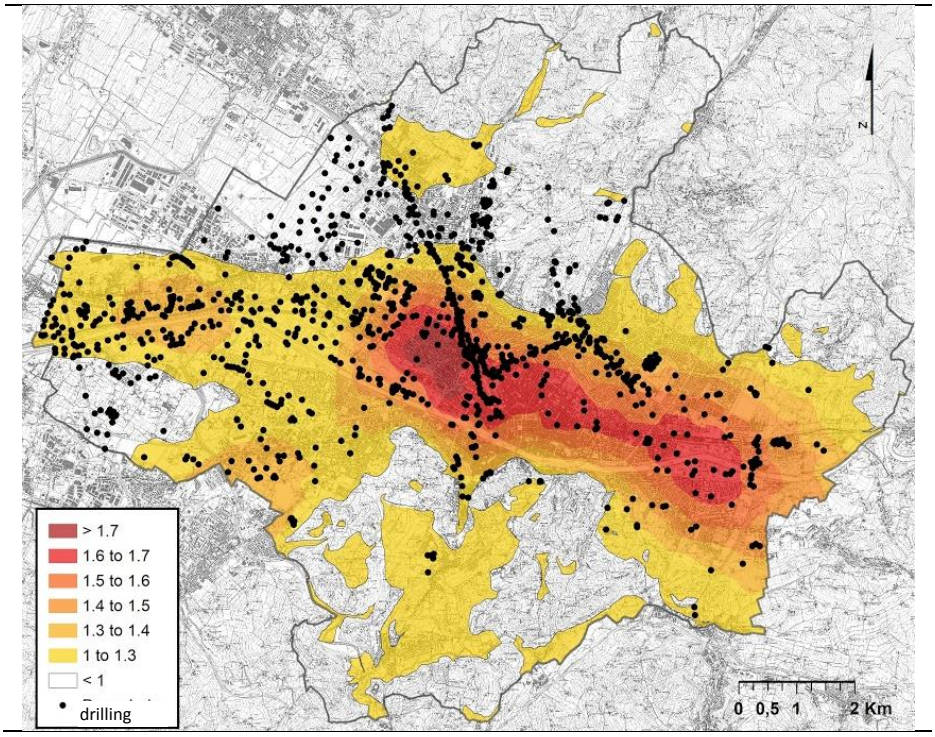

Figure 2: Map of the amplification factor (from: [10])

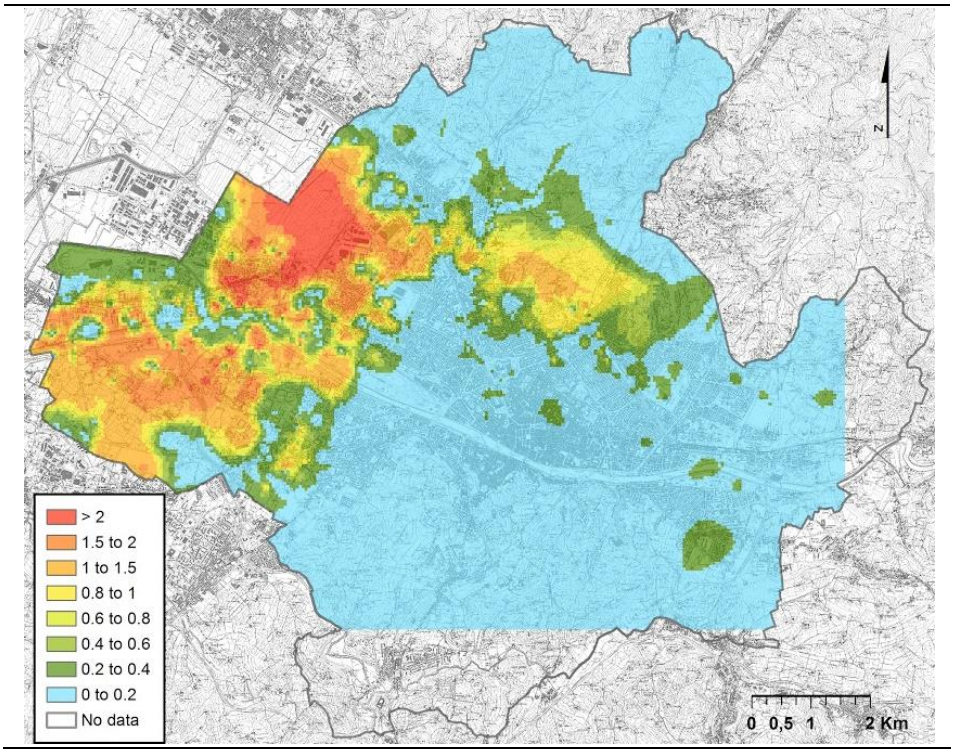

Figure 3: Map of the proper period (in seconds) of the soil.

The same experimental campaign has provided the map of the fundamental periods of the area, shown in Figure 3.

Even in this case the information provided by the two types of investigation have been integrated, i.e. the strathigraphies found through the drilling proofs have been represented by the mechanical properties and the shear velocity (v_s) values provided by the downhole investigations. For each drilling the filtering process through the soil columns has provided the fundamental frequency of the soil. The map of the fundamental periods of the soil cannot be considered as an hazard map; nevertheless it has a crucial role in the evaluation of the buildings vulnerability, since it affects the intensity of the seismic acceleration which each building will face at the occurring of an earthquake.

As can be observed in Fig. 3, only a relatively small area, represented in green, presents a period compatible to the buildings ones (0.20s - 0.60s). The amount of the seismic acceleration expectable by each building as an effect of its position can be related both to the relationship between the fundamental period of the building and the one of its foundation soil, and to the amplification factor. The maps shown in Figs 2 and 3, therefore, should be compared to the map of the fundamental period of the buildings, shown in the next section.

4 HAZARD MAPS OF THE BUILDINGS

4.1 The buildings population

The buildings population consists of about 55,000 unities. No distinctions are made about their use: residential, scholastic, commercial and industrial buildings have been considered as well. Each unity has been classified through an *ID*, and the parameters adopted in the database are the total height, the surface, the volume and the age range. Fig. 4 shows the classification of the buildings population of the entire city referred to the age of construction and to the total height.

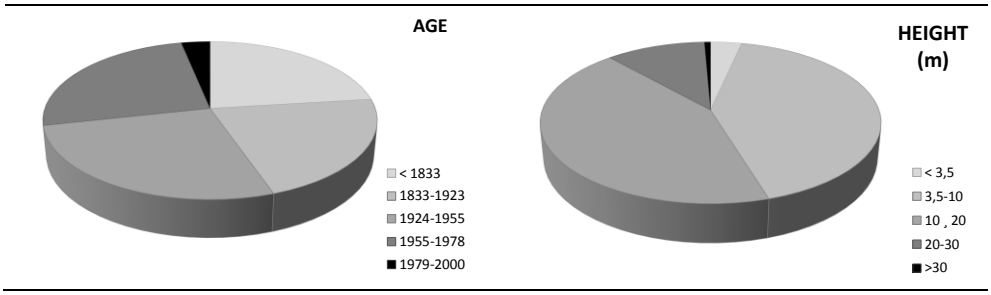

Figure 4: Database referred to the entire city of Florence.

In this work, a more detailed classification has been made on the residential buildings of the city, external to the most historical center - which is the object of another research - i.e. about 40000 buildings. In this database, the number of information has been upgraded, by the introduction of the type of structure. The buildings, indeed, have been classified after their main technology/material. The considered classes are: masonry (*M*), reinforced concrete (*RC*) and other structures (*OS*). The *OS* class comprehends buildings below 3.5m, and the structures not belonging to any of the previous classes. The buildings population of the area basically does not present any steel unities, which, anyway, would belong to the *NC* class. Fig. 5 shows the classification of this more specific database. The total height of the buildings, together with their material, leads to achieve an evaluation of their fundamental period of vibra-

tion. It should be noted that only few buildings exceed the height of 30 m. This evidence depends on an ancient law, passed in the XIII century, still in force, which topped the height of the civil buildings to 50 "florentine braccia" (about 30 m).

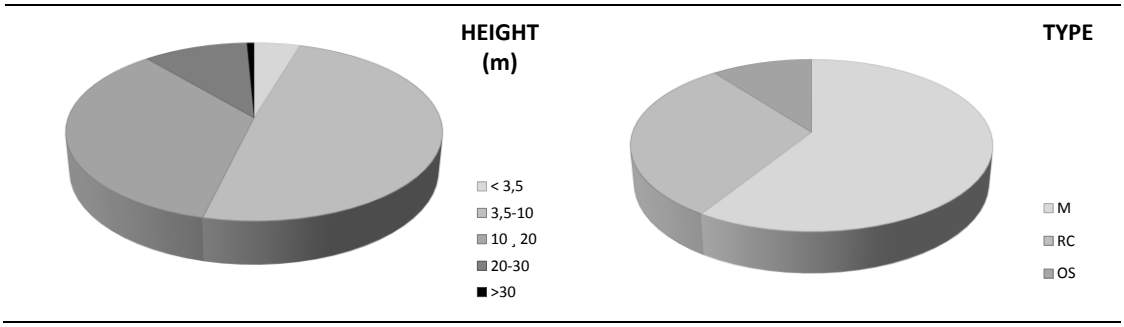

Figure 5: Upgraded database referred to the residential building of the city of Florence (with the exclusion of the historical center)

4.2 The dynamic characterization

The fundamental period (T_0) of the buildings population is a derivative information provided for the database, as a function of the total height of each building and its type class, as explained in the previous section. The vibrational properties of the buildings can be evaluated by performing an eigenvalue analysis on a mechanical model representing the structural behavior, or by calibrating approximate expressions, based on the observation of experimental data [15]. The empirical approach is the most largely adopted so far, and it is followed even by the main International Codes [16, 17, 18, 19]. In this work the simplified relationships proposed by the Italian [10] and European [20] technical Codes, which are identical each other, have been adopted:

masonry buildings: $$T_e = 0.050\, h^{0.75} \quad (1)$$

RC framed buildings: $$T_e = 0.075\, h^{0.75} \quad (2)$$

where h is the building eight (in meters). The provided period depends only on the total height of the building and on its constructive system (masonry vs framed structure). The reliability of (1) and (2) could be argued. It is well known, in fact, that the dynamic response of buildings depends on their stiffness, which experiences a considerable decrease during the seismic excitation; depending on the level of assumed damage, a different amount of stiffness - and consequently of the period - can be assumed [21]. In most cases, the period values provided by the most recent empirical expressions [15] [22] are larger than the ones found by following the Code approach. The most accurate expressions which evaluate the period of buildings, however, require a large number of information, like the amount of walls in the two main directions (wall systems), or the presence and quantity of infilled walls inside the structure (framed systems). Therefore, at the current time, the adopted Code expressions seem to be suitable to the work purpose, and compatible to the collected information.

The obtained T_0 values, however, should be considered as a lower limit for the buildings period. Fig. 6 shows the map of the Period found for the buildings population (the map has been slightly cut, to lead a larger size of the plot). In the same figure, the percentage of the period ranges of the database has been shown.

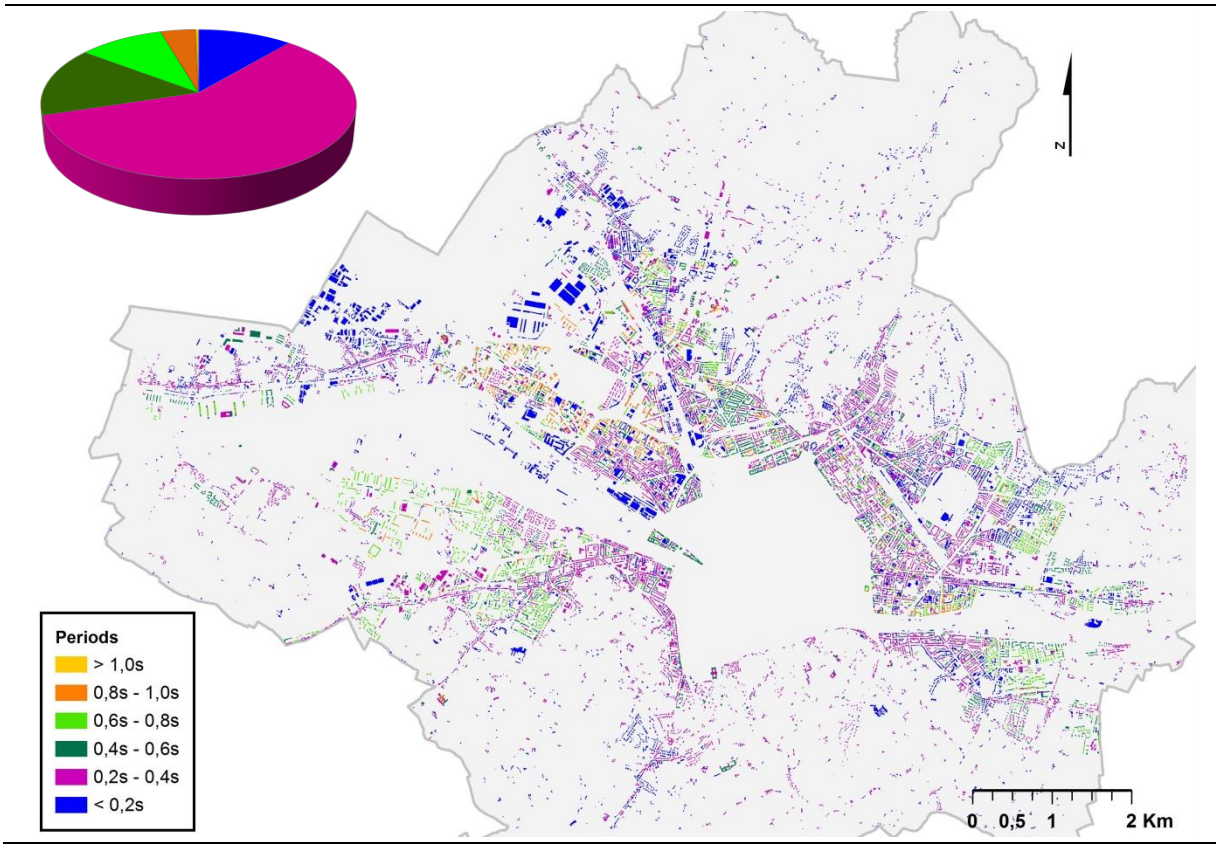

Figure 6. Map of the fundamental periods (T_0) of the buildings population.

4.3 The "resonance index" map

The maps representing the period distribution found for the buildings (Fig. 6) and for the soil (Fig. 3) have been compared, in order to find the "resonance map", which express how much the fundamental period of each building differs by the one of its foundation soil. The resonance index (*RI*) has been expressed as the ratio between the period of the building and the one of the soil (equation 3):

$$RI = T_{building} / T_{soil} \quad (3)$$

The obtained *RI* values have been classified in five different classes, listed in Table 1, which express the vulnerability of the buildings population regard the resonance phenomena. Since the periods found for the buildings can easily lengthen, due to the occurring of structural damage, the *RI* values over the unity are supposed to represent absence of resonance.

Table 1: Assumed ranges for the resonance index (RI)

RI range	Expected resonance phenomenon
0.0 - 0.3	No resonance
0.3 - 0.6	Low resonance probability
0.6 - 0.9	Possible resonance for moderate/strong earthquakes
0.9 – 1.1	Elastic resonance
> 1.1	No resonance

With reference to the introduced *RI* classification, the most "dangerous" ranges, i.e. the ones of the maximum resonance, are the one around the unity (0.9-1.1) and the one between 0.6 and 0.9, which represents the building with a fundamental period slightly lower than the one of their foundation soil. This last *RI* range can be dangerous at the occurring of moderate or strong earthquakes, which could induce a large increase of the elastic period of the buildings. The *RI* values below 0.3, instead, can be assumed to represent a low probability of resonance. The classification proposed in Tab. 1 should be assumed as a simplified instrument to evaluate the resonance problems; to achieve a more affordable classification, a more detailed description should be needed about the buildings, and more accurate expressions should be adopted to estimate the fundamental period of the buildings. Moreover, especially for isolated buildings, the two first periods, along the two main directions, should be considered, to avoid that the second vibrational mode could have resonance problems with the soil.

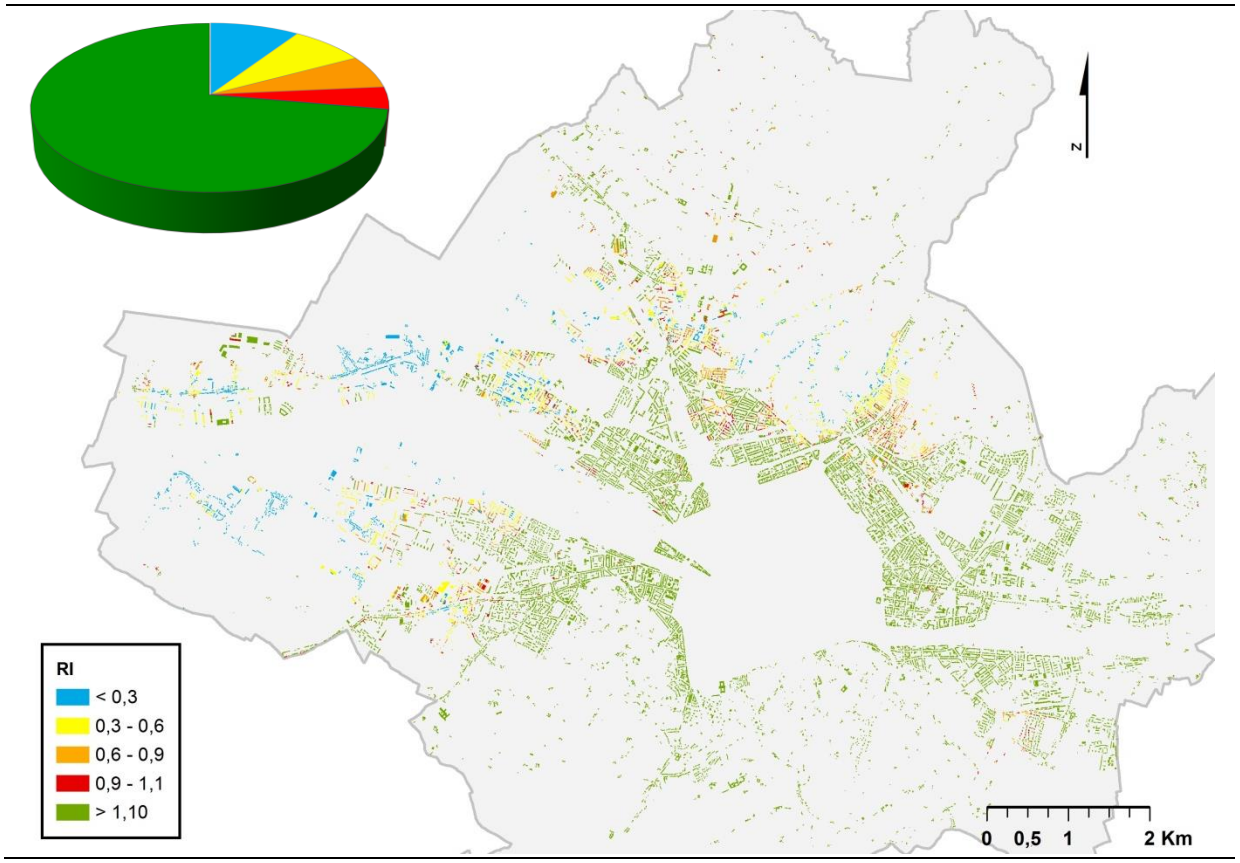

Figure 7. Resonance map.

5 CONCLUSIVE REMARKS

In this work an evaluation of the seismic vulnerability has been made on the area of Florence. To this purpose the dynamic properties both of the soil and of the buildings population of the urban area have been checked.

The hazard of the area has been achieved by performing an extensive experimental campaign over the area soil, consisting of 1,850 drillings and 32 downhole tests. The information provided by the two types of testing have been combined, returning a mapping of the funda-

mental frequency of the soil all over the Florence area. The same investigation has provided the distribution of the amplification factor over the selected area.

The existing database referred to the buildings population has been upgraded, by introducing further information about the constructive system and the materials of all buildings, and by determining their vibrational period by means of the conventional expressions provided by the Technical Codes. A vulnerability index, *RI*, has been introduced to express the probability of the buildings to experience resonance phenomena. *RI* has been defined as the ratio between the period of the buildings and the one of their foundation soil, and a classification has been introduced to evaluate the resonance probability of each building. A further map, expressing the *RI* classification, has been provided for the urban area of Florence.

The obtained *RI* map should be improved, by introducing further information about the buildings geometric and mechanical properties, and by evaluating the buildings fundamental periods through more accurate expressions.

Abstract. *This article presents SPO2FRAG V1.0, the first (beta) version of the Static PushOver to FRAGility software. The SPO2FRAG software is an interactive and user-friendly tool that can be used for approximate, computer-aided calculation of building seismic fragility functions, based on static pushover analysis. It is coded in MATLAB® environment and is currently under development at the Department of Structures for Engineering and Architecture of the University of Naples Federico II. At the core of the SPO2FRAG tool lies the SPO2IDA algorithm, which permits analytical predictions for incremental dynamic analysis summary fractiles at the single-degree-of-freedom system level. By effectively interfacing SPO2IDA with a series of operations, intended to link the results of static pushover analysis with the variability that typically characterizes non-linear dynamic structural response, SPO2FRAG provides an expedient solution to the computationally demanding task of analytically evaluating seismic building fragility, which would otherwise require a large number of non-linear dynamic analyses.*

1 INTRODUCTION

Seismic risk and loss estimation studies performed within a probabilistic framework employ structural fragility (or vulnerability) functions, which provide the probability of exceeding some predefined performance limit state in a single seismic event, given a certain level of seismic intensity. In the case of structure-specific studies, the trend is to rely increasingly on analytical derivation for these fragility functions. State-of-the-art in analytical fragility estimation is the use of non-linear dynamic analyses – for example, incremental dynamic analysis (IDA, [1]), the cloud method [2] or multi-stripe analysis [3]. However, despite the advantages of the analytical approaches over the damage probability matrices and empirical fragility curves employed earlier, their chief disadvantage remains the computational burden involved [4], which may include the selection and manipulation of hazard-consistent ground motion records.[1]

In order to sidestep the computationally demanding methods of seismic structural assessment that involve non-linear dynamic analysis, engineers have long relied on approximate methods, such as static non-linear procedures, which estimate seismic demand of the structure by making recourse to an equivalent single-degree-of-freedom (SDOF) oscillator [6]. A simple and effective link between IDA and static non-linear analysis has been provided by the SPO2IDA algorithm [7], which acts as a predictive equation of the fractile IDA curves for SDOF systems with multi-linear pushover curves. The SPO2IDA algorithm forms the backbone around which the SPO2FRAG (Static Pushover to Fragility) tool, a MATLAB® coded software whose presentation is the objective of the present paper, is built. SPO2FRAG offers an expedient solution to the analytical derivation of seismic fragility for buildings and can provide support to previously developed seismic risk assessment software such as the one described in [8].

The remainder of this article is structured in the following manner: first a brief presentation of past research most relevant to the development of the SPO2FRAG tool is provided. This is followed by an operational description of the software itself, complete with a flowchart and graphical user interface (GUI) description. Subsequently, an example application is provided, accompanied by a comparison of the SPO2FRAG output with a set of fragility functions derived by means of IDA. Finally, some commentary and discussion on development concludes the article.

2 BACKGROUND

2.1 Static pushover to IDA

The most fundamental concept behind SPO2FRAG is the ability to predict efficiently IDA results of a given SDOF system without having to actually run any analysis, a prediction achieved thanks to SPO2IDA. On any monotonic static pushover curve (SPO), some characteristic regions can be typically identified: an elastic portion leading up to the yield point, a post-yield region characterized by positive stiffness (hardening) extending up to the capping point, a descending branch exhibiting negative stiffness (softening) and sometimes even a final residual strength segment (Fig. 1a). Based on the observation that the 16%, 50% and 84% fractile IDA curves of SDOF systems also exhibit distinctive characteristics within the ductility intervals that delimit these SPO segments, the SPO2IDA algorithm was developed. SPO2IDA comprises a set of equations that can directly predict the three summary fractile IDA curves for any

[1] It is appropriate to recall at this point that, in principle, fragility curves are site-specific. This is because the records employed to run non-linear dynamic analyses should be selected based on the joint and conditional distributions of hazard variables (e.g., magnitude, source-to-site distance, and accelerations) specific for the site. To overcome issues of this nature, the software discussed in the paper assumes conditional independence of first-mode spectral acceleration with respect to other hazard variables; see also [5].

SDOF system, with a given quadrilinear backbone geometry; this introduces an approximation but has the advantage of eschewing the need for laborious computations. An example of SPO2IDA-predicted fractile IDA curves is given in Fig. 1b, where the predictions are compared against the corresponding fractiles of explicitly calculated IDAs.

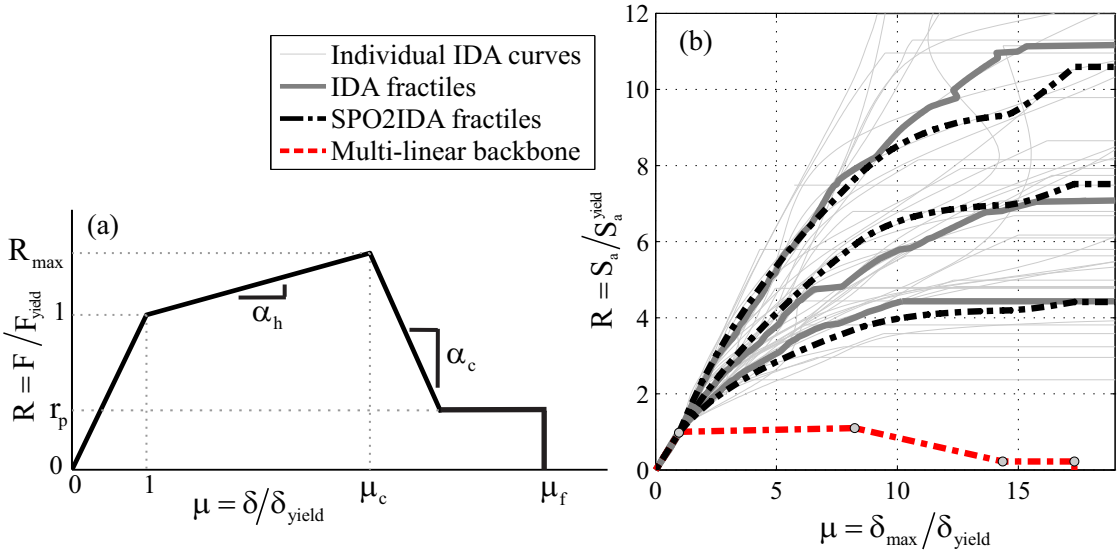

Figure 1: (a) Generic SDOF oscillator's quadri-linear backbone curve plotted in reduction factor (R, ratio of maximum to yield force) – ductility (μ, ratio of maximum to yield displacement) coordinates and (b) an example of SPO2IDA-predicted 16%, 50%, 84% fractile IDA curves, super-imposed over the fractile and individual IDAs calculated analytically for the same SDOF system using the FEMA P695 [9] far-field set of forty-four records. Backbone geometry is defined by the parameters α_h (post-yield to elastic stiffness ratio), μ_c (ductility at capping point marking the beginning of the descending branch), a_c (post-capping to elastic stiffness ratio) and μ_f (fracture ductility.)

2.2 Multi-linear fit of the monotonic backbone curve

Another important part of the SPO2FRAG algorithm is the automatization of obtaining a multi-linear backbone for the equivalent SDOF oscillator. As recently as – roughly – a decade ago, the norm for the implementation of static non-linear procedures (e.g., [10]) used to be a combination of simple elastic-perfectly-plastic or bi-linear hardening approximations of SPO backbones coupled with R-μ-T relationships (e.g., [11]) that only consider some central value of inelastic response. Under these circumstances, empirical "rules of thumb" for the multi-linear fit chosen for the SPO may have been good enough, but this may no longer be the case.

Advances in computing power and the sophistication of numerical modelling, for the non-linear aspects of structural behavior, have gradually led to SPO curves containing appreciable initial curvature (in cases where cracking is a factor) and descending post-peak-strength branches. In order to exploit the capabilities of more powerful R-μ-T relationships, such as SPO2IDA, there is a need for an efficient fully quadrilinear fitting scheme of such elaborate SPO backbones. A set of rules to that effect was proposed in [12], based on a study that employed IDA of SDOF systems with curvilinear and piece-wise-linear backbones.

2.3 SDOF to MDOF conversion of the fractile IDA curves

SPO2IDA can provide (an estimate of) the 16%, 50% and 84% fractile IDA curves of an equivalent SDOF system, processing a piecewise-linear backbone curve derived from the SPO of a given structure. The SDOF IDAs naturally come in reduction factor-ductility terms and therefore, in order to relate these IDA curves back to the original MDOF system, a series of

conversion operations are necessary (see Fig. 2). These conversions entail passage from non-dimensional coordinates R - μ to spectral acceleration – roof drift format, the possibility of adding the response variability at the nominal yield point that the MDOF system experiences due to the effect of higher modes (but is lost on its SDOF counterpart, [13]) and possibly a roof drift to inter-storey drift conversion, since the latter is oftentimes better suited for the definition of limit-state thresholds.

2.4 IM-based parametric fragility functions

The final output and stated objective of SPO2FRAG is the estimation of fragility functions for building-type structures. A fragility function provides the conditional probability that a structure will exceed a limit-state threshold ("fail") in a single seismic event, given a certain ground motion intensity measure (IM) level. If it is assumed that the level of seismic intensity causing failure (or, equivalently, the capacity of the structure per limit-state in IM terms, $IM_{C,LS}$) is a random variable that follows some specific model, for example the log-normal distribution, determining the fragility function boils down to estimating the mean-of-the-logarithm of capacity per limit-state, η , and the logarithmic standard deviation, β . This can be seen in Eq. 1, where $\Phi(\bullet)$ denotes the Gauss function.

$$P\left[IM_{C,LS} \le im\right] = \Phi\left(\frac{\ln im - \eta}{\beta}\right) \tag{1}$$

When the median and 16%, 84% fractile IDA curves are provided for the structure, one may estimate these two parameters by adopting a threshold engineering demand parameter (EDP) value (or probability distribution thereof) for each limit state – see for example Fig. 2c.

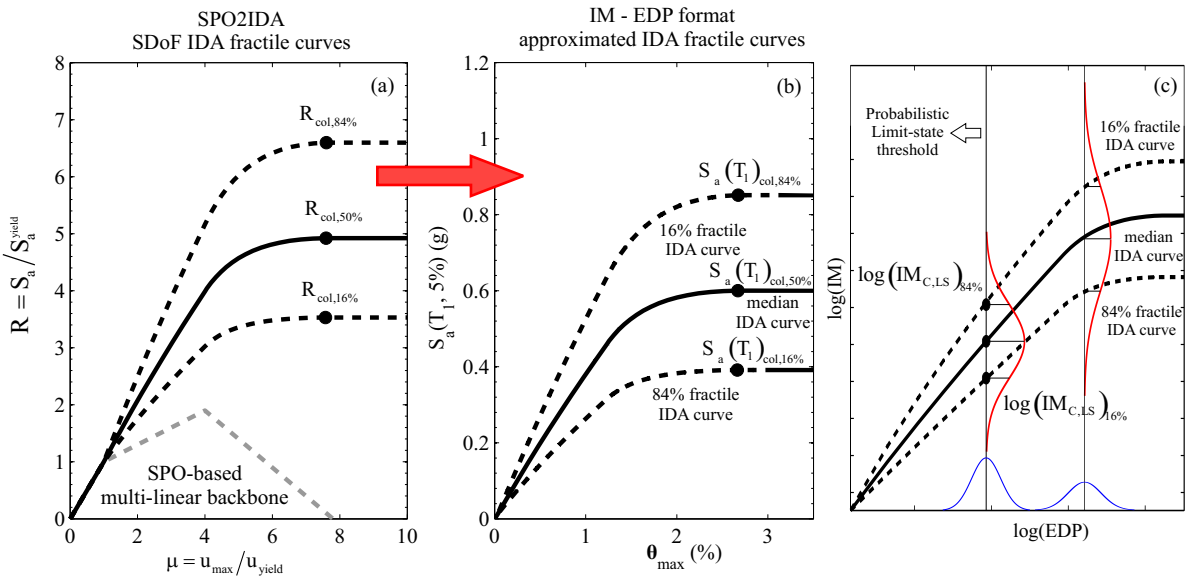

Figure 2: (a) Example of SPO2IDA-predicted 16%, 50% and 84% fractile SDOF IDA curves in terms of reduction factor – ductility, (b)conversion to first mode spectral acceleration – inter-storey drift ratio, (c) estimation of fragility function parameters assuming a log-normal distribution for the seismic intensity level causing exceedance of each limit-state threshold, $IM_{C,LS}$.

2.5 Model uncertainty in seismic structural response

SPO2FRAG simulates non-linear dynamic analysis via the SPO2IDA algorithm. Actual IDA, using a deterministic numerical model of the structure, can provide an estimate of record-to-record (aleatory) variability characterizing structural response. However, modelling parameters (such as material properties, member geometry, mass distribution, etc.) may also exhibit their own uncertainty, which will necessarily affect the distribution of $IM_{C,LS}$. Furthermore, some specific cases may violate some of the assumptions behind IDA to a certain extent, which can also result in additional uncertainty infiltrating the results. One, very simple, approach towards accounting for this additional uncertainty is to consider that the mean logarithmic capacity η is itself a random variable, assumed, for example, normally distributed with a standard deviation β_U (e.g., [14]). This additional parameter can be either obtained directly from relevant studies in the literature or estimated still via SPO2IDA [15].

3 SPO2FRAG, OPERATIONAL OUTLINE

3.1 Graphical user interface and flowchart

The SPO2FRAG software revolves around a GUI that allows the user prompt visualization of all intermediate results produced by the various modules and sub-routines. The individual modules that comprise the operational part of the software are the input interfaces, automatic multi-linearization module, dynamic characteristics toolbox, SPO2IDA module, interfaces for definition of limit states, their corresponding thresholds and any additional sources of uncertainty, the fragility function module and the output post-processing module. A flowchart of SPO2FRAG's operation is presented in Fig. 3 and a more detailed description of the same is given in the following paragraphs.

3.2 Data input, pre-processing and multi-linear fit

SPO2FRAG operates on the premise that the user performs the necessary SPO analysis using outside structural analysis code. Thus, the entry-level part of the tool is the data input interface, which reads SPO force-displacement results from either a text or a spreadsheet file. Preferentially, SPO displacements at all stories are requested; this lateral deformation profile can then be used by the program to internally calculate modal characteristics and convert maximum roof drift to maximum inter-storey drift. In cases where only roof displacement - base shear results are available in terms of SPO, the subsequent *Dynamic Characteristics Input* window will require vibration period, modal participation factor and participating mass ratio to be input by the user, along with floor masses and storey heights.

Subsequently, user input is subjected to some rudimentary checks for consistency and/or obvious errors and the roof displacement – base shear curve is then fed to the automated piecewise linear fitting algorithm. This algorithm allows for a full quadrilinear fit (elastic, hardening, softening and residual plateau segments) based on [12], but the user may also request bilinear or elastic-perfectly plastic fits (e.g., in cases where strength degradation was not included in the numerical model of the SPO). The GUI windows and dialogue boxes relevant to this input procedure can be seen in Figs. 4, 5.

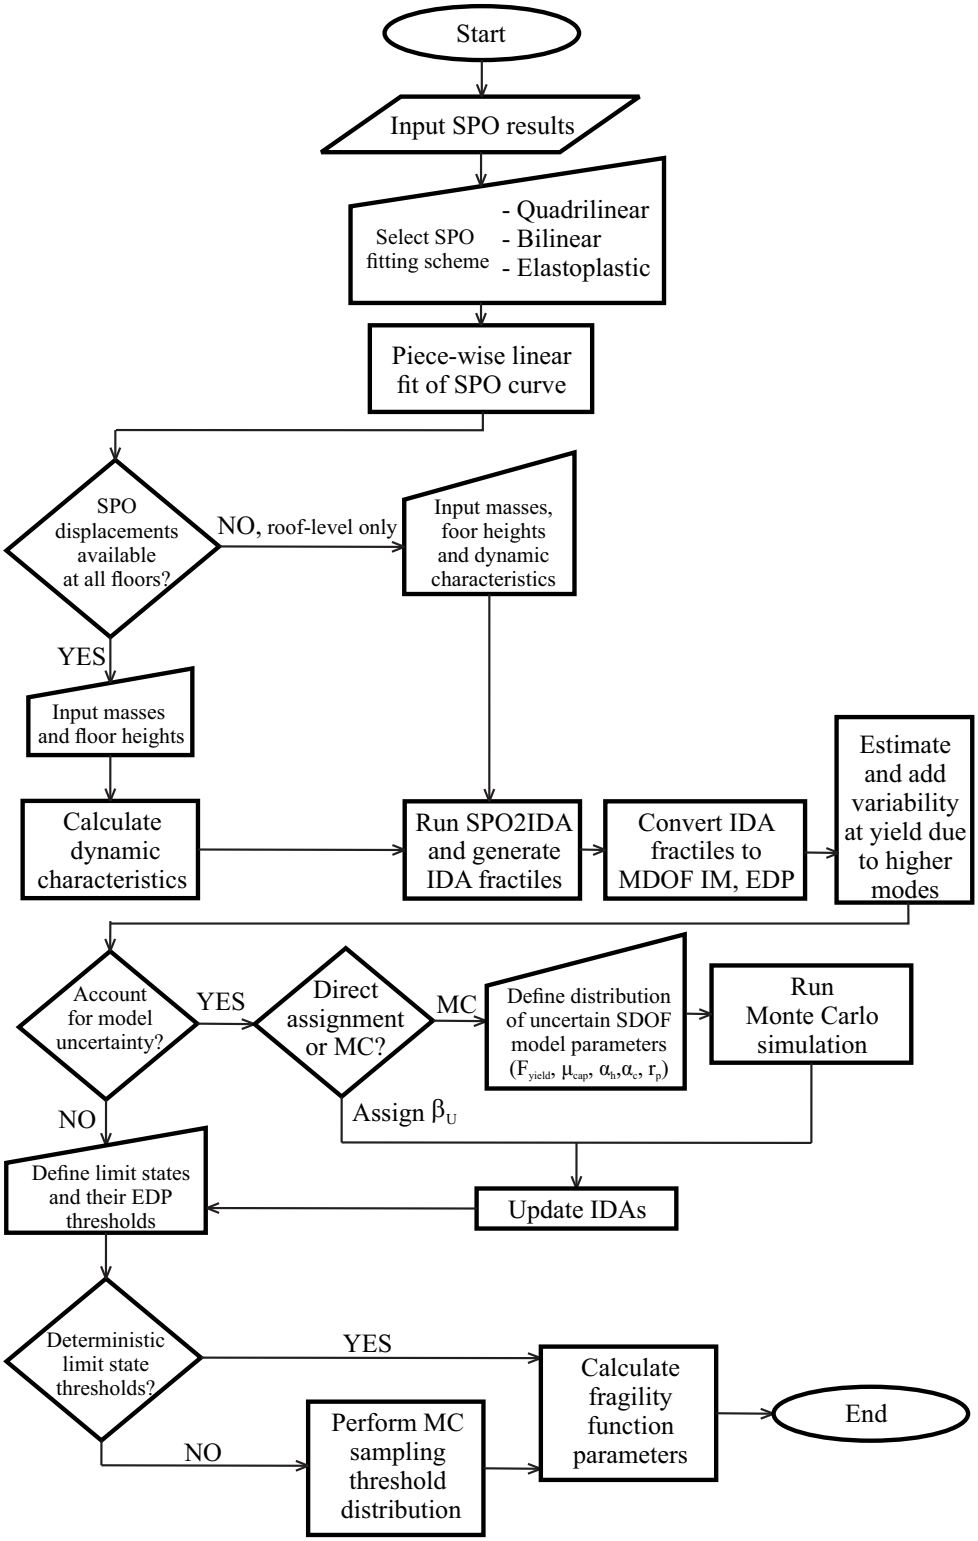

Figure 3: SPO2FRAG V1.0 flowchart.

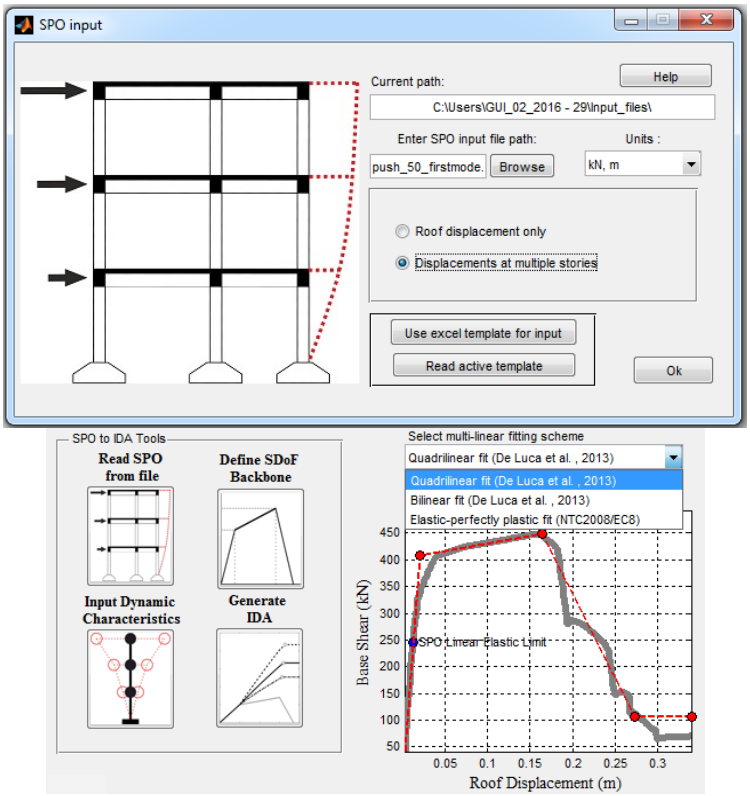

Figure 4: SPO data input from file window (upper panel) and GUI excerpt after piece-wise linear fit of the SPO curve (lower panel).

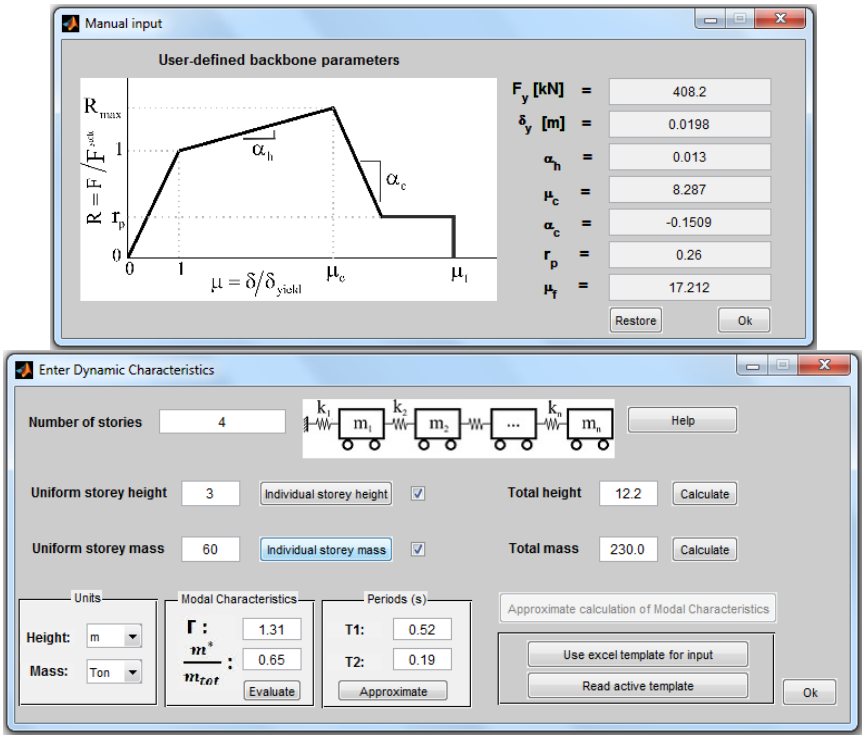

Figure 5: Dialogue box reporting the backbone parameters resulting from implementation of the multilinear fit algorithm (center) and input of dynamic characteristics window (lower part).

3.3 SPO2IDA and SDOF to MDOF conversions

Once data input is completed and a multi-linear fit of the SPO curve has been obtained, the SPO2IDA algorithm is launched, providing the 16%, 50% and 84% fractile SDOF IDA curve predictions in R-μ terms. The SPO2IDA output is automatically converted into spectral acceleration – drift format, using the dynamic characteristics of the structure. In cases where the SPO displacements at all storeys have been provided, the IDAs are converted in maximum interstorey drift ratio (IDR) terms by default; otherwise, EDP is set to roof drift. Even in the latter case, the user may still choose to convert to IDR, by selecting an appropriate approximation for the lateral post-yield deformation profile.

After this operation, an issue pertaining to the MDOF IDA curves that remains to be addressed is the fact that the MDOF system should exhibit greater record-to-record variability than its equivalent SDOF, due to the effect of higher modes of vibration. This additional variability is estimated by means of in-built empirical rules, injected at the nominal yield point and propagated along the IDA 16% and 84% fractiles.

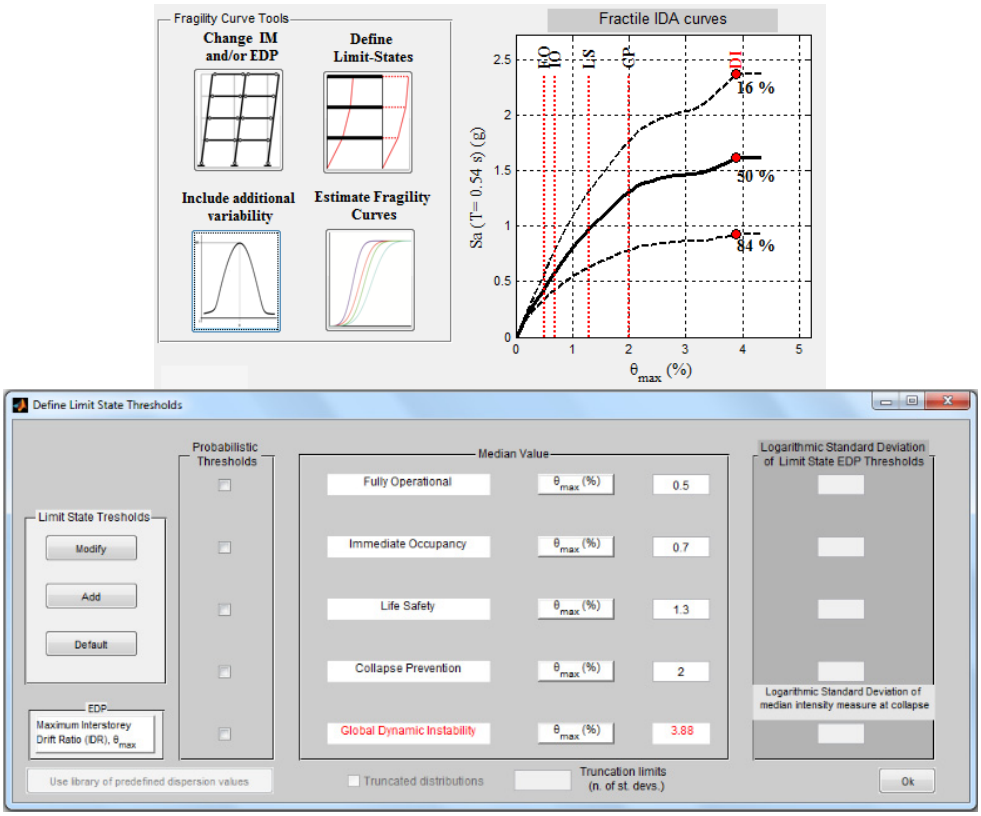

Figure 6. GUI excerpt showing the approximate (predicted) fractile IDA curves after completion of SDOF to MDOF conversion (upper panel) and window for the definition of limit states and limit-state-thresholds in terms of EDP (lower panel).

3.4 Limit-states and handling additional uncertainty

By default, the SPO2FRAG tool recognizes four limit states: *fully operational*, *immediate occupancy*, *life safety* and *collapse prevention* (see [16] for definitions). In cases where the SPO exhibits a negative-stiffness, softening branch a fifth limit state, *dynamic instability* will appear, corresponding to the IDA flat-lines. The user may also define more limit states via the GUI. In all cases, the user must define thresholds in terms of EDP, which determine exceedance of each limit state. Such thresholds need not be deterministic; the user has the option to treat them in a

probabilistic manner, by assuming that some thresholds follow a lognormal distribution, whereas the median and log-standard deviation of said distribution must be defined (Fig. 6).[2]

In cases where the user wishes to include (additional) modelling uncertainty into the calculation, two alternative options are available in the relevant GUI panel. First option is to define a logarithmic standard deviation β_U for mean logarithmic capacity η at one of the predefined limit states. This additional uncertainty is then propagated along the IDA curves. The second option is to consider some of the parameters that define the SDOF multi-linear backbone curve as random variables. In this second case, it is possible for the user to define the variance of the backbone parameters one wishes to treat probabilistically (log-normal distribution is assumed where the median is by default taken as the value initially provided by the automated fitting algorithm). Subsequently, Monte Carlo simulation is performed internally, where SPO2IDA realizations are created by sampling from within the user-defined parameter distributions and the IDA fractiles are updated accordingly.

3.5 Estimation of fragility curve parameters

Once the series of operations described above have been concluded, the fragility function parameters per limit state can be estimated based on the resulting approximated IDA curves of the structure. In the case of deterministic definition for the limit state EDP thresholds the logarithmic mean η is taken simply as the logarithm of the median IDA value at each threshold EDP level. The standard deviation β can be estimated as either the distance (in log-space) between the median and 84% fractile IDA or half the distance between the 16% and 84% fractile IDAs, at the discretion of the user (the latter being the default option, Eq. 2).

$$\begin{cases} \eta = \ln IM_{C,LS}^{50\%} \\ \beta = \ln\left[IM_{C,LS}^{50\%} \,/\, IM_{C,LS}^{16\%} \right] \text{, or alternatively} \\ \beta = 1/2 \cdot \ln\left[IM_{C,LS}^{84\%} \,/\, IM_{C,LS}^{16\%} \right] \end{cases} \tag{2}$$

In cases where the user has defined a probability distribution for the EDP threshold, rather than a deterministic value thereof, the parameter estimation procedure remains conceptually the same. The difference lies in the fact that Eq. 2 is applied for a number of EDP threshold realizations per limit state, sampled from the user-defined distribution and the final parameter estimates are provided by Monte Carlo simulation.

4 EXAMPLE APPLICATION

4.1 Four-storey “modern code” RC frame

In order to provide a fully-worked example of SPO2FRAG usage, a four-storey, bare, reinforced concrete (RC), plane frame was employed. This frame belongs to a symmetrical building designed under EN 1998-1 provisions in the context of a previous study (see [17] for more details) and was modelled numerically using the OpenSees open-code, structural analysis software [18]. Overall dimensions, member cross-sections, floor masses, shapes and periods of the first and second vibration modes and the SPO curve resulting from a first-mode-proportional

[2] Note that, for the sake of consistency limit state ranking (from milder to more severe) is adjusted automatically by the software, based on the corresponding user-defined (median or deterministic) thresholds.

lateral load profile are reported in Fig. 7. Inelasticity in the RC members was modelled following the concentrated plasticity approach, with plastic hinges at members' ends represented by rotational springs featuring trilinear backbones and hysteresis loops exhibiting mild pinching [19]. Concrete cracking was accounted for via the smeared crack approach of reducing the elastic pre-cracking stiffness of each member according to axial load [20].

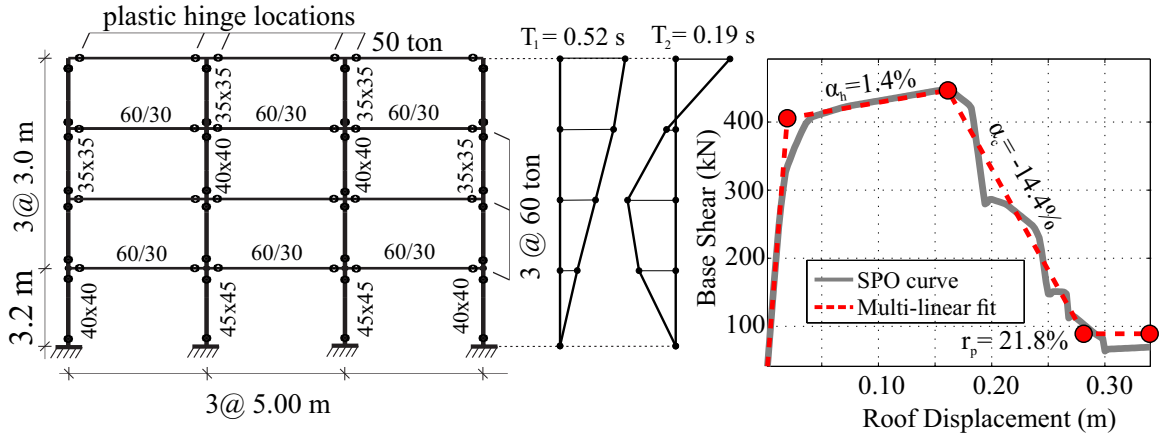

Figure 7: Dimensions, member cross-sections, floor masses, first two modes of natural vibration and first-mode SPO curve of the code-conforming four-storey RC frame used in the SPO2FRAG example application.

4.2 Example – fragility function calculation through SPO2FRAG

The SPO curve of the four-storey RC frame presented in the preceding paragraph is used as input for SPO2FRAG; displacements at all four diaphragms are provided via the input interface.

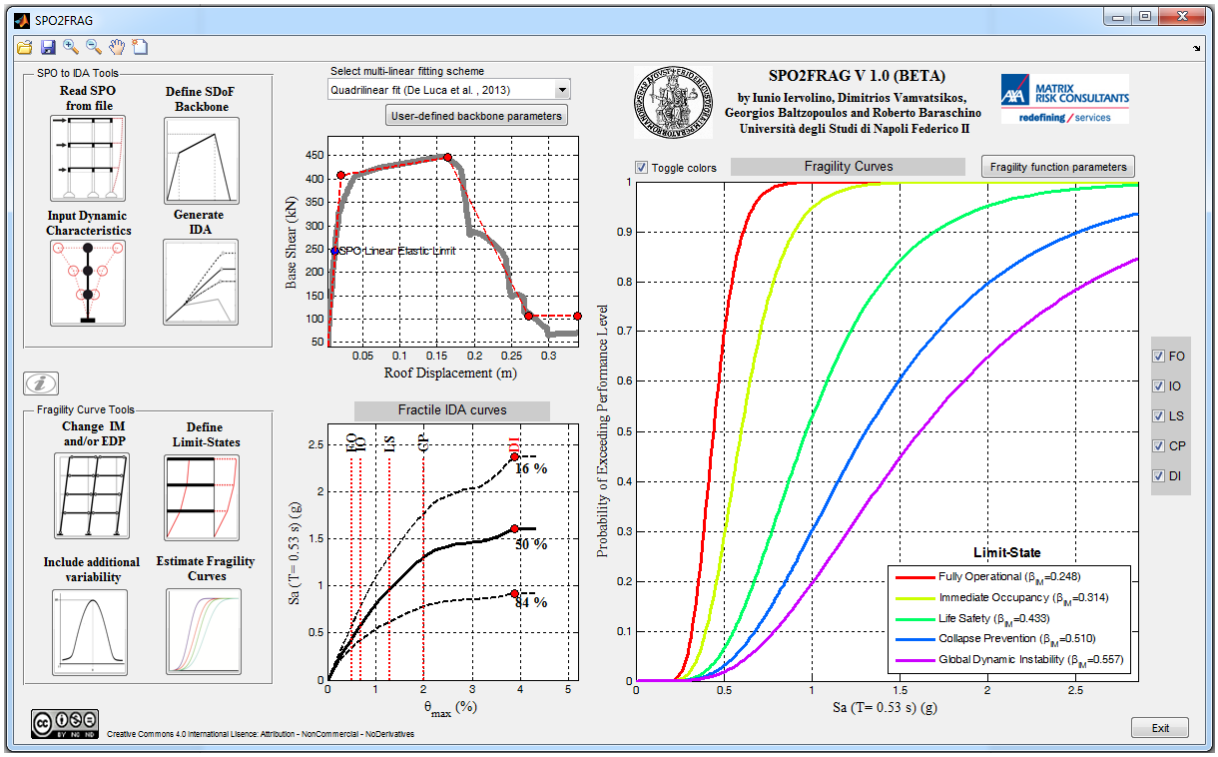

Figure 8: GUI view after implementation of the SPO2FRAG tool for an eight-storey "high-code" bare RC frame.

The roof displacement – base shear SPO is then subjected to a multilinear fit by the algorithm based on [12] (resulting fit is visible in Figs. 7, 8 and the corresponding backbone parameters in Fig. 4). Due to the availability of SPO results at all storeys, the only further input required, prior to obtaining the SPO2IDA approximate IDA fractiles, are the storey heights and masses (vibration period, modal participation factor and participating mass ratio are all calculated internally).

For this particular example, deterministic EDP thresholds (in terms of IDR) were assumed for the calculation. Indicative IDR thresholds for each limit state were calculated based on the *acceptance criteria* plastic rotation values for RC members found in [16]. A snapshot of the GUI display at the conclusion of this SPO2FRAG run can be seen in Fig. 8.

5 SPO2FRAG VS. IDA

It is only natural that the reference solution for the SPO2FRAG software should be the rigorous IDA procedure, i.e., the very same computational result that the tool is meant to emulate. Therefore, the same four-storey RC frame model that formed the basis of the preceding example application was also subjected to IDA using a set of forty-four records (far-field set in [9]; acceleration recordings from twenty-two stations, both horizontal components used separately). The resulting individual and fractile IDA curves can be seen in Fig. 9, in terms of both roof drift ratio (RDR) and IDR. The corresponding SPO2FRAG output is superimposed for comparison.

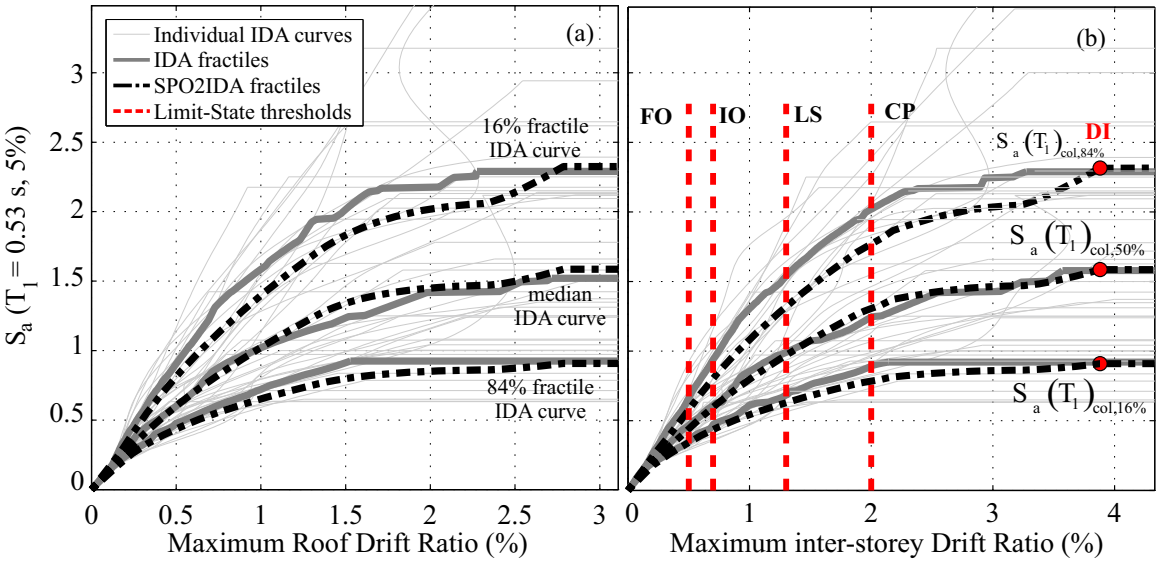

Figure 9: Comparison of SPO2FRAG approximated IDA fractiles with actual IDA results for a four-storey, high-code, bare RC frame using as EDP (a) roof drift ratio and (b) inter-storey drift ratio.

It can be observed that the adherence of the approximate SPO2FRAG result to its analytical counterpart is equally good for both cases of RDR and IDR, where the 50% and 84% fractile IDAs are concerned, but less so for the 16% curve. One of the reasons behind this is the fact that the shape of the SPO employed in this example (first-mode proportional lateral load profile) was able to capture one of the more unfavorable failure mechanisms (see also [13]). A comparison between the fragility functions resulting as SPO2FRAG output and those calculated by means of IDA can be found in Fig. 10.

Another meaningful comparison that can be made between the IDA and SPO2FRAG results, is between the annual rates of exceeding each limit state, λ_{LS}, as calculated by integrating the

fragility functions from the two procedures with the hazard curve for a given site, according to Eq. 3.

$$\lambda_{LS} = \int_{IM} P\left[IM_{C,LS} \le im\right] \cdot \left|d\lambda_{im}\right| \tag{3}$$

In Eq. 3 the notation λ_{im} is used to signify the rate of exceeding a given IM value while for the fragility function the notation introduced in Eq. 1 is followed. For this example in particular, the seismic hazard curve for the site of Caivano in southern Italy (in terms of 5% damped spectral acceleration at a period of 0.53s) was employed – Fig. 11. This hazard curve was calculated using the software REASSESS [21]. For this calculation the seismic source zones model of [22] was considered; Gutenberg-Richter [23] seismicity parameters for these zones were provided by [24], [25] and the ground motion prediction model used was that of [26].

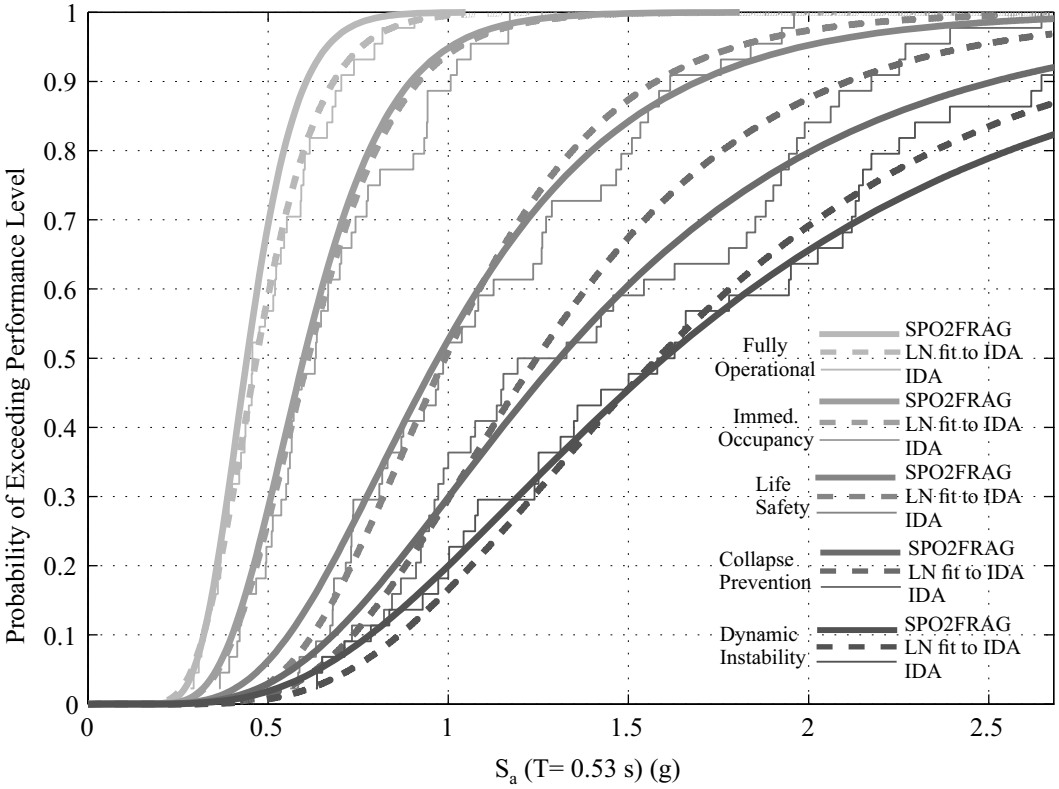

Figure 10: Comparison of fragility functions generated by SPO2FRAG and the same fragility functions estimated by means of IDA (see also Fig. 9). In both cases, the parameters of a log-normal (LN) distribution were estimated (see Table 1).

The results of these calculations can be found in Table 1, along with the estimators of the parameters corresponding to the curves appearing in Fig. 10. The estimators of the log-mean capacity per limit-state, η, correspond to taking the logarithm of the median IDA value for both of the IDA and SPO2FRAG cases. The estimator for the standard deviation of the logs, β, in the case of SPO2FRAG was the distance between the median and 16% fractile IM (see Eq. 2). In the case of IDA β was taken as the sample moment estimator of the standard deviation. It can be seen that the results display a reasonably good agreement between the approximate and rigorous procedure on all accounts.

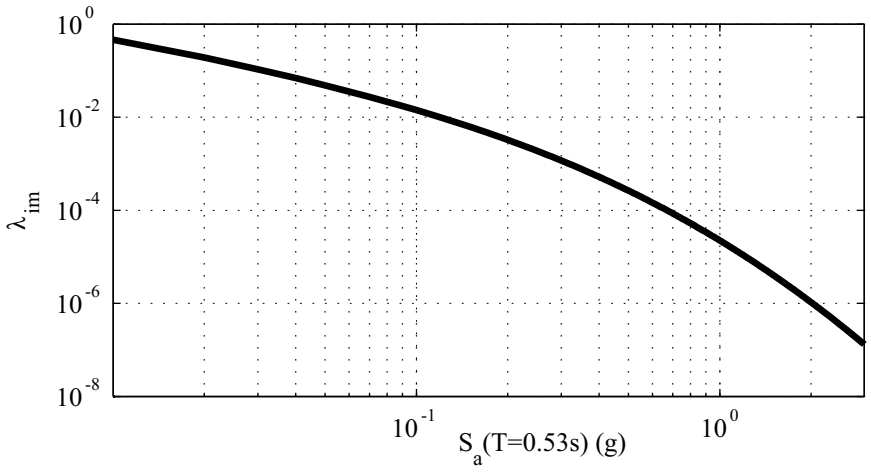

Figure 11: Hazard curve for an Italian site: annual rate of exceedance of 5% damped spectral acceleration at a period of 0.53s (period of equivalent SDOF of the four-storey frame in the example application).

Limit state	$\exp(\eta)$ (IDA)	$\exp(\eta)$ (SPO2FRAG)	β (IDA)	β (SPO2FRAG)	λ_{LS} (IDA)	λ_{LS} (SPO2FRAG)
Fully Operational	0.456 g	0.442 g	0.294	0.187	$4.9\cdot10^{-4}$	$4.5\cdot10^{-4}$
Immediate Occupancy	0.631 g	0.599 g	0.318	0.269	$2.0\cdot10^{-4}$	$2.1\cdot10^{-4}$
Life Safety	0.988 g	0.972 g	0.362	0.401	$5.3\cdot10^{-5}$	$6.6\cdot10^{-5}$
Collapse Prevention	1.260 g	1.308 g	0.410	0.484	$2.8\cdot10^{-5}$	$3.5\cdot10^{-5}$
Global Dynamic Instability	1.590 g	1.584 g	0.571	0.534	$1.7\cdot10^{-5}$	$2.4\cdot10^{-5}$

Table 1: Parameter estimators for the log-normal fragility functions of the illustrative example (see also Fig. 10) and corresponding calculated annual rates of exceeding each limit state at a site in Southern Italy.

6 CONCLUSIONS

This article dealt with the introduction of the SPO2FRAG V1.0 software. It is an interactive tool, coded in MATLAB® , that can be used for approximate, computer-aided calculation of building seismic fragility functions, based on static pushover analysis. It was shown that SPO2FRAG can provide a convenient and expeditious solution to the problem of analytical calculation of building fragility functions, at least in cases where the basic assumptions behind SPO analysis and IDA hold.

In a future, second version of the SPO2FRAG tool, whose development is currently underway, additional options are expected to be available. These additional features will include, among others the possibility to manage input consisting of more than one SPO curve per structure (corresponding to either loads applied in two principal directions of a three-dimensional structure, or different load patterns applied in the same direction – or both) and an in-built library of deformation limits per limit state from the literature.

Abstract. *Disaster risk reduction has become a global urgent need. Similarly to other natural hazards, earthquakes may cause significant damages on a large scale. In Europe, seismic events mainly affect historical city centers, which are characterized by dense urban structure, usually constituted by ancient masonry and pre-code R.C. buildings, often in aggregate sequence. Historical city centers are very much part of the European cultural heritage and their preservation is considered a strategic issue for the EC due to their tangible and intangible values. Furthermore, it is an undisputable fact that natural disasters may have severe negative short-term economic impacts on the built environment and adverse longer-term consequences for economic growth and development. For this reason, the development of an efficient digital tool for urban seismic risk assessment and resilience enhancement becomes essential. With this aim, an original numerical procedure is proposed in this paper, based on multidisciplinary concepts combined in an innovative way. First of all, the concept of Limit States for the Minimum Urban Structure is introduced and described by means of simple mechanically based models. Then, elliptically distributed vulnerability indices are worked out by considering multidirectional seismic hazard, and 2D seismic risk assessment computation is performed. The results are implemented within the GIS software, where they are easily shown and discussed thanks to the graphical mapping tool. The proposed approach allows the definition and evaluation of a global intervention plan for resilience enhancement at the urban scale. Finally the proposed numerical procedure is applied for validation to the Italian city-center of Concordia Sulla Secchia (Italy), damaged by the 2012 Pianura Padana Earthquake (PPE). The predicted damage scenarios are compared with the actual post-seismic damage scenarios in order to evaluate the accuracy of the proposed evaluation procedure.*

1 INTRODUCTION

Disaster risk reduction is one of the biggest global challenge, as attested by the U.N. [1]. The first step to achieve disaster resilience enhancement is to propose unified guidelines for disaster management. Among all natural events, earthquakes produce most damage on a vast scale. They cause high number of casualties, severe economic damages and are a major threat for cultural heritage sites. In Europe, historical city centers represent an essential part of the cultural heritage. This immeasurable asset is a "strategic resource for a sustainable Europe" that need to be preserved [2]. Among all European countries, Italy holds the highest number of listed heritage sites as confirmed by UNESCO (*whc.ujnesco.org*). Seismic risk assessment and urban risk management improvement is the only way to avoid casualties, damages, and consequent settlements abandonment.

2 PROBLEM DEFINITION

Most authors express seismic risk, *R*, as the relationship between hazard, vulnerability and exposure, as reported in Eq. (1):

$$R_{ie|T} = |(H_i \otimes V_e) \otimes E|_T \tag{1}$$

where *H* is the hazard, i.e. the probability of exceedance of the seismic activity level of intensity *i*, during a specified recurrence period *T*; *V* is the vulnerability, i.e. the intrinsic predisposition of the *e-th* exposed element to suffer damage, resulting from a seismic event of intensity *i*; *E* is the exposure of all the *e-th* exposed elements. *H* and *E* are directly linked to the site geological properties and the social and economical value of buildings respectively. V, on the contrary can be determined with different methods [3]. Detailed approaches, highly efficient for individual buildings, become ineffective while moving to urban scale analysis. In fact, the use of less sophisticated but more practical methods is required by such complex task.

Currently, one of the main assessment methods used by researchers is the combined approach of the *Vulnerability Index* method [4, 5, 6] and the *Macroseismic* method [7, 8]. The first method determines the vulnerability of buildings as a weighted sum of 11 parameters, which represents the main features that influence the buildings' response to a seismic event. To determine the vulnerability index, a detailed inspection of buildings is required, regarding both geometrical and structural aspects. I_v, have always to fall within the range $0 \div 100$. The Macroseismic method derives from the definition of the European Macroseismic Scale, *EMS-98* [9] and related *mean damage grades*, $\mu_D \in [0 \div 5]$, and *Damage Probability Matrixes* (DPMs). Buildings are ranged into 6 vulnerability classes with an assigned *Vulnerability parameter*, V, which can be correlated with the I_v parameter of the aforementioned method, using Eq. (2). Then, using a probabilistic approach, it is possible to determine the damage level the constructions will undergo after an earthquake as well as the number of collapsed or unusable buildings and the seismic effect on the population.

$$V = 0.592 + 0.0057 \cdot I_V \tag{2}$$

This approach presents some main limitations:

a) it considers only masonry constructions;

b) it does not take into account the effects of buildings in aggregate sequence;

c) it considers the overall vulnerability as the simple sum of buildings' vulnerabilities.

Therefore, a complete methodology for seismic risk assessment and management at urban scale is still lacking.

3 MULTIDIRECTIONAL URBAN RELIABILITY ASSESSMENT (MURA-SH) METHOD

In this work, a new methodology is presented as "Multidirectional Urban Reliability Assessment - Seismic Hazard (MURA-SH)" method [10], based on the improvement of the previously described method.

3.1 Vulnerability index integration for masonry aggregates

A modified approach to the aggregate evaluation proposed by [11] is used: 5 additional parameters (see Tab. 1) are considered together with the 11 ones of the original Vulnerability Index Method [4, 5, 6]. The additional parameters take into account the building's behaviour when inserted into an aggregate sequence. It is important to remark that contiguity of buildings can either increase or reduce the seismic vulnerability within the range of ±30% of the detached building vulnerability.

Parameters		Class C_{vi}				Weight
		A	B	C	D	p_i
P12	Interactions in elevation	0	15	25	45	1.25
P13	Floor plans interactions	0	5	15	45	1.75
P14	Presence of offset ceilings	0	25	35	45	0.75
P15	Structural of typological heterogeneity	0	10	20	45	1.50
P16	Percentage difference within facade openings	0	15	35	45	1.25

Table 1: Vulnerability Index I_V additional parameters for masonry buildings in aggregate sequence

3.2 Proposed $I_V - V$ correlation for R.C. buildings

Historical city centers often present an heterogeneous mix of masonry and R.C. constructions. In this work, a mathematical correlation between the Vulnerability Index method and the Macroseismic approach for R.C. building is proposed, as reported by Eq. (3).

$$V = 0.8568 - 0.0083 \cdot I_V - 0.000039 \cdot I_V^2 \tag{3}$$

The proposed correlation is determined following the same analytical steps described in [3] but, unlike the linear correlation used for masonry buildings, a quadratic correlation is adopted for R.C. constructions.

3.3 Vulnerability ellipses for directional risk assessment

Buildings have usually a non regular plant shape and present different structural properties in each direction. Vulnerability is considered as the sum of isotropic and anisotropic factors [12]. The isotropic factor consists of all features not related to the input direction, like building's material quality and age. The anisotropic one includes all features dependant on the input direction, like the structural strength and stiffness as well as the boundary conditions. For this reason, each building vulnerability can be geometrically represented by an *ellipse*. Since buildings are arranged in a city according to different orientations, seismic events of similar intensities but different directions can produce different effects. In the current work, a directional risk assessment is proposed, following 3 subsequent steps:

a) Main directions *x* and *y* of the building under assessment are found out (Fig. 1a). Vulnerability indexes I_X and I_Y are then determined in both directions, by considering the different resistant areas in *x* and *y* direction. I_X and I_Y are now the semi-axes of the

vulnerability ellipses (Fig. 1b);

b) An external reference system is fixed (for example, in this case, cardinal axes E-N). The angle between the x main direction and the cardinal axes E is called θ, (Fig. 1c). By considering $I_X = a$ and $I_Y = b$, the vulnerability ellipse is determined through Eq. (4):

$$\frac{(x \cdot \cos\theta + y \cdot \sin\theta)^2}{a^2} + \frac{(y \cdot \cos\theta + x \cdot \sin\theta)^2}{b^2} = 1 \tag{4}$$

c) Given a possible earthquake direction, α, vulnerability ellipses return the corresponding vulnerability value I_α for each building.

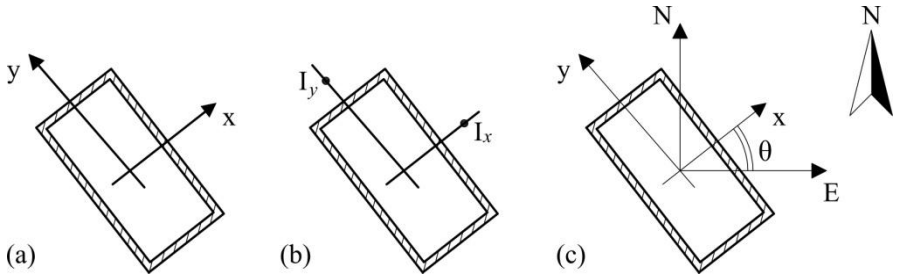

Figure 1: (a) Main directions of a building; (b) vulnerability indexes I_X and I_Y along main directions and (c) θ angle definition.

3.4 Definition of urban system reliability

The overall vulnerability of a city is not the simple sum of all buildings' vulnerability. Different constructions have different roles, which make them more or less relevant for the settlement, and their overall functioning is possible thanks to the accessibility of connection elements (routes, bridges, public open spaces, ecc). Furthermore, urban management policies must deal with the emergency phase after an earthquake, as well as with the *minimum urban structure* [13] preservation, in order to prevent the settlement abandonment. In this work, a performance-based approach for the urban system has been introduced, by adopting the definition of the *limit conditions for settlements* [14, 15]. Following this approach, the probability of the *e-th* building to undergo a certain damage level $P(D_k)|_e$, is accounted in a model that represents the overall city behavior with reference to the most significant limit conditions, expressed as CLE (emergency), CLV (life-saving) and CLD (damage).

- **CLE condition** - Only essential activities for the emergency phase are considered and the majority of the buildings can undertake even severe damages. The CLE is represented by a *series* of emergency sub-systems (see Fig. 2).

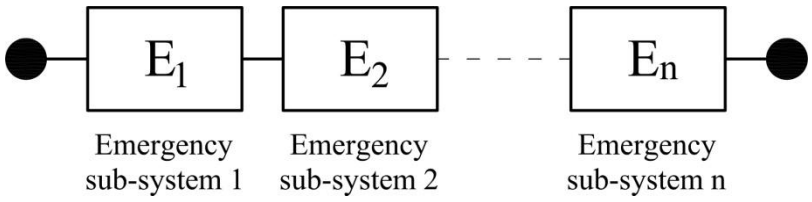

Figure 2: Urban system behaviour of the emergency limit condition (CLE)

Each *emergency sub-system* includes a strategic building, whose operation is essential in the emergency phase, and all "interfering" buildings related to it. An interfering building is an ordinary building that faces a strategic connection route (from/towards a strategic building or an emergency area). The CLE survival probability (*urban reliability*) is evaluated using Eq. (5).

$$P[\text{system survival}] = \prod_{i=1}^{n}(1 - P_i) \tag{5}$$

The component's failure probability P_i is defined according to the *importance class* c_u of buildings [16]. In particular, only the collapse, even partial, has to be prevented for interfering buildings (c_u= I, II), while any activity has to continue without interruption for strategic buildings (c_u= III, IV), see Eq. (6).

$$\begin{aligned} &c_u = \text{I, II (interfering)} \quad P_i = P(D4) + P(D5) \\ &c_u = \text{III, IV (strategic)} \quad P_i = P(D2) + P(D3) + P(D4) + P(D5) \end{aligned} \tag{6}$$

- **CLV condition** - The whole settlement is considered. The complete functionality of all strategic buildings is guaranteed, and only modest-to-long interruption of ordinary urban functions is accepted. The behaviour of the city is represented by a series-parallel combination of strategic and ordinary sub-systems (see Fig. 3). Each strategic sub-system includes an emergency system (see CLE) along with their "redundancy", i.e. other strategic systems of similar functions but not essential during the emergency phase. Ordinary sub-systems are considered in order to recover the settlement pre-seismic standard, including residential and economic activities. The CLV probability is evaluated using Eq. (7).

$$P[\text{system survival}] = \prod_{i=1}^{n}\left(\prod_{j=1}^{m} P_{ij}\right) \tag{7}$$

where P_{ij} accounts the interaction of the considered sub-systems and is defined by Eq. (6).

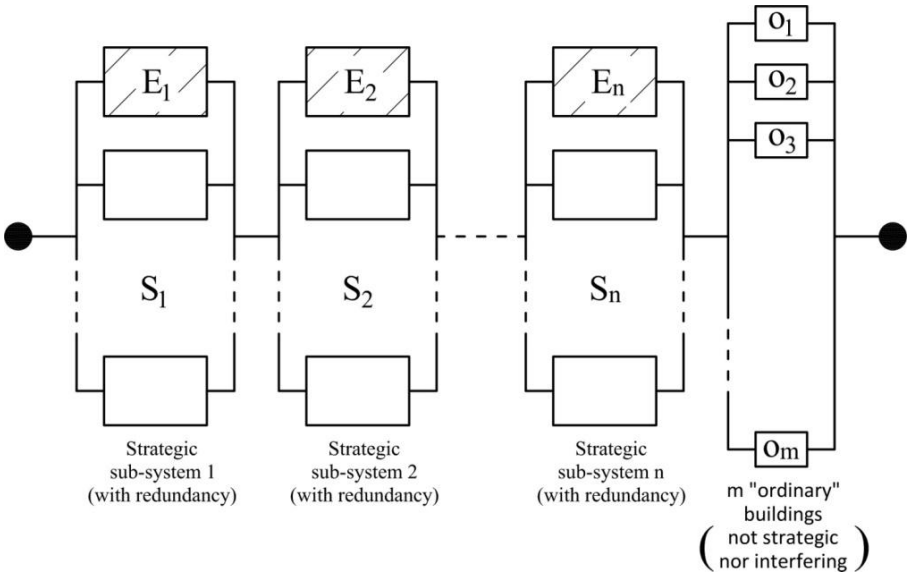

Figure 3: Urban system behaviour of the life-saving limit condition (CLV)

- **CLD condition** - Conceptually similar to the CLV, the only short-to-modest or partial interruption of ordinary urban functions is accepted. The behaviour of the city is still represented by a *series-parallel system* (see Fig. 3), and the urban reliability is evaluated using Eq. (7) where P_{ij} is defined by Eq. (8). The CLD represents the possibility for the settlement to undergo limited damage after an earthquake in order to guarantee the shorter recovery time targeted by the urban management policy.

$$c_u = \text{I, II (ordinary)} \qquad P_i = P(D3) + P(D4) + P(D5)$$

$$c_u = \text{III, IV (strategic)} \quad P_i = P(D2) + P(D3) + P(D4) + P(D5)$$

4 COMPUTER-AIDED RISK ASSESSMENT

The MURA-SH method application can be time-consuming even for small settlements, mainly due to the complexity of the urban system reliability model and the multi-directional damage scenarios evaluation. The development of a computer-aided procedure for the MURA-SH numerical implementation becomes highly efficient from the computational point of view by using the MATLAB® software. The proposed numerical procedure is presented in herein.

The preliminary phase of the procedure consist on the definition of a *.txt* input file listing all the required data of the MURA-SH method. The input files format holds seven columns and as many rows as the number of buildings under assessment. The columns data contain the following information:

- Vulnerability index along *x*-main direction, I_X;
- Vulnerability index along *y*-main direction, I_Y;
- θ angle, see Eq. (4);
- Structure Identifier (ID = 0 for masonry buildings, ID = 1 for R.C. buildings and ID = 2 for other structural types);
- Local soil amplification factor related to each building, F_a,
- Importance class, c_u [16];
- Occupants' number.

All data are loaded from the input file and vulnerability ellipses are created for every building using Eq. (4). Then, a coordinates transformation from the local to the global reference system is arranged. Finally, oriented vulnerability indexes I_α are evaluated.

Indexes I_α have to be converted into vulnerability values V_α using Eq. (2) and (3) depending on the structural type. Mean damage grades, μ_D, are evaluated for increasing intensities in the range $I_{EMS-98} = 5 \div 12$ with the equations of the Macroseismic method [8], but assuming the ductility factor, Q, equal to 2.1 for masonry buildings and 3 for other buildings. This assumption is introduced to consider that masonry structures can undergo local failure modes with limited ductility, when the global behavior is not guaranteed by the structural features.

Then, damage distributions histograms are defined making use of the $Beta$ probability density function (PDF), already included in the MATLAB® library as "betapdf". Numerical integration is made within defined intervals with the MATLAB® "trapz" function. Evaluated

damage probabilities are listed in matrixes for increasing intensities in the range $I_{EMS-98} = 5 \div 12$.

Total damage occurrence probability is used for losses evaluations, assessing the number of damaged or unusable buildings as well as the number of casualties and severed injured or homelessness. Equations to evaluate these data can be found in [3].

Finally, computed probabilities are combined to determine the reliability of the urban system, using equations introduced in §3.4, depending on the considered limit condition (CLE, CLV, CLD). The overall settlement reliability is evaluated for every direction α and for increasing intensities $I_{EMS-98} = 5 \div 12$. The proposed method application allows to easily predict which earthquake direction will cause the worst damage scenario, and the evolution of the settlement performance from moderate to strong earthquake intensity.

The overall MURA-SH numerical procedure is summarized in flowchart of Fig. 4.

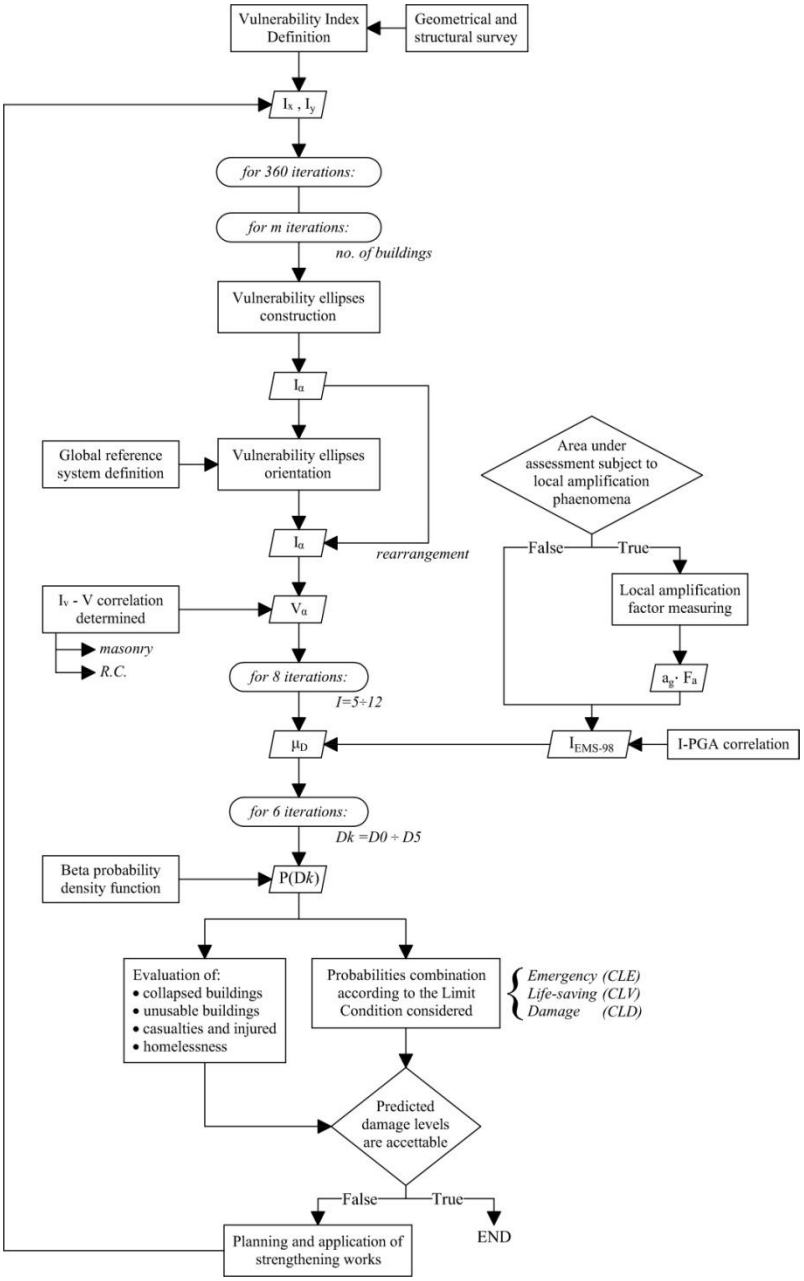

Figure 4: The MURA-SH method flowchart.

5 MODEL VALIDATION ON A CASE STUDY

Italy has recently experienced a seismic event (PPE, 2012). Among all the affected settlements, the city of Concordia sulla Secchia has a peculiar historical city center, constituted by an heterogeneous mix of masonry and R.C. constructions, built in different periods of time and mostly in aggregate sequence. The Municipal authorities of Concordia commissioned a post-earthquake survey, regarding its CLE sub-system, to the University of Ferrara, gathering geometrical and structural features of the majority of the buildings. Thanks to the available information, the MURA-SH method has been applied to the CLE sub-system of Concordia and μ_D values have been obtained for the PPE event. The PPE registered intensity that hit he city was within the range $I_{EMS-98} = 7 - 8$ (source: INGV) and the spatial distribution of seismic waves had the WNW-ESE predominant direction, i.e. 22° East (source: Italian Civil Protection).

Predicted damages were subsequently compared to the observed ones [10]. The comparison shows that, for $I_{EMS-98} = 7$, the predicted damage matches the observed damage on 15 of the 42 total number of buildings, with a positive feedback on the 36% of cases; for $I_{EMS-98} = 8$, the predicted damage matches the observed damage on 19 of the 42 total number of buildings, with a positive feedback on the 45% of cases. Maximum I_{EMS-98} registered during the PPE was equal to 8, and Concordia Sulla Secchia was the second most affected city. Therefore, it is reasonable to deduce that the actual intensity event that hit the settlement was closer to the upper bound of the measured range. The MURA-SH procedure needs to undergo more validations to improve the results accuracy. However, recognizing the task complexity, the obtained results are considered promising.

Some numerical results obtained with the MATLAB® procedure are shown in Fig. 5, where the collapse probability is represented along with the survival probability (*reliability*) of the CLE sub-system. Starting from intensity $I_{EMS-98} = 6$, the collapse probability assumes positive values and rapidly increases while the reliability drops to zero, accordingly with the CLE series system definition.

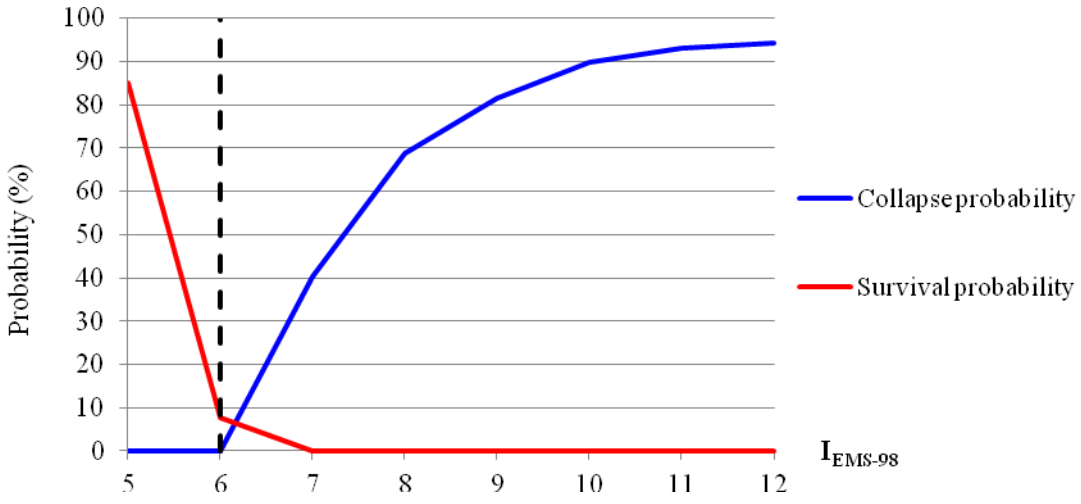

Figure 5: Collapse probability and survival probability of Concordia sulla Secchia CLE sub-system for increasing seismic intensities.

Furthermore, assessment output values can be reported directly on a city map (see Fig. 6), using the geospatial processing program ArcMap, of the Esri's ArcGIS suite (*http://desktop.arcgis.com/en/arcmap/*). With this representation it is possible to have an immediate overview of the earthquake effects for different directions and increasing seismic in-

tensities. A unique "feature identifier", also called FID, has to be assigned to every building in order to correctly refer corresponding output results. Assessment output values need to be previously organized in Excel files, using different sheets for increasing seismic intensities. Different colour maps can be used to represent the effects of increasing seismic intensities, and to identify most vulnerable areas.

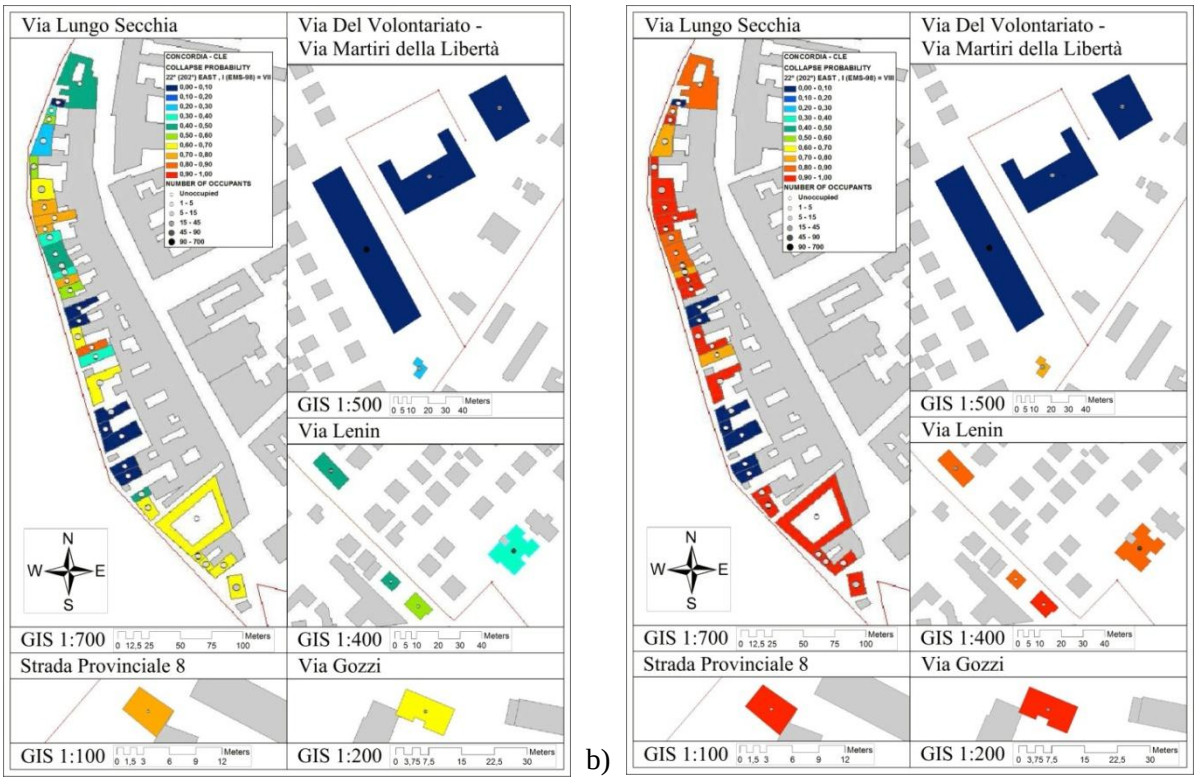

Figure 6: Mapping results of the collapse probability for the Concordia sulla Secchia CLE sub-system for (a) $I_{EMS-98} = 7$ and (b) $I_{EMS-98} = 8$.

6 CONCLUSIONS

In this work, a new methodology for the risk assessment at urban scale called MURA-SH method has been proposed. The MURA-SH method includes R.C. buildings in the evaluation, takes into account the effect of buildings aggregate sequence and performs multi-directional assessments, using the vulnerability ellipses. The MURA-SH method applies a performance-based approach to the settlement, with the definition of the urban system reliability. Thanks to its features, this method can predict whether the settlement will be able to withstand an earthquake, and what performance loss it will endure. The MURA-SH method has been implemented in a computer-aided procedure using the MATLAB® software. The obtained output results can be easily visualized with simple curves and GIS maps.

The proposed MURA-SH method has been applied on the case study of the historical city centre of Concordia sulla Secchia (Italy). The settlement experienced the PPE (2012) and a post-seismic survey of the CLE sub-system was carried out. The possibility to compare predicted damage scenarios to the observed ones has been extremely important to test the MURA-SH method accuracy. From the comparison, a matching rate of 45% ($I_{EMS-98} = 8$) was found. The procedure needs to undergo more validations to improve the results accuracy. However, recognizing the task complexity, the MURA-SH method results are considered promising.

Abstract. *Using large-scale seismic risk assessment studies for reduction of potential losses is becoming an evermore popular trend around the globe. Accordingly, a number of different models and techniques for the characterization of the different risk variables have proliferated in the recent years. Furthermore, the quality, or accuracy, of risk estimates will be certainly higher when a truly integrative model is employed, characterizing hazard, (physical and social) vulnerability and exposure in the most complete as possible manner. Regions with a large percentage of non-seismically designed buildings are particularly vulnerable to seismic events and are those that can benefit the most from risk assessment studies for decision making. As such, the main purpose of this study is to propose a framework for integrated seismic risk assessment in Palestine, where earthquake induced risk awareness is still at an early stage. A methodology to combine an existing state-of-the-art hazard model with new vulnerability and exposure models, specifically built upon local field surveys and national data collection, is proposed. The outcome of the study will enable the identification of the regions that are more vulnerable to earthquakes and future rapid loss assessment at regional scale.*

1 INTRODUCTION

The seismic activity in Palestine is not negligible and is largely affected and controlled by geodynamic processes acting along the Dead Sea Transform (DST). The DST is a north-south striking left-lateral shear zone extending from the incipient oceanic ridge (Red Sea) in the south to the Taurus plate collision in the north (Turkey). About 105-110 km of left-lateral displacement between the African and Arabian tectonic plates took place along this fault system during the last 15 million years. Historically, estimated events reached up to IX in the Modified Mercalli Scale in the Dead Sea region. In the same area, the determinable magnitudes of the recorded earthquakes range between 1.0 and 7.0 on the local magnitude Richter scale.

Together with observed seismicity, the Palestinian region faces important issues related to structural and societal factors. First, a high vulnerability, as a direct result of a high percentage of weak buildings not complying with seismic design requirements, thus with high potential for damage and losses. Secondly, measures of seismic risk mitigation are not enforced with national and public policies, which results in an absence of effective control of design and construction practice. The two aforementioned elements are exacerbated by the weakness in the general institutional capacity in disaster management, by insufficient professional capabilities of both engineers and decision makers and by a lack of awareness of citizens on seismic risk matters.

In the light of such facts, strategic directions were devised for the implementation of seismic disaster risk reduction. Recently, the population of Palestine has become more aware of the concept of seismic risk, significantly due to the results of the FP7-SASPARM (Support Action for Strengthening Palestinian-administrated Areas capabilities for Seismic Risk Mitigation) project, held during 2013 and 2014. SASPARM activities were focus on the strengthening of the research capabilities of An-Najah National University through the development of a comprehensive database of existing research data, the promotion of training for scientists and students in the field of seismic risk with the collaboration of European partners – EUCENTRE (European Centre for Training and Research in Earthquake Engineering) and IUSS (Institute for Advanced Study). Subsequently, new activities proposed within the DG-ECHO SASPARM 2.0 (2015-2016) project are further raising such awareness and strengthening their capabilities to cope with seismic risk. Engagement in training courses and workshops takes place not only at the local community level but also even Palestinian stakeholders, governmental (GO) and non-governmental (NGO) institutions, students and practitioners are effectively involved. One of the major goals of the SASPARM 2.0 initiative is the development of an integrated seismic risk model for Palestine, based on a state-of-the-art hazard model and in-field collected vulnerability and exposure data. The city of Nablus, the first Palestinian city to join the UNISDR's Making city resilient campaign, constitutes the case study area for the implementation and calibration of the model. In this paper, the framework for the achievement of the integrated model for the challenging Palestinian region is described, together with the main assumptions and assessment of options for the different risk components.

2 CONTEXT – THE SASPARM 2.0 PROJECT

The activities of SASPARM 2.0 (Support Action for Strengthening Palestine capabilities for seismic Risk Mitigation) are organised into eight main operative tasks, comprising the collection of vulnerability data and implementation of vulnerability models; training for targeted groups; development of self-assessment tools to understand potential unsafe situations and the related mitigation measures (retrofitting and insurance coverage). The project is managed by the same consortium of SASPARM and is creating a Web-Based Platform (WBP) for seismic

risk mitigation, which integrates a database of vulnerability data on buildings, collected on field.

The awareness of the community is a fundamental step in the resilience process, since the citizens have to monitor their individual properties and be able to understand, with and, when feasible, without the advice of an expert, if their house can withstand an earthquake or if retrofit is required, applying seismic standards. On the other hand, practitioners as well as governmental (GO) and non-governmental (NGO) stakeholders have to be made aware of the importance of the right application and implementation of the new Seismic Building Code. The outcomes and tools released during SASPARM 2.0 will put together all the available information on the different risk components for a better management and mitigation of seismic risk in Palestine. An overview of the framework defined for the development of an integrated risk model for Palestine, together with the description of choices and assumptions for the main risk components is given in the following sections.

3 SEISMIC HAZARD

The Eastern Mediterranean region, due to its geological structure that is characterized by the junction of major tectonic plates (African, Arabian and Eurasian) results in very high tectonic activity. Over the time, the region has indeed frequently witnessed natural hazard phenomena, resulting in great losses of life and property. Field studies and investigations indicate that large portions of the land surface, population and infrastructure of the region have been subjected to earthquakes in the past or will be subjected to earthquakes in the future [1].

Seismicity information including historic and prehistoric data indicates that major destructive earthquakes have occurred in the Jordan – Dead Sea region (Fig.1). The most recent earthquake (M_L 5.2) took place on February 11th, 2004 [2].

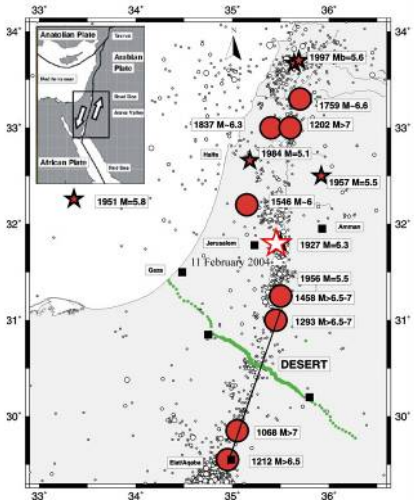

Figure 1. Seismic Activity in the Dead Sea Transform Region for the period 1000 - 2007.

Currently, in Palestine the in-use seismic hazard map dates back to 1997 [3]. It is defined in terms of peak ground acceleration, which is assessed for 10% of exceedance in 50 years for generic rock (Fig.2). Based on such hazard map, Palestine has been divided in four seismic zones: 1, 2A, 2B and 3. Adopting the American Uniform Building Code (UBC97), a seismic zone factor (Z) has been associated to each of them (Fig.3).

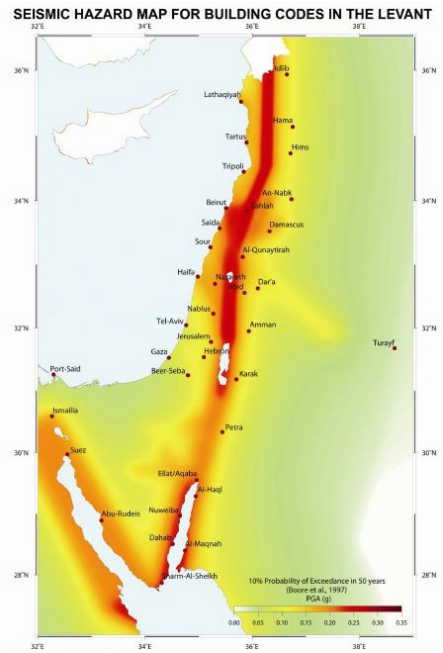

Figure 2. Hazard Map with 10% probability of exceedance in 50 years [2]

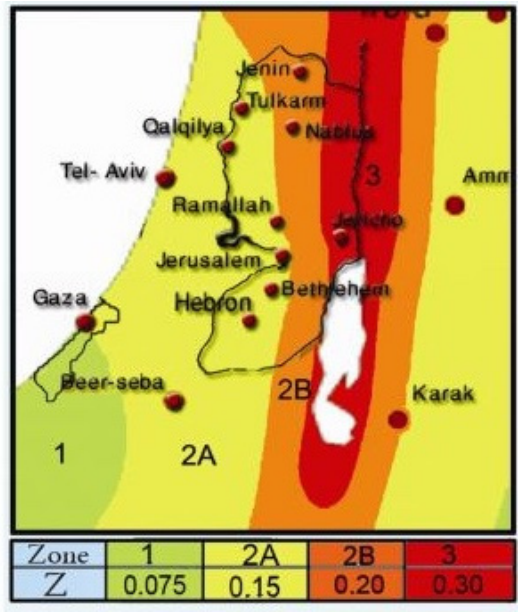

Figure 3. Seismic Zone Factors in Palestine according to Hazard Map and UBC 97.

Additional initiatives have been undertaken to improve such hazard map, aiming to improve the global and regional seismic hazard evaluation in the Eastern Mediterranean region. Specifically, three projects up to the early 2000s are worth mentioning:

i. GSHAP (Global Seismic Hazard Assessment);
ii. SESAME (Seismotectonic and Seismic Hazard Assessment of Mediterranean Basin); and
iii. ESC/WG-SHA (European Seismological Commission Working Group on Seismic Hazard Assessment).

The first regional seismic hazard map developed for the European – Mediterranean region in terms of peak ground acceleration was GSHAP (1992-1999) and was compiled based on the integration of independent hazard results of a number of different test areas and regional and national programs [4]. During the GSHAP project, no attempts were made to harmonize the individual regional or national seismogenic models in the Mediterranean.

For such reason, a further endeavour for the regional hazard assessment in the Mediterranean was carried out within SESAME (1996-2000). By considering a new geometry implementation to avoid the lack of data between different regional sources or gaps at border areas, SESAME succeeded in the final unified seismogenic source model for the Mediterranean region, which consists of 346 sources. Each source was characterized by the corresponding seismicity parameters in terms of minimum and maximum magnitude and earthquake occurrence rates, as illustrated in Fig. 4 [5].

The third project, ESC/WG-SHA, was completed in 2002, and resulted in a unified seismic hazard modelling for Europe and the Mediterranean, integrating the GSHAP Central Northern Europe results with those from SESAME for the Mediterranean (Fig. 5). This comprehensive model for seismic hazard assessment allows, for the first time, the generation of hazard maps, expressing ground motion in different parameters, for different soil conditions and probability levels [6].

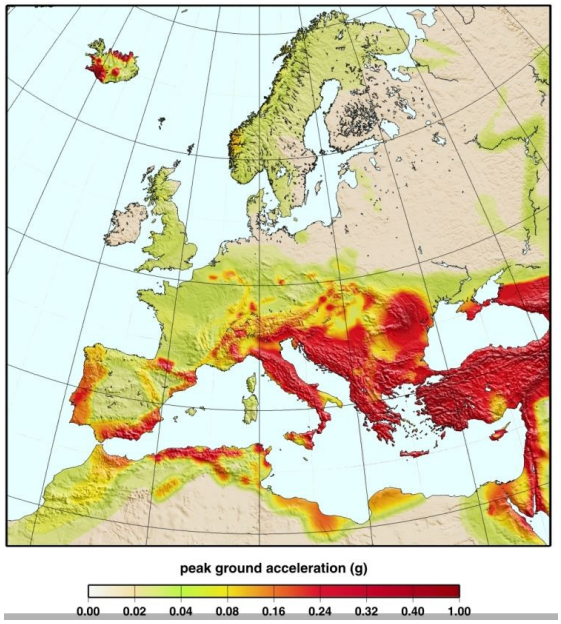

Figure 4. SESAME map with 10% probability of exceedance in 50 years for stiff soil condition [5]

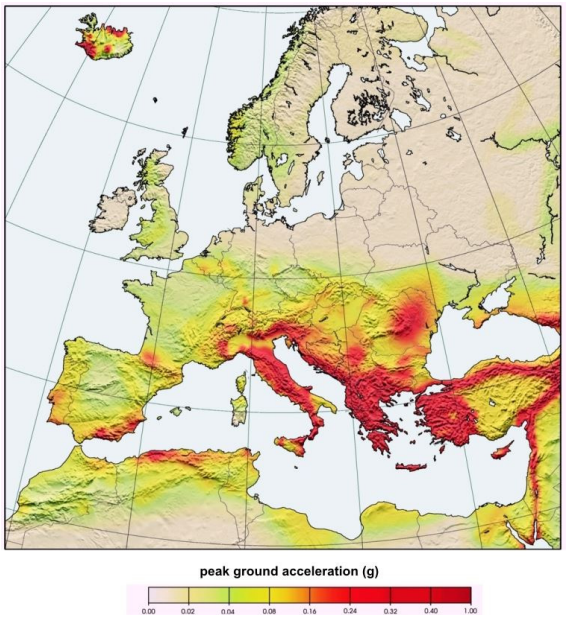

Figure 5. ESC/WG-SHA map with 10% probability of exceedance in 50 years for stiff soil condition [5]

For the development of the integrated risk model of the study herein presented, the use of a further updated hazard model is planned. The updated model is part of the outcomes of the EMME (Earthquake Model of the Middle East Region) project, which aimed at the assessment of seismic hazard, the associated risk in terms of structural damages, casualties and economic losses and also at the evaluation of the effects of relevant mitigation measures in the Middle East region. EMME was carried out between 2010 and 2013 and the final products have just been publicly released [7].

The model for Palestine will thus make use of the most up-to-date hazard data from the EMME initiative. The hazard model will be further employed to selection of real records for fragility analysis (input for Section 4 – Vulnerability), through disaggregation and PSHA calculations (using OpenQuake [8]) for the Nablus municipality.

4 VULNERABILITY

The vulnerability model will foresee two components: physical, calculated for a number of building classes that constitute the taxonomy for Nablus and social, taking into account the feedback provided by the population through specifically developed questionnaires.

4.1 Physical vulnerability

Physical vulnerability is a measure of how prone a building is to damage for a given severity of the ground shaking. The aim of most research works dedicated to this subject is to give a mathematical formulation to vulnerability. The two widely used formulations to describe the vulnerability are: damage probability matrices and fragility curves. The latter describe the conditional probability of exceeding a certain damage limit state in terms of the selected intensity measure of the ground motion. The same probability in discrete terms is a component of a damage probability matrix. In the technical literature, damage probability matrices have been produced when the vulnerability studies are based on observations: data from post-earthquake surveys are treated probabilistically to identify the conditional probability of damage and hence the terms of the damage probability matrices. On the other hand, fragility

curves are calculated when the vulnerability studies are mechanics-based, i.e. the seismic behaviour of structures is modelled. The model can be more or less simplified as a function of the level of knowledge of the building stock. The option of quantifying the vulnerability through damage probability matrices is not feasible in Palestine, since databases of damages occurred after past earthquakes are not available. Therefore, sets of fragility curves will be defined for the as built structural typologies identified in Nablus first and then in other Palestinian municipalities.

The case study of Nablus foresees a web database to gather physical vulnerability data on buildings. The definition of a catalogue of building typologies is the first step for large scale vulnerability assessment. Recognition of structural types in Nablus was undertaken by a selected group of practitioners already trained during SASPARM. As it will be described with more detail in [9], the as-built in Nablus can be classified according four main building types: reinforced concrete frame buildings; shear walls buildings; masonry buildings; buildings with soft storey **(**Fig. 7). Once the building types have been identified the seismic vulnerability of each type is assessed.

Citizens, practitioners and university students are the main groups involved in the in-situ collection of building data through specially designed forms. The collection forms, one detailed for practitioners and one more simple for citizens, aim to detect the structural characteristics of Palestinian buildings and it is a self-assessment tool to understand how their own buildings are made up of (Fig. 6). The forms allow a quick evaluation as a first cataloguing of the building stock, since they are made of typological and metrical data of the structures. The practitioners' form is composed of six sections, while the citizens' one of four. The sections of the forms are summarised in Table 1.

Section	Practitioners	Citizens
1	Identification of the Building	Identification of the Building
2	Description of the Building	Description of the Building
3	Structural Data	Main material of the Building's Vertical Structure
4	Regularity	Notes
5	Geomorphological Data	
6	Notes	

Table 1. Sections of the collection forms for practitioners and citizens.

Before collecting structural data, training activities were fundamental for the three main local stakeholders – university students, citizens, and practitioners. Both forms were introduced to the students of the An-Najah National University because their support to both the citizens in filling in the forms related to their properties and the practitioners during their field surveys is of fundamental importance. Then, practitioners were trained on the content of the forms and for increasing their knowledge on seismic design and seismic risk prevention. Then, citizens were trained in understanding the type of information required in the form. Practical examples were used for supporting the training. Direct engagement of GO and NGO stakeholders is carried out with the organisation of seminars, workshops, lectures in a collaborative effort between the partners of the Consortium.

Survey data will not just be stored in the on-line georeferenced platform and grouped according to their structural typology, but a specific vulnerability assessment will be performed. Sets of fragility curves will be identified according to their structural types, first in Nablus and, then, in other Palestinian municipalities, hence providing a collection of vulnerability functions that best fit the Palestinian region.

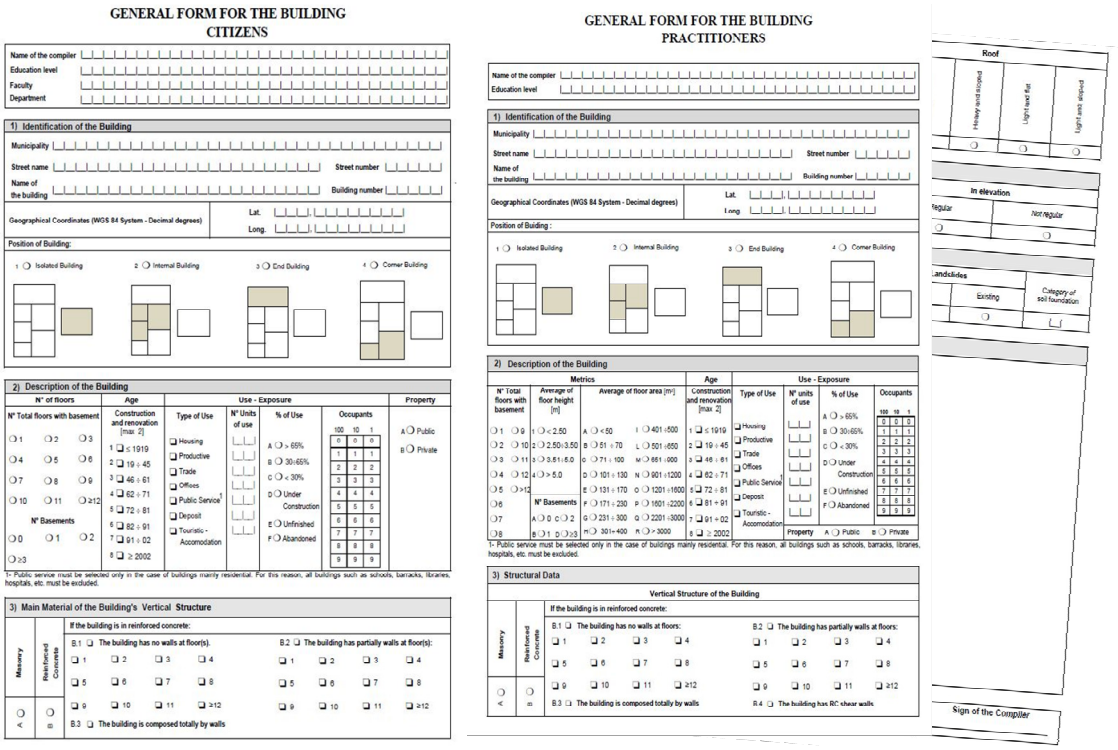

Figure 6. Collection Forms.

Nonlinear static analysis [10; 11] will be used for the estimation of the structural demand in the buildings, through a refinement of the SP-BELA (Simplified Pushover – Based Earthquake Loss Assessment) procedure [12; 13]. The method defines the nonlinear behaviour of a random population of buildings through a simplified pushover and displacement-based procedure. The application of the simplified pushover methodology leads to the assessment of a large number of buildings with reasonable computational effort [14; 15], as in the real case study.

Figure 7. RC Building, Building with Soft Storey failure mode, Shear Wall Building and Masonry Building (Clockwise Order).

With the aim of extending the applicability of SP-BELA to the Palestinian context, special attention has to be given to the structural typologies that mainly characterise the building taxonomy, such as frame systems with dominant torsional response and/or vertical/horizontal irregularities [16]. For this reason, SP-BELA procedure will take into consideration suitable correction factors derived from Incremental Dynamic Analysis of a selected groups of different irregular RC building typologies. Finally, the vulnerability curves will be generated comparing the displacement capacity limits identified on the pushover curve and the displacement demand, defined from a response spectrum, for each building in the random population.

4.2 Social vulnerability

Beside the assessment of fragility curves for physical assets, a non-negligible aspect in terms of vulnerability comes from society with its own knowledge, conditions and cultural context. In order to build indicators, able to capture the social characteristics, publically available databases (e.g. national census) are not satisfactory, and a specific tool needs to be defined, as the "Scorecard approach" based on a participatory assessment process [17].

In detail, this approach will measure the concept of city resilience to crisis and disasters. As established in the Hyogo Framework for Action (HFA) and more recently in the United Nations campaign for urban disaster reduction [18], the resilience is "the capacity of an individual, community, organization, city and nation to respond, cope and recover from disaster". Further, UN-ISDR established a set of indicators for measuring resiliency and these were implemented in six key areas in the Scorecard (Table 2).

Theme	General Question
Awareness and advocacy	What is the level of awareness and knowledge of earthquake disaster risk?
Social Capacity	What are the capacities of the population to efficiently prepare, respond and recover from a damaging earthquake?
Legal and institutional arrangements	How effective are mechanisms to advocate earthquake risk reduction in your quarter?
Planning, regulation and mainstreaming risk mitigation	What is the perceived level of commitment and mainstreaming of disaster risk reduction through regulatory planning tools?
Emergency preparedness, response and recovery	What is the level of effectiveness and competency of disaster management including mechanisms for response and recovery?
Critical services and public infrastructure resiliency	What is the level of resilience of critical services to disasters?

Table 2. Scorecard themes.

The Scorecard is built with specific questions and answer schemes for each key areas and has been adapted to Nablus background to meet peculiarities. To really measure resiliency, questionnaire will be spread among population and the municipal representatives and an evaluation of potential gaps will be assessed especially for critical areas where further analysis are needed.

5 EXPOSURE

The other relevant factor in the general risk assessment is exposure. The model would like to take into account people, property, systems and other elements present in the case-study area that are thereby subject to potential losses. It is developed to be comprehensive and in agreement with both vulnerability and hazard models, also considering the latest available area to produce up to date estimates.

Data used to build the exposure model can be prepared using two approaches:

i. Using data available to the general public and coming from an official source;
ii. Collecting data directly on the site through the forms already employed for the collection of fragility data. This is a more accurate version but is also strongly dependent on the effective participation of the involved citizens.

A hybrid approach will most likely be employed, in which the exposure model will be initially set up using census and/or national databases data. This version will then be updated and/or validated with real data collected in-situ.

As far as the first approach is concerned, the Palestinian Central Bureau of Statistics [19] has been used to collect databases, statistical data and key indicators (e.g. Housing condition, Population, Price Indices). Some difficulties arise due to the unavailability of some information at the same geographical level. For example, the distribution of the population is available at all levels from Country to Municipality but the number of house units is not. A possible solution to overcome this issue is to disaggregate the number of house units from the national level into the municipality level using the population as proxy. The proposed model takes into account indicators that best describe the exposed asset, such as relative percentages of buildings, floor area, building type and replacement cost. The final aim at this level is to come up with an updated model that could be applied at different levels of resolution.

5.1 Preliminary exposure data

Regarding the types of residential buildings, there are three main typologies: individual houses, apartments (multi-storey buildings) and villas. Respectively, the percentages of distribution of the typologies are 44%, 54% and 2%.

As far as the floor area is concerned, preliminary data for Nablus shows that most of the housing units, around 36%, have an average area of 139.5 m^2, followed by 25% with an average area of 100 m^2 (Fig. 8).

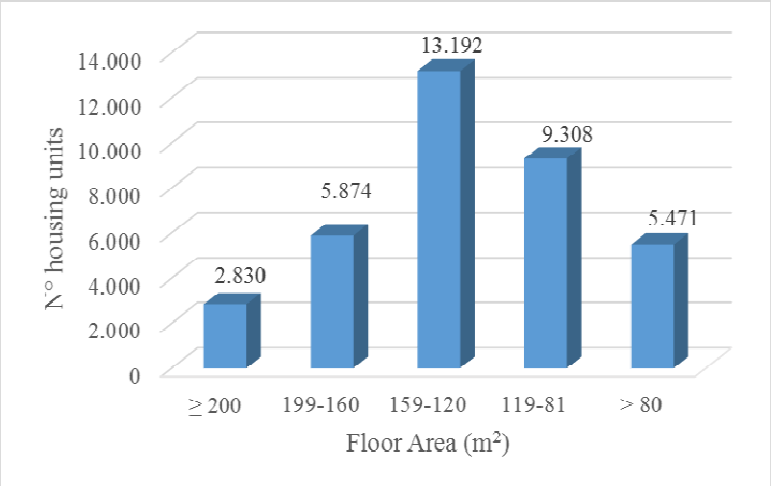

Figure 8. Distribution of housing units by floor area in Nablus.

Finally, with respect to the replacement cost, two methodologies were adopted to obtain the best results accounting for the wide variety in the region in terms of lack of homogeneity due to consecutive changes in the local law and variation in the construction materials and building techniques.

The first procedure takes into account data available on the governmental statistics website. The replacement cost is calculated by knowing the yearly expenditure on new buildings with specific materials (e.g. stone, masonry), adding the number of squares meter licensed in that specific year for that specific class. Table 3 illustrates an example of such data processing for stone buildings.

Year of survey	Construction material of external wall	Licensed area in 1,000 m^2	Expenditure in 1,000$
2014	Stone	2,719.9	249,897.3

Table 3. Example of calculation for replacement cost.

Taking into account the figures presented in Table 3, the final replacement cost comes as 91$/$m^2$.

On the other hand, the second procedure is based on expert opinion, using feedback from practitioners, engineers, engineering associations, etc. The replacement cost varies according to the building types: 550-600$/$m^2$ for apartments in multi-storey buildings, 750$/$m^2$ for individual houses and at least 900$/$m^2$ in case of villas. When comparing with the data from the official website, a large gap is observed with the reality of construction for the Nablus case study.

6 LEGAL AND REGULATORY FRAMEWORK

Finally, the development of an integrated risk model in Palestine will also enable the elaboration of guidelines and recommendations to promote local risk governance and management. Such task will include and redefine, if needed, the respective inputs of various GO and NGO Institutions by suggesting roles and possible forms of partnership between the three main stakeholders: government, private sector, including the (re)insurance and finance sectors, and the civil society (scientific/academic institutions, civil society organizations, media, the general public). Guidelines focusing on common procedural frameworks for encouraging and, whenever feasible, setting-up new partnerships and a set of methods and tools for cooperation between the different actors or stakeholders will be released at the end of the project. In this way, tailor-made recommendations will be available for the various institutional (policy, legislative and organizational) frameworks and cultures in Palestine. Therefore, the guidelines to be developed will be useful to quantify and assess physical, environmental and social resilience also from the risk governance point of view. In particular, to reach this aim, a questionnaire has been developed on the basis of the Self-Assessment Guiding Tool annexed to the G20/OECD Methodological Framework on Disaster Risk Assessment and Risk Financing (http://www.oecd.org/gov/risk). The questionnaire has been spread among the three main stakeholders in Palestine. The outcomes of the questionnaire will be processed suggesting roles and possible forms of partnership between the three main actors for a better management of seismic risk.

7 CONCLUSIONS

This paper intended to provide a general overview of the construction of a first-hand integrated seismic risk model for the Palestinian territory, using the municipality of Nablus as pilot study. A detailed framework including considerations around the different risk components – hazard, vulnerability and exposure – was presented.

The hazard model is established essentially on the basis of the recent EMME project that covered the entire Middle East region with significant detail and up-to-date tools (OpenQuake). The model will be further exploited to select real records to accurately develop a building fragility model.

The vulnerability model is largely comprehensive, as it includes both physical and social vulnerability components. Furthermore, both are modelled with different levels of detail, using census/database data and in-situ collected information. Indeed, the latter aspect, fulfilled through the use of specifically developed survey forms, constitutes one of the major novelties of this study. Fragility curves for a predefined building taxonomy are built using expedite nonlinear static analyses, adapted to the Palestinian in-built. On the other hand, social vulnerability indices are identified and established based on tailored questionnaires distributed to the general population and stakeholders in Nablus.

Finally, the exposure model builds upon extensive public data collection and feedback from several experts in the field. The entire model relies significantly on the cooperation with local bodies, entities and universities, yielding a double effect: sharing information and increasing awareness.

The general framework is seen as a pilot study, starting from the area of Nablus city, characterized by a difficult political context. Ultimately, the goal is to extend it to other regions in Palestine as well as to neighbour countries that features similar in-built environment. The achievements of risk assessment and loss estimation results in this case study, particularly the ones based on crowdsourcing data, also represent an enrichment for Europe.

ACKNOWLEDGMENTS

This research has been carried out under the project “ECHO/SUB/2014/694399 SASPARM 2.0 Support Action for Strengthening PAlestine capabilities for seismic Risk Mitigation”. Project Co-funded by ECHO – Humanitarian Aid and Civil Protection.

Keywords: site-specific PSHA, logic tree, disaggregation, conditional hazard, conditional mean spectrum.

Abstract. *A stand-alone software for the probabilistic assessment of seismic hazard is developing. In its final version, it shall be structured in three modules for: (i) site-specific, (ii) scenario-based and (iii) multi-site (regional) analyses. This paper focuses on (i), which is devoted to single-site probabilistic seismic hazard analysis (PSHA).*
Seismic sources can be either zones or individual faults. The algorithm to compute PSHA is implemented assuming, classically, that the process of occurrence of earthquakes on each seismic source follows a homogeneous Poisson process; the processes for different sources are independent.
The required input data are: (1) the source(s) geometry and the annual rate(s) of occurrence of earthquakes in the magnitude interval of interest; (2) the distribution of magnitude given the occurrence of one earthquake; (3) the ground motion propagation model (GMPM); (4) the soil classification at the site for which hazard is evaluated. Regarding (1-3), the user is aided by some library implemented in the software.
REASSESS also is able to account for model uncertainty, in fact, logic trees can be built based on alternatives for the source's annual rate of earthquake occurrence, magnitude distribution and GMPM.
The strength of REASSESS, beyond the user-friendly interface, stays in the PSHA computation algorithms. These have been coded in MATLAB®, targeting accuracy and reduced computing time. Its potential for earthquake engineering and engineering seismology applications is illustrated by a few applications discussed in the paper.

1 INTRODUCTION

The case of probabilistic seismic hazard assessment for a specific site is consolidated [1, 2] and acknowledged by the most advanced national and international seismic codes (e.g., [3, 4]). Indeed, there are several computer programs for site-specific probabilistic seismic hazard analysis (PSHA) publicly available or produced as proprietary codes. On the other hand, the attention toward the seismic hazard assessment for multiple sites is growing recently (e.g., [5, 6, 7]) and the developed knowledge has not found yet its direct application in the engineering practice.

The aim of the work partially presented in this study is to develop a user-friendly software for both site-specific and multi-site PSHA. The name of the tool is *REgionAl, Site-SpEcific and Scenario-based Seismic hazard analysis* (REASSESS) and, as the name suggests, it will be divided in three modules. The one preliminarily presented in this contribution is about site-specific PSHA, while the others are under-development.

The flow chart in Figure 1 schematically summarizes the main features of the site-specific module. Input parameters, defined by the user or selected from embedded databases, are the geographical coordinates and soil condition of the site of interest, the seismic sources, the magnitude distributions and the annual rates of earthquake occurrence (within the magnitude limits of interest) for each source, and the models of ground motion propagation (parameters and GMPMs can be multiple if a logic tree is adopted [8]). The primary outputs are the hazard curves for the selected intensity measures, which, along fragility curves (e.g., [9]), can be the input for seismic risk assessment software (e.g., [10]). Additionally, the software is able to provide the disaggregation of seismic hazard [11] and, according to the latter, the distribution of conditional hazard [12] (i.e., the distribution of a secondary intensity measure conditional to the occurrence or exceedance of a primary one). Moreover, when spectral ordinates are chosen as intensity measures, REASSESS provides the uniform hazard spectrum (UHS) [2] for a given return period and the conditional mean spectrum (CMS) [13] (in which disaggregation is also involved).

Each of these issues is analyzed in the following sections providing the essential basics of PSHA and the details about the software implementation. In the final part, the main features of the graphical interface and some results of illustrative analyses are shown.

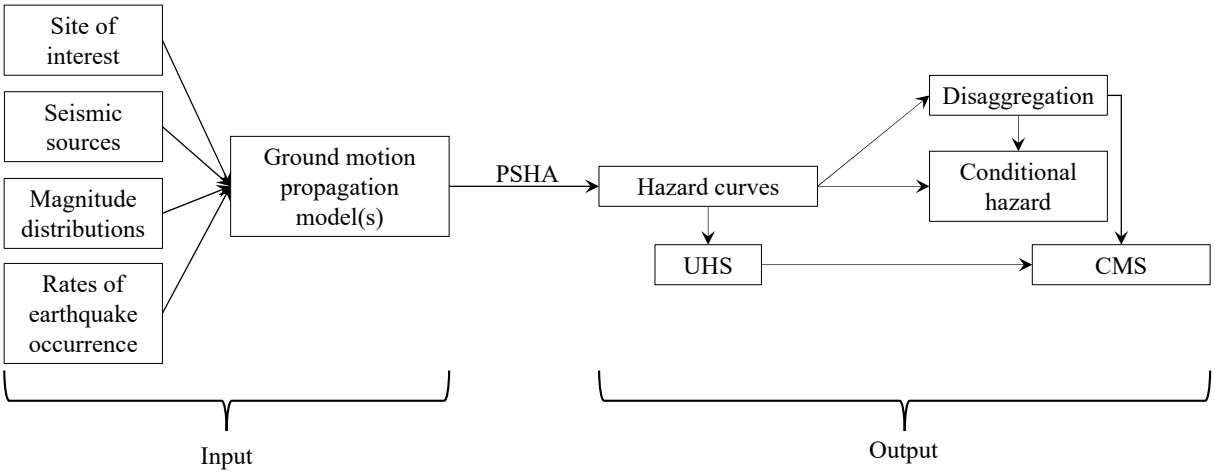

Figure 1. Flow chart of the first module of REASSESS

2 PROBABILISTIC SEISMIC HAZARD ANALYSIS

PSHA aims at computing the rate (λ_{im}) of seismic events exceeding a ground motion intensity measure (IM) threshold (im) at a specific site. When more than one seismic source affects the site, the rate is due to superposition of the contributions from each source, as illustrated in Equation 1 where n_s is the number of sources. In the equation, M is the event magnitude, R is the source-to-site distance, ν_i is the mean annual rate of earthquakes within a magnitude range of interest at source i, $f_{R,M,i}$ is the joint probability density function (pdf) of R and M for the i-th source. The exceedance probability of an intensity measure threshold, given a magnitude and distance pair, $P\left[IM > im \middle| r,m\right]$, is the complementary cumulative distribution function of the IM, which is provided by a ground motion propagation model.

$$\lambda_{im} = \sum_{i}^{n_s} \nu_i \cdot \int_r \int_m P\left[IM > im \middle| r,m\right] \cdot f_{R,M,i}(r,m) \cdot dr \cdot dm \tag{1}$$

Equation 1 accounts for the uncertainties related to seismic hazard. In some cases, however, the choice for models and distributions to be used in PSHA may not be straightforward. In these cases, the use of a logic tree, which is also implemented in REASSESS, allows to deal with model uncertainty [8]. Indeed, according to the logic tree, λ_{im} is computed as a weighted average of alternative models; the weight assigned to each model is the probability of that model being correct (see Section 2.4 for further details).

Plotting λ_{im} as a function of im provides the hazard curve. In the following section, it is described how computation of hazard curves has been coded in REASSESS, targeting accuracy and reduced computing time.

2.1 Calculation of PSHA via matrix algebra

The algorithms of REASSESS have been developed in MATLAB® [14] and the hazard integral is approximated by matrix operations, for which MATLAB® is especially effective [15]. Such operations are described in this section referring to the case of a single source, for the sake of simplicity. Moreover, it has to be clarified that in the algorithms of REASSESS the joint magnitude-distance distribution in Equation 1, is computed as the product of the distribution of distance conditional on magnitude and the marginal distribution of magnitude itself (Equation 2):

$$f_{R,M}(r,m) = f_{R|M}(r|m) \cdot f_M(m) \tag{2}$$

In the following, the discretized values of event magnitude and source-to-site distance involved in PSHA will be indicated as $\{M\} = \{m_1, m_2, \ldots, m_k\}$ and $\{R\} = \{r_1, r_2, \ldots, r_s\}$ of dimensions $1 \times k$ and $1 \times s$, respectively. The ground motion intensity measure at the site is discretized in the vector $\{IM\} = \{im_1, im_2, \ldots, im_q\}$ of dimension $1 \times q$.

The GMPM is accounted for via a $(k \cdot s) \times q$ matrix, $[A]$, in which each column represents the exceedance probability of a specific IM value conditional to magnitude and distance arranged in the form of Equation 3. Different columns of the matrix only differ by the IM threshold considered.

$$[A]=\begin{bmatrix} P[IM>im_1 \mid m_1,r_1] & \cdots & P[IM>im_q \mid m_1,r_1] \\ P[IM>im_1 \mid m_2,r_1] & \cdots & P[IM>im_q \mid m_2,r_1] \\ \vdots & \vdots & \vdots \\ P[IM>im_1 \mid m_k,r_1] & \cdots & P[IM>im_q \mid m_k,r_1] \\ \vdots & \vdots & \vdots \\ P[IM>im_1 \mid m_1,r_s] & \cdots & P[IM>im_q \mid m_1,r_s] \\ P[IM>im_1 \mid m_2,r_s] & \cdots & P[IM>im_q \mid m_2,r_s] \\ \vdots & \vdots & \vdots \\ P[IM>im_1 \mid m_k,r_s] & \cdots & P[IM>im_q \mid m_k,r_s] \end{bmatrix} \quad (3)$$

The pdf of magnitude, $f_M(m)$, is approximated by finite probabilities of event's magnitude belonging to *k* intervals; i.e., $\{P[m_1],P[m_2],\ldots,P[m_k]\}$. These probabilities, arranged in the form of a column vector, are the elements of the $[B]$ matrix in Equation 4. In fact, this matrix has *q* identical columns, each of which is made of the magnitude probability vector repeated *s*-times.

$$[B]=\begin{bmatrix} P[m_1] & \cdots & P[m_1] \\ P[m_2] & \cdots & P[m_2] \\ \vdots & \vdots & \vdots \\ P[m_k] & \cdots & P[m_k] \\ \vdots & \vdots & \vdots \\ P[m_1] & \cdots & P[m_1] \\ P[m_2] & \cdots & P[m_2] \\ \vdots & \vdots & \vdots \\ P[m_k] & \cdots & P[m_k] \end{bmatrix} \quad (4)$$

Similarly, the $[C]$ matrix is a row vector with $(k \cdot s)$ elements. The first *k* elements are the conditional probabilities of r_1 conditional to the *k* magnitude values. The elements from $k+1$ until $2k$ are the probabilities of r_2 conditional to the each of the magnitudes and so on, until r_s conditional to all magnitudes; i.e., Equation 5.

$$[C]=\begin{bmatrix} P[r_1|m_1] & P[r_1|m_2] & \cdots & P[r_1|m_k] & \cdots & P[r_s|m_1] & P[r_s|m_2] & \cdots & P[r_s|m_k] \end{bmatrix} \quad (5)$$

At this point, the operation of pointwise multiplication between two matrices of the same dimensions has to be recalled (i.e., the *Hadamard product* [16]). It is here indicated by the $\odot$ symbol and provides a resulting matrix of the dimensions of those multiplied. Its elements are the products of the corresponding elements in the original matrices. More specifically, $[D]=[A]\odot[B]$ implies that the resulting matrix has each element of the type: $d_{ij}=a_{ij}\cdot b_{ij}$.

Therefore, the unit-time rates of exceedance of the *im* values considered, $\{\lambda_{im_1},\lambda_{im_2},\ldots,\lambda_{im_q}\}$, can be obtained by the product in Equation 6, where the dot represent matrix multiplication.

$$[\lambda_{im}]=\begin{bmatrix} \lambda_{im_1} & \lambda_{im_2} & \cdots & \lambda_{im_q} \end{bmatrix}=\nu\cdot[C]\cdot([A]\odot[B]) \quad (6)$$

2.2 Soil effect

The GMPMs provide the (usually lognormal) cumulative density function of the IM at the site of interest given the magnitude of the earthquake, the source-to-site distance and some possible additional seismic parameters (e.g., soil site condition). In most cases, the different soil conditions at the site are considered in the GMPMs through modification factors that operate only on the mean of the (lognormal) distribution. When such kinds of GMPMs are chosen for PSHA, i.e. when the standard deviation of the residuals of the GMPM does not depend on the soil class, a deterministic relationship between the hazard curves for different soils exists [17]. This allows REASSES to provide hazard curves for any kind of soil conditions performing a single analysis.

In particular, it has been demonstrated that, if the soil in the GMPM only affects the mean given magnitude and distance, for example via addition of a coefficient θ_{soil}, as it often happens, then once the hazard curve is obtained for a reference condition (e.g., rock), the hazard curve for soil, $\lambda_{im_{soil}}$, is obtained by horizontally translating, in log scale of the abscissa, the original curve, $\lambda_{im_{rock}}$, by a factor equal to the soil coefficient in the GMPM (Equation 7).

$$if\ \log(im_{soil}) = \log(im_{rock}) + \theta_{soil} \Rightarrow \lambda_{im_{soil}} = \lambda_{im_{rock}} \tag{7}$$

2.3 Seismic sources and magnitude distributions

In REASSESS, seismogenic zones and/or finite tridimensional faults can both be inputs for PSHA. Seismogenic zones are geographic areas with homogeneous seismicity; i.e., each location has the same probability to be the location of the earthquake and the magnitudes of events in each location are independent and identically distributed random variables. For the characterization of seismogenic zones, the software requires the following input parameters: (i) the geographic coordinates of the vertexes of the source, (ii) the seismic parameters and (iii) the predominant faulting style, if known. Regarding (ii), it is assumed that the distribution of the magnitude of the earthquakes is described by a truncated exponential distribution consistent with the Gutenberg-Richter (GR) relationship [18]; hence, the seismic parameters of (ii) are the slope of such a relationship, together with minimum and maximum magnitude and the mean annual rate of earthquake occurrence in the seismic source zone. The pdf of the epicentral distance is derived from the uniform distribution of the epicenters within the fault. However, the GMPM may refer to one among a variety of distance metrics; e.g., the minimum distance from the horizontal projection of the rupture, known as Joiner and Boore distance (R_{jb}) [19]. In the V1.0 of REASSESS the epicentral distances are converted into R_{jb} according to [20].

The definition of the zones is not the only possibility in REASSESS. In the software, some known databases of seismogenic zones are already implemented. These are, referring to Italy, the seismogenic zones described in [21] with the seismic parameters taken from [22, 23]. At the European scale, the database of seismogenic zones provided by the SHARE research project (available at http://www.share-eu.org/, last accessed 22/02/2016) is embedded.

On the other hand, finite tridimensional faults can also be considered. The geometry and location of the single fault have to be known in this case. The required input parameters are the geographical coordinates of the vertexes of the fault and the *rake*, *strike* and *dip* angles (see [8] for example). A uniform probability distribution of the epicenter on the fault plane is assumed. Regarding the distribution of magnitude, apart from the GR, REASSESS V1.0 al-

lows the definition of a characteristic model [24] that may be more appropriate in the case of individual faults.

2.4 Logic tree and GMPMs

PSHA is often implemented considering a logic tree, which allows accounting for model uncertainty [2, 8]: indeed, it allows the use of alternative models, each of which is assigned a weighing factor that is interpreted as the probability of that model being correct. The sum of the weights of all the alternative models must be equal to one. When the logic tree is of concern, λ_{im}, is computed through Equation 8 in which p_j and $\lambda_{im,j}$ are the weight and the result of each branch of the logic tree, respectively; n_b is the total number of branches.

$$\lambda_{im} = \sum_{j=1}^{n_b} \lambda_{im,j} \cdot p_j \tag{8}$$

In REASSESS accepted models' heterogeneity refers to: (i) parameters of the magnitude distributions (i.e., magnitude range and *b*-value), (ii) mean annual frequency of earthquake occurrence on the sources and (iii) GMPMs. In particular, (i) and (ii) may be from direct input of the user, while GMPMs have to be chosen among a set of already implemented models. To guide the user, general indications about the tectonic regime each GMPM refers to [25] are provided.

An example of logic tree is shown in Figure 2 in which two alternatives for the total rates $\{\nu_1, \nu_2\}$, Gutenberg-Richter parameters (synthetically identified as GR_1 and GR_2) and propagation models ($GMPM_1$ and $GMPM_2$) are adopted. The relative likelihood of each alternative model is arbitrarily chosen and reported in parentheses.

REASSESS requires the user to provide the total weight of each branch skipping the implementation of a relative likelihood for each alternative model. Hence, the software automatically verifies that all the weights of the branches sum up to one.

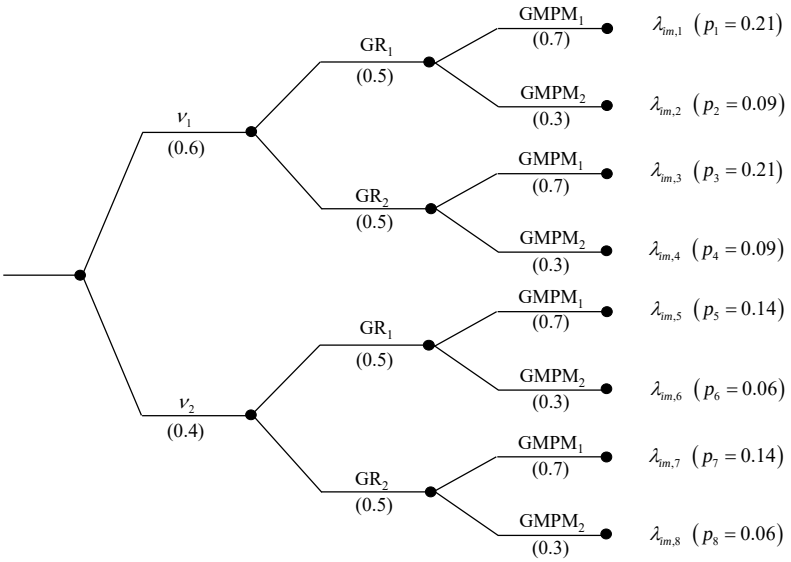

Figure 2. Example of logic tree.

3 DISAGGREGATION, CONDITIONAL HAZARD AND CONDITIONAL MEAN SPECTRA

Once hazard curves are ready, REASSESS also allows enhancing the characterization of the seismic threat for the site in three ways. The first is the disaggregation of the seismic hazard [11] that can be calculated for several exceedance rates; i.e., several values of the intensity threshold. Disaggregation is a procedure that allows the computation of the pdf of $\{M,R,\varepsilon\}$ given the exceedance, or occurrence, of a chosen hazard threshold, $f_{M,R,\varepsilon}\left(m,r,\varepsilon\middle|IM>im\right)$, being ε the number of standard deviations *im* is away from its median value estimated by the assumed GMPM. Analytically, such a distribution can be computed through Equation 9 that refers to the case of single seismic source and multiple-branches arranged in a logic tree. In the equation, in the case of disaggregation of the exceedance hazard, I is an indicator function equal to one if IM is larger than the threshold and zero otherwise. The subscript refers to the *j-th* branch of the logic tree.

$$f_{M,R,\varepsilon}\left(m,r,\varepsilon\middle|IM>im\right)=\frac{\sum_{j}^{n_b}\nu_j\cdot I\left(IM>im\middle|m,r,\varepsilon\right)\cdot f_{M,R,\varepsilon,j}\left(m,r,\varepsilon\right)\cdot p_j}{\lambda_{im}} \tag{9}$$

A discussion of the possible uses of disaggregation (e.g., [26]) is out of the scope of this paper however it is worth noting that, although disaggregation for the exceedance of the hazard threshold is a traditional choice, in the context of performance based earthquake engineering disaggregation for the occurrence of the IM may be more appropriate. REASSESS allows to compute disaggregation of both ground motion intensity exceedance and occurrence hazards.

The software also allows the computation of conditional hazard [12] and uniform hazard spectra and conditional mean spectra [13]. The former is the distribution of a secondary IM conditional on the exceedance (or occurrence) of a primary IM for which the hazard has been calculated. This allows assessing the hazard consistent distribution of more than one IM, which is equivalent to vector-valued PSHA [27]. In REASSESS, once the UHS for a fixed return period has been calculated, it is possible to choose a spectral period defining as primary parameter, IM_1, the corresponding pseudo-spectral acceleration and asking for the conditional distribution of the secondary intensity measure, IM_2, chosen among a few considered.

The distribution of conditional hazard, $f\left(\log IM_2\middle|\log IM_1\right)$, is computed under the assumption of joint lognormality of the two IMs conditional to the hazard variables and according to Equation 10 in which $f\left(\log IM_2\middle|\log IM_1,M,R,\varepsilon\right)$ depends on the GMPM of IM_2 and $f\left(M,R,\varepsilon\middle|\log IM_1\right)$ is the disaggregation of the seismic hazard (occurrence or exceedance) for IM_1.

$$f\left(\log IM_2\middle|\log IM_1\right)=\int_M\int_R\int_\varepsilon f\left(\log IM_2\middle|\log IM_1,M,R,\varepsilon\right)\cdot f\left(M,R,\varepsilon\middle|\log IM_1\right)\cdot dm\cdot dr\cdot d\varepsilon \tag{10}$$

Finally, the conditional mean spectrum can be computed. It is a target response spectrum able to account for the statistical correlation of residuals between different spectral ordinates of the same GMPM. This issue, which is disregarded in UHS, is believed helpful for hazard-compatible record selection [28].

The analytical definition of CMS is reported in Equation (11) in which $\mu_{\log Sa(T_2)}$ and $\sigma_{\log Sa(T_2)}$ are the mean and the standard deviation of the logarithm of the pseudo-spectral acceleration $(\log Sa)$ at the vibration period T_2 and depend on the selected GMPM; $\rho_{\log Sa(T_2)|\log Sa(T_1)}$ is the model of correlation between spectral ordinates at two different periods (the one implemented in REASSESS is [29]). The values of M, R and ε are taken from the disaggregation of $\log Sa(T_1)$. In fact, if M, R and ε are chosen to be representative of the whole disaggregation distribution (e.g., modal values). Equation 11 can also be the basis for marginalization with respect to M, R and ε, via $f\left(M,R,\varepsilon\middle|\log Sa(T_1)\right)$, to obtain $\mu_{\log Sa(T_2)|\log Sa(T_1)}$ (this is the case of the REASSESS).

$$\mu_{\log Sa(T_2)|\log Sa(T_1),M,R,\varepsilon} = \mu_{\log Sa(T_2)}(M,R) + \sigma_{\log Sa(T_2)}(M)\cdot\rho_{\log Sa(T_2)|\log Sa(T_1)}\cdot\varepsilon(T_1) \tag{11}$$

4 GRAPHIC USER INTERACE

The main features of the graphic user interface (GUI) of REASSESS are described in this section.[1] The GUI is conceptually divided in three sections identified in Figure 3 with the dotted red lines. The first section is dedicated to the definition of input parameters required for PSHA. The site is defined by the geographical coordinates and the soil class. The latter is provided through the Vs30 (expressed in m/s^2) that is, the shear wave velocity of the top 30 m of the subsurface profile (see Section 2.2).

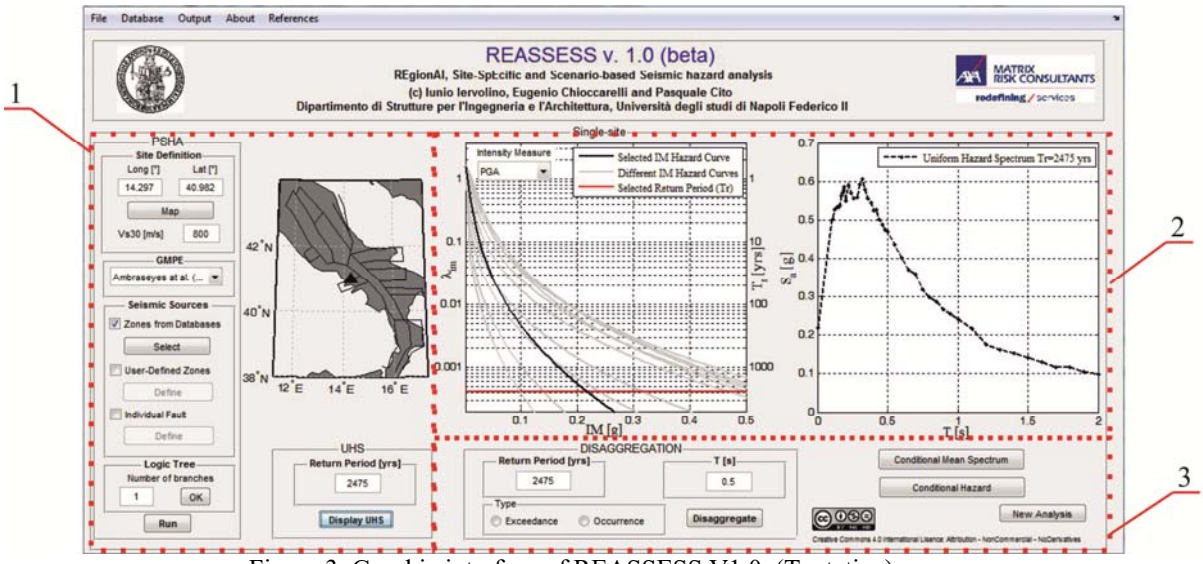

Figure 3. Graphic interface of REASSESS V1.0. (Tentative)

The GMPM is selected with a pull-down menu in which all the implemented GMPMs are reported (see Section 2.4). Then the seismic sources have to be characterized. The user is first required to choose between embedded databases of known seismogenic sources, user-defined seismogenic sources and individual faults. These three choices are not exclusive so it is possible, as an example, to integrate sources from databases with information derived from specific studies. For each seismic source, a separate window with all the required parameters (see Section 2.3) appears. Site and source locations are shown in a map. The user is also required to

[1] The development of the other two modules of the software may cause some modification to the GUI. However, the main features described in this section will be maintained.

choose between single- or multiple-branch of logic tree; the features of the different branches of the logic tree are specified in a separate window. A return period of interest is also required.

Hitting the *run* button, PSHA is performed and the hazard curves are plotted in the second section of the GUI. In the illustrative case of Figure 3, selected GMPM refers to pseudo-spectral accelerations. Hence, the UHS is computed for the selected return period $\left(T_r = 1/\lambda_{im}\right)$ and reported in same section.

Finally, the third section is for the analyses that can be performed after PSHA. These are disaggregation, conditional hazard and conditional mean spectra (see Section 3).

5 ILLUSTRATIVE EXAMPLES

In this section, how the site-specific module of REASSESS works is shown via some illustrative examples. A site (40.982N, 14.297E) close to Naples, in the Campania region (southern Italy), is selected and reported in Figure 4 with a star. Seismic sources are the seismogenic zones of [21]. The limiting magnitudes for each zone as well as the slope of the Gutenberg-Richter relationship and the mean annual rate of earthquake occurrence on the zones are those reported in [22, 23]. In the same papers, the prevalent faulting style for each zone is also reported. These are divided in four categories: normal (N), reverse (R), strike-slip (SS) and undetermined (U).

The selected GMPM is that of [30] that provides the distribution of peak ground acceleration (PGA) and pseudo-spectral accelerations for forty-six oscillation periods between 0.1 and 2.0s. The model is defined within the intervals of magnitude and distance equal to [4.0, 7.6] and [0km, 200km], respectively. In REASSESS, the GMPMs are always applied in their definition ranges. Hence, the seismogenic zones contributing to the hazard are those (or their portions) within 200km from the site. Moreover, although in the original paper [30], the attenuation model was independent on the rupture mechanism, the latter is considered via the modification factors provided by [31].

According to these criteria, the seismogenic zone within 200 km from the site are reported in Figure 4. Seismic parameters of these zones are summarized in Table 1.

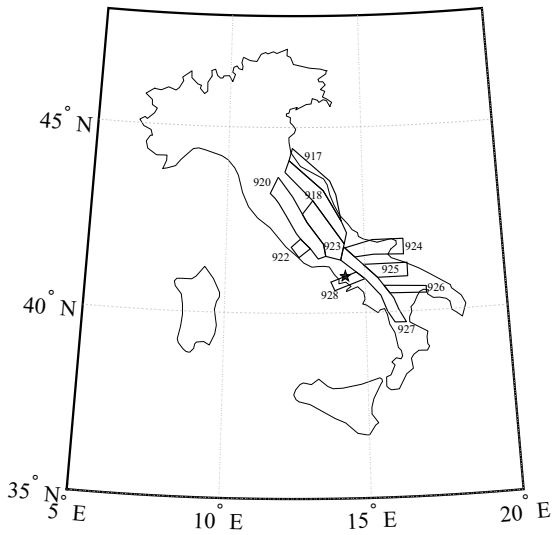

Figure 4. Selected site (star) and the seismogenic zones involved in the hazard analysis.

Zone	M_{min}	M_{max}	ν	b	RM
917	4.3	6.1	0.121	0.794	R
918	4.3	6.4	0.217	0.84	U
920	4.3	5.5	0.317	1.503	N
922	4.3	5.2	0.09	1.409	N
923	4.3	7.3	0.645	0.802	N
924	4.3	7	0.192	0.945	SS
925	4.3	7	0.071	0.508	SS
926	4.3	5.8	0.061	1.017	SS
927	4.3	7.3	0.362	0.557	N
928	4.3	5.8	0.054	1.056	N

Table 1. Parameters associated to each zone: minimum (M_{min}) and maximum magnitude (M_{max}), annual rate of earthquake occurrence (ν), negative slope of GR relationship (b) and rupture mechanism (RM).

For the selected site, the UHS are here derived. Referring to rock site, Figure 5a shows the UHS' for the annual exceedance probabilities equal to about 2%, 0.2% and 0.04%, corresponding to return periods of 50, 475 and 2475 years, respectively. On the other hand, the UHS' for T_r equal to 2475 years and the three different soil conditions provided by [30] are reported in Figure 5b: rock, stiff and soft soil.

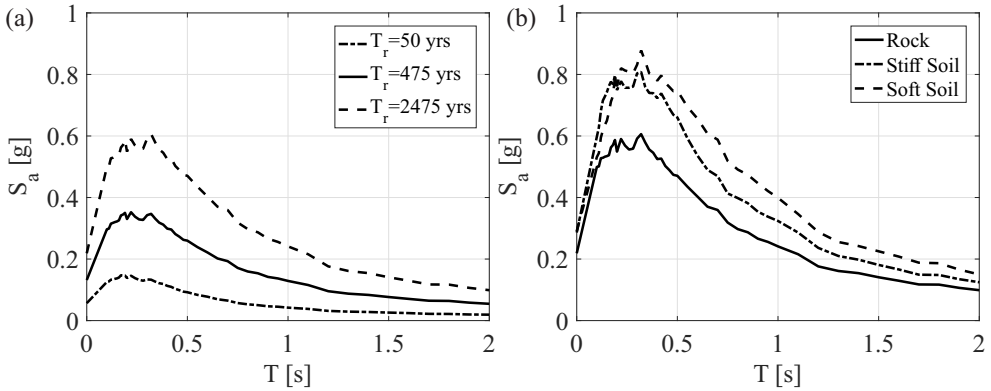

Figure 5. (a) UHS for different return periods on rock soil and (b) for a T_r = 2475 years and different soil conditions.

A simple case of logic tree is also discussed. Two GMPMs are selected: $GMPM_1$ [30] and $GMPM_2$ [32] (and [33]) with associated weights equal to 0.7 and 0.3 respectively. No other sources of model variability are considered. Hence, resulting logic tree is a simplified form of that reported in Figure 2 (Figure 6a). The UHS for $T_r = 2475$ years and rock soil condition are derived from the two alternative branches of the logic tree and shown in Figure 6b together with their weighted mean (note that the spectrum is computed only at the spectral periods common to both GMPMs).

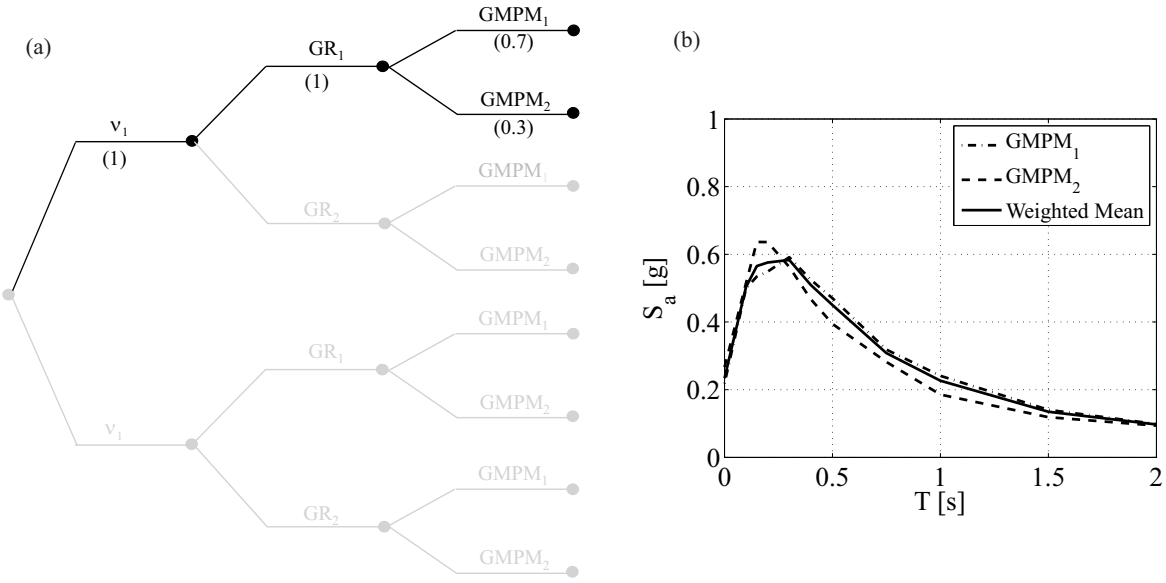

Figure 6. (a) Simplified adopted logic tree and (b) resulting UHS.

Referring to the case of single-branch (Figure 5), the occurrence disaggregations of the UHS for $T_r = 2475$ years, rock soil condition and three spectral periods equal to 0.2s, 0.5s and 1.0s are reported in Figure 7 (a, b, and c, respectively). According to these disaggregation distributions, the CMS' are computed and reported in Figure 7d together with the UHS.

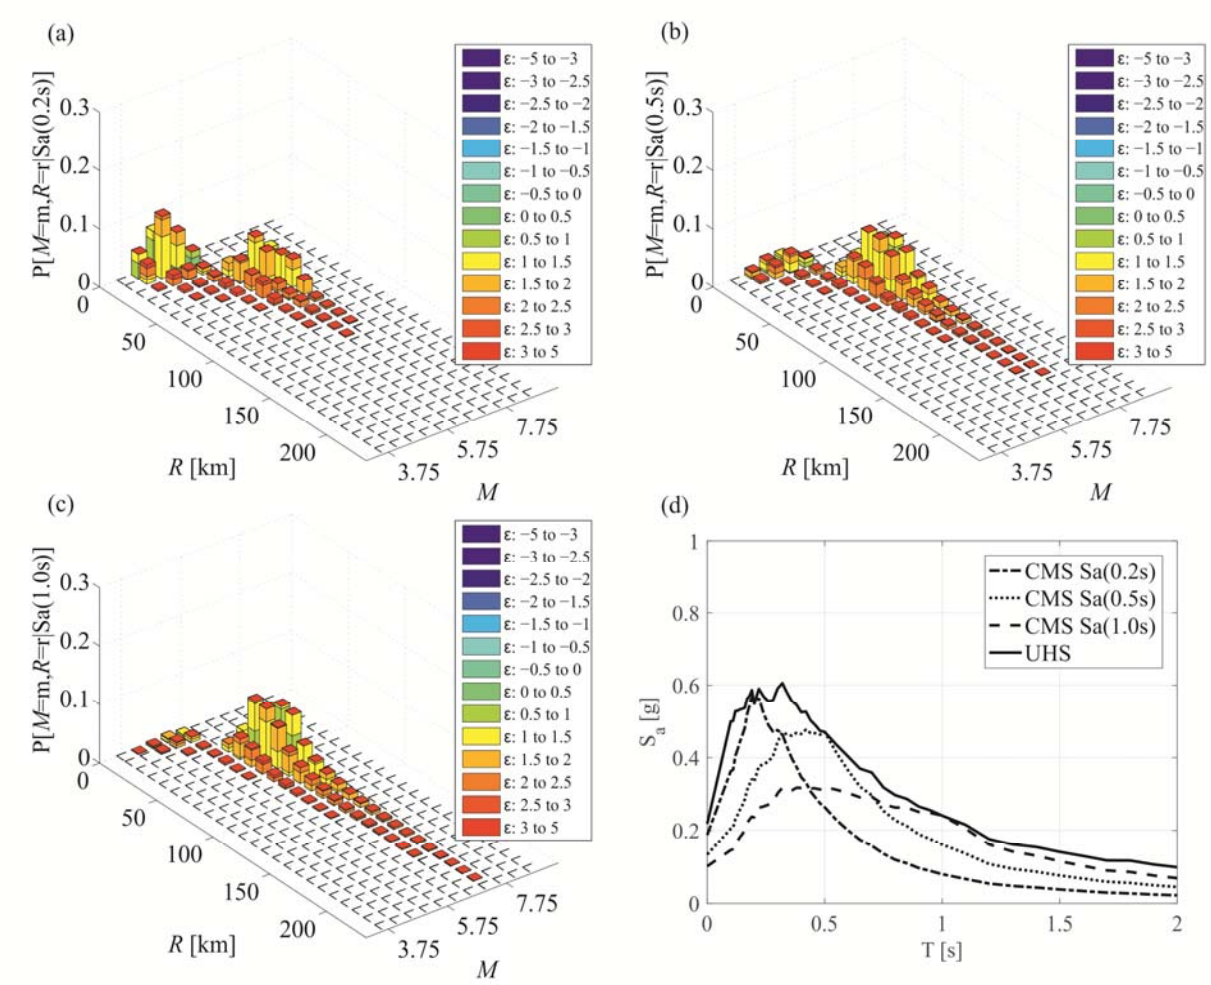

Figure 7. Disaggregation distributions for the occurrence at Tr = 2475: spectral period equal to (a) 0.2s, (b) 0.5s and (c) 1.0s. (d) Corresponding conditional mean spectra for rock and UHS.[2]

6 CONCLUSIONS

A stand-alone software for the probabilistic assessment of seismic hazard is developing. The first module is dedicated to site-specific probabilistic seismic hazard analysis (PSHA), and a preliminary description of it was provided with this paper.

PSHA is consolidated, but hazard assessment may still be demanding for earthquake engineering researchers and is very rare for practitioners. In this context, the REASSESS software is presented as a user-friendly and computationally-efficient option to tackle PSHA.

The present version of REASSESS is able to address the following issues:

- PSHA for several intensity measures accounting for model uncertainty;
- disaggregation for occurrence or exceedance hazard;
- conditional hazard for secondary intensity measures, when spectral acceleration is the primary one;

[2] As a general comment to Figure 7, it is to recall that the REXEL, a software for record selection [34], also provides disaggregation distributions for Italian sites [35]. Although REXEL relies on the same models used in these illustrative applications, the disaggregations of REASSESS are expected to present some differences with respect to those of REXEL. These are due to different computational choices between the two software, which, however, provide comparable outputs.

- uniform hazard and conditional mean spectra.

REASSESS, so far, only deals with site-specific PSHA; however, in some cases, the assessment of the seismic hazard requires considering multiple sites at once. This happens when the analysis of spatially distributed systems is of concern, or when aggregated losses for portfolio of structures and/or supply chains are of interest. The need to account for all the uncertainties and the statistical dependencies involved, make the seismic hazard for multiple sites a not straightforward task. It is a specific goal of the ongoing developments of REASSESS to address multi-site probabilistic hazard assessment, which will include, as special cases, scenario-based regional analyses.
